Foreword

VOLUME 55 of the Transactions of The American Society of Mechanical Engineers contains the individual sections published during 1933 under the sponsorship of the Society's professional divisions, as well as the annual Record and Index. The technical papers and reports that make up this volume represent the Society's annual contribution to the permanent record of mechanical-engineering achievement. Most of these papers and reports were presented at meetings of the Society and of its professional divisions and local sections, and were issued originally in pamphlet form. These pamphlets appeared in sections, each section being sponsored by one of the Society's professional divisions. Other papers published by the Society but not included in the Transactions may be located by means of the Index on page 87 of the Record and Index which forms a part of this volume.

All sections of the Transactions are bound together at the end of the year for the convenience of libraries and of engineers who wish all of the papers in permanent form. Copies of the bound Transactions will be found in depositories located in selected engineering, university, and public libraries throughout the world. A complete list of these depositories will be found on pages 83 to 86 of the Record and Index. Copies of the bound Transactions have also been set aside for sale.

The Record and Index of the A.S.M.E. for 1933 which forms a part of these Transactions, is the permanent record of the Society's activities for the year. It includes lists of committees, reports of meetings and committee activities, memorial notices of deceased members, as well as indexes of special A.S.M.E. publications and of *Mechanical Engineering*.

In this volume the papers of each section are grouped together and are numbered serially. The sections are arranged alphabetically. Each paper is designated by a symbol composed of key letters followed by the volume number and paper number. The letters refer to the section of the Transactions to which the paper is assigned. Thus AER refers to the Aeronautic section, IS to the Iron and Steel section, etc. The arrangement of the index and designations for locating material are explained at the beginning of the index, page 96 of the Record and Index, at the end of this volume.

THE PUBLICATIONS COMMITTEE

Progress in Aeronautical Engineering

MILITARY AERONAUTICS

By B. D. Foulois[1]

THE development of military aircraft during the last year has resulted in better performance and increased reliability. The flying characteristics of aircraft have been increased considerably by aerodynamic, structural, and propeller research. New data have been gained, especially with reference to streamline wheels and retractable landing gears. Cockpit covers are being employed to lessen the air resistance. The present tendency is toward closed cockpits for all types of aircraft.

The high stresses resulting from increased speeds now being reached have required more detailed analyses of airplane structures. Research into new construction methods and the attendant applications of better materials have made it possible to compile new and improved design standards. These standards and criteria have been incorporated in a new seventh edition of the "Handbook of Instructions for Airplane Designers."

Propeller development has been directed toward improvement of aluminum-alloy types and production of controllable propellers. Various alloys of magnesium are being developed with the object of utilizing the large savings in weight made possible by this metal. Welded aluminum alloys are also being tested. Two types of controllable propellers have survived preliminary tests and are being given service test. New propeller-testing apparatus has recently been installed at Wright Field and is being utilized in the study of the problem of reducing propeller noises, both in the air and on the test stands. This problem is one of such difficulty that a great amount of research will be necessary before any practical results may be expected.

Structural Designs

Structural research is being particularly directed toward wing design. With the same power, the high performance of military airplanes is directly dependent upon a proper combination of aerodynamic and structural qualities. With this in mind, stress analysis and design were completed for an all-spot-welded corrosion-resistant steel wing of stressed-covering, single-web, cantilever type. The structural members are utilized for the distribution of engine coolant vapor and for collecting the condensate in the wing for return to the engine. This arrangement eliminates the drag and much of the weight of the conventional airplane radiator.

The facilities for stress research have been improved by the development of new equipment for measuring strains in aircraft structures during static test. In carrying out static tests, the stresses in the airplane structures have been actually measured instead of merely finding the ultimate stresses of various types of complete structures. It has been a general practice to use the McCollum-Peters electric strain gages for the study of each structure while under static load, which makes possible a more accurate check of each stress analysis.

A new mechanical type of vibratory tensiometer and frequency meter has been designed and tested to provide a means of measuring the rigging loads and the loads in flying and landing wires when a structure is statically loaded. This apparatus has been successfully used to determine tension loads in round, square, and elliptical wires and tierods and to determine the natural frequency of various types of propeller blades. A new instrument for more accurately and quickly measuring chords of wings having thick airfoil sections has been developed and is being used with good results.

Aircraft

The standard pursuit-type airplanes are Boeing P-12's and Curtiss P-6's.

The air-cooled type typified by the P-12 has proved quite satisfactory in service. They are powered with SR-1340 engines. The liquid-cooled type is typified by P-6E and has been generally satisfactory, although trouble has been experienced with powerplant installations. These airplanes are powered with V-1570 engines, Prestone cooled.

The B/J Y1P-16 is a biplane aircraft powered with a V-1570 liquid-cooled engine. (See Fig. 1.)

Fig. 1 Berliner Joyce Y1P-16 Biplane

New types under test include the Boeing P-26 and Curtiss XP-23. The P-26 is an all-metal semi-low wing, wire-braced airplane. An unusual feature of this model is the fixed stabilizer. Longitudinal stability is procured by small trailing edge flaps on the elevators, operated from the cockpit in the same manner as the conventional adjustable stabilizer. This airplane promises to attain a speed of over 200 mph at 6000 ft.

The XP-23 is a metal monocoque biplane powered by a G1V-1570 engine and side-type supercharger.

The Douglas BT-2C is a standard basic training airplane.

A new attack airplane, the XA-8 (Curtiss), has been given full performance tests. As a result thirteen of this type have been ordered by the Air Corps. They are powered with V-1570E Conqueror engines. The XA-8 is of all-metal construction with low cantilever wing, externally braced. Slots and flaps are used. The monocoque fuselage has a complete convertible pilot's cockpit inclosure and a partially convertible gunner's cockpit inclosure. Two fixed, free-firing guns are located in wheel fairings on each side above the landing wheels. A high speed of 190 mph can reasonably be expected of this plane.

A considerable advance is represented by the Boeing B-9 bombardment airplane. This airplane, powered with an R-1860 engine, showed remarkable performance. It is also being tested with the G1V-1570 engine to secure comparative results with each power plant. The Boeing plane is a low-wing monoplane with monocoque-fuselage, all-metal construction, with retractable landing gear.

[1] Major-General, U. S. Army; Chief, Air Corps, War Department, Washington, D. C.

Presented at the session of the Aeronautic Division, Thursday morning, December 8, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Personnel of the Executive Committee of the Aeronautic Division for 1932: Elmer A. Sperry, Jr., Chairman; Alexander Klemin, Secretary; Carl B. Fritsche, Porter H. Adams, William B. Mayo, and Fred G. Coburn. Associates: H. H. Blee, J. L. Walsh, P. G. Johnson, T. A. Morgan, Archibald Black, V. E. Clark, J. H. Doolittle, W. F. Durand, E. E. Aldrin, William Knight, Bernt Balchen, Jerome Lederer, and T. P. Wright.

The Glenn Martin light bomber airplane is also a low-wing monoplane of all-metal construction. It has developed an unusually high rate of speed in preliminary tests.

The Douglas light bomber is being given service tests. Seven of these planes have been procured, powered with GV-1570E engines.

Standard observation types comprise the Thomas Morse O-19E, the Douglas series O-25C and O-38B, and Curtiss O-39.

Now undergoing service test as a corps observation airplane is the Douglas O-31. This airplane has smooth-skin monocoque fuselage and the G1V-1570-C power plant. The first seven have a gull wing externally braced with tierods. The last five airplanes will have cantilever gears and larger rear cockpits. A high speed of 195 mph can reasonably be expected from these types.

Another service-type observation is the Curtiss YO-40A of the sesquiplane type, powered with SR-1820 Wright Cyclone and equipped with retractable landing gear. One plane of the Army observation type is undergoing test. The Douglas Y1O-35 has a gull-type externally braced wing with monocoque fuselage, retractable landing gear, and two G1V-1570E engines. A normal high speed of 178 mph can be reasonably expected.

The General Aviation YO-27 has a fuselage of tubular steel construction, fabric covered. Two G1V-1570C engines are installed ahead of the leading edge of the wings. The undercarriage retracts into the engine nacelles. The pilot's cockpit has a convertible inclosure. A high speed of 170 mph can be reasonably expected.

An interesting development is the TC-13 airship, non-rigid type of 360,000 cu ft capacity, as compared with 210,000 cu ft for the present standard TC airship.

This airship is now under construction and will employ two-geared air-cooled engines, resulting in 700 hp available for driving specially designed three-bladed propellers. As far as is known, this is the first application to non-rigid airships of geared air-cooled engines, and with the propeller designed for a low rpm consistent with the air speed, a very quiet and efficient installation will result. Another feature of the airship is the five-fin control surface arrangement, with which it is expected to improve ground clearances for maneuvering, low speed control, and surface stability at the higher speeds, and to simplify the rudder-control mechanism. It is expected to obtain a high speed of 65 mph for an endurance of 15 hr, a cruising speed of 52.6 mph for 35 hr, or a hovering speed of 25 mph for an endurance of 100 hr. The airship will be equipped with an observation car that may be lowered a distance of 1500 ft below the airship for special forms of observation. Air blowers, bomb racks for 700 lb of bombs, a long-range radio set, and sleeping and galley accommodations constitute the other major items of equipment. The observation car and windlass arrangement, air blowers, sea anchor, ballast pick-up, and auxiliary power-plant unit for the radio set are being developed by the Lighter-Than-Air Unit.

Another development along this line is the TC-14 airship car, which will be interchangeable with the car on the TC-13 airship, but will omit the bombing and observation-car equipment in favor of a three-engine power-plant installation. This feature is also considered as an innovation in non-rigid airship design. Two of the engines will be geared air-cooled radial engines, whereas the third will be an inverted air-cooled engine of approximately 100 hp mounted in the rear of the car which will drive a controllable- and reversible-pitch propeller. By this arrangement it is expected, through fuel economy, to increase the endurance of the airship at slow hovering speeds, as well as to permit more flexibility of the power-plant installation for take-off and landing conditions.

New automatic pressure-control equipment represents the first attempt to devise a means of automatically regulating and controlling the internal pressure in airship envelopes while in flight to compensate for fluctuations of the internal pressure caused by bumpy weather or changes in air speed. Heretofore, this has been manually controlled by operation of eight controls, which can be eliminated by this device. The inspection equipment for airship envelopes is also a new development and consists of a gas helmet and related air-supply system by means of which it is possible to enter and remain in the gas compartment of an inflated airship for an extended period of time and conduct inspection and minor repairs to the interior of the envelope. This equipment will obviate the necessity for deflation of envelopes to accomplish repairs to ballonets, internal air lines, and suspensions, and should thus increase the life and simplify the maintenance of airship envelopes.

The motorized observation-balloon project has been continued by altering present airship equipment. Tests will be conducted during the latter part of this year to determine the feasibility of motorizing the observation balloon, in order that the balloon may be flown from one position to another rather than maneuvered over the ground while attached to a cable, which is the present standard practice.

Power Plant

Power-plant developments were generally concerned with improvements in performance of service engines and accessories. A large number of tests were conducted, including carburetors, cooling systems, fuels, lubricants, spark plugs, radio ignition shielding, magneto and battery ignition, pressure indicators, silencers, and superchargers.

A new laboratory was completed affording more efficient facilities for dynamometer tests and fuel research. This laboratory is equipped with refrigeration and air-exhaust apparatus to provide a simulation of winter and altitude conditions.

This installation allows the testing of engines under approximate altitudes as high as 30,000 ft with a temperature of —55 F and an air pressure equivalent to the barometric reading at that altitude. This apparatus also permits testing of engines and accessories under simulated severe-weather conditions.

In general, improvements in air-cooled engines have been obtained by a means of higher gear-ratio superchargers, higher compression ratios, and improved cooling characteristics. Many tests were carried out to locate the cause of difficulties reported by the service and to institute proper corrections. The development in liquid-cooled engines is being directed toward obtaining engines with ratings approaching 1000 hp. Some difficulty has been experienced with liquid-cooled engines in service, but steps have been taken to eliminate the source of trouble.

Lubricating Oil. A problem of lubricating oil is the occurrence of decomposition, resulting in production of solid gummy deposits in the cylinder. Correction requires research into lubricating-oil properties. Studies undertaken along this line have resulted in drastic revisions in specifications, the new oils showing marked improvements in conditions of the engines after extended periods of research.

For the present, the Air Corps specifications for oil require a flat viscosity curve nearly equal to the best Pennsylvania characteristics and fairly low pour points, which necessitates rather severe but not the severest dewaxing. Decomposition characteristics are not specified, but are apparently fairly uniform as a result of control of viscosity-temperature curve characteristics. The Air Corps is entering upon a fairly large-scale test program of oil produced by aluminum-chloride synthesis. Preliminary tests and investigation have shown very encouraging results.

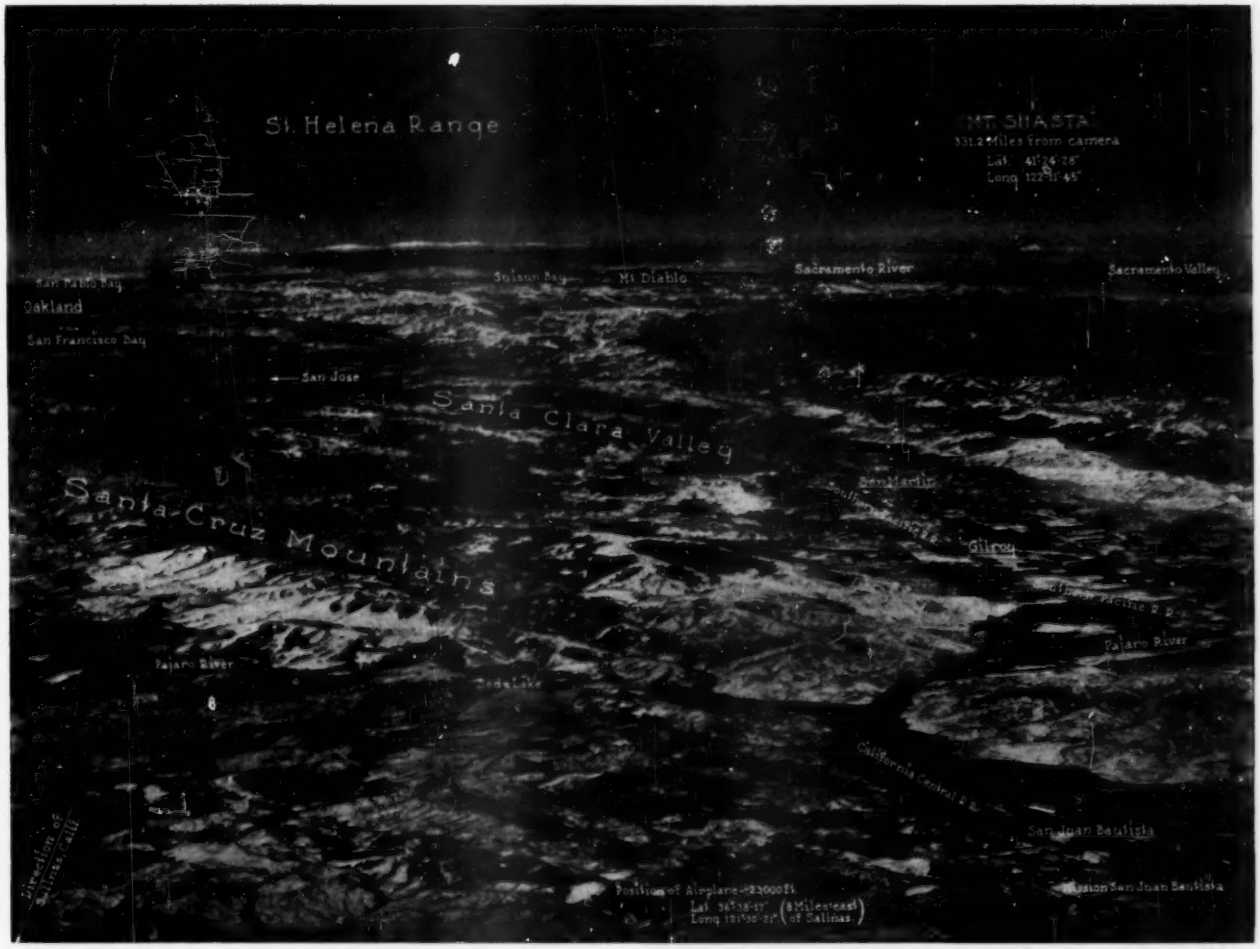

FIG. 2 LONGEST RANGE PHOTO EVER OBTAINED

(Taken in January, 1932, by Captain A. W. Stevens, Chief of Aerial Photographic Unit, Wright Field, flying at an altitude of 23,000 ft, and clearly showing Mt. Shasta at a distance of 331.2 miles, the one exposure covering 7200 sq miles, which also is the greatest amount of the earth's surface ever encompassed in one photograph.)

Engine Pressure Indicators. Development of engine pressure indicators has resulted in two types being successfully developed. The electric-telemeter type was designed to show pressure variations either by observation on a screen or by photographic record. This indicator has the advantage of showing every cycle of engine operation, in terms of either a pressure-volume or a pressure-time relation. The other type developed was of the sampling valve type, which takes a record on a standard steam-engine indicator. By means of these indicators the valve timing of engines has been improved, especially in the case where back pressure is imposed on the exhaust system.

EQUIPMENT

Aerial Navigation. Definite progress has been made in the field of aerial navigation through extensive research and experiments in application of radio phenomena to fog flying and blind landing. New gyroscopic turn and flight indicators have been developed in cooperation with the industry.

A radio compass has been developed which functions as an accessory to the standard aircraft receiver and gives visual indication of the correct direction for flight toward any selected radio-transmitting station. Successful flight landings have been made by the aid of this compass, in some cases supplemented by the high-frequency or ultra-short-wave field-boundary marker.

The fog landing system developed by the Air Corps is characterized by simplicity and low weight. An inexpensive ground transmitter of the 50-watt airplane type is used as contrasted to the costly and complicated radio beacon. Results have been so satisfactory in tests at Wright Field that this system will be put in service in a few selected Air Corps stations very soon. Further tests are in progress to standardize operating procedure and insure the maximum of reliability. A thorough investigation of radio shielding has been carried out. It is realized that radio sets are seriously hampered by interferences emanating from other electrical appliances on the airplane. Over 90 per cent of this normal interference has been eliminated by a new system of electrical installations on aircraft. Basically it employs two-wire ungrounded current in solid conduit with no fuses. The solid conduits have proved more efficient than the braid shielding system. Important phases of this work include integrally shielded starting motors, spiral-slot generator armatures, double-shielded generator controls, a more satisfactory ground for booster magneto and coil, and integrally shielded storage batteries. It is of interest to note that with this system a single conduit can be satisfactorily used from the pilot's cockpit to the engine compartment.

Three mapping projects were completed, for the U. S. Geological Survey, the Coast and Geodetic Survey, and the Corps of Engineers. These projects used the T-3A five-lens cameras

and obtained photographs from which maps were subsequently prepared.

Extremely encouraging results have been procured with the new Kryptocyanine film, which is used for the purpose of obtaining long-distance and high-altitude photographs. This is used in conjunction with the 89-A filter, which excludes practically all visible light; thus the photographs are taken with infra-red light. This type filter and film will be supplied to the service during the coming year. During experimental work with this film some very interesting pictures were taken. In January, 1932, Captain A. W. Stevens, Chief of the Aerial Photographic Unit, Wright Field, flying at 23,000 ft, obtained a picture of Mt. Shasta from a distance of 331.2 miles. (See Fig. 2.) This is the longest-range photograph ever obtained, and in one exposure covers the greatest amount of the earth's surface (7200 sq miles) ever encompassed. The negative was made from a point more than 100 miles farther south than the last point from which Mt. Shasta was visible with unaided vision. Captain Stevens also obtained the highest altitude photograph of history in an exposure made at 39,150 ft of territory lying in the vicinity of Rushville, Ind.

Besides the developments mentioned, a large number of other improvements have been made, especially in the direction of increasing the strength and reliability of aircraft.

Special mention of the Air Corps Inspection System should be made. Instituted several years ago, it has been constantly improved, and it is directly responsible for lessening the number of matériel failures. Besides prescribing detailed and uniform methods of aircraft inspection, all unsatisfactory performance reports are analyzed and the defects found are corrected. As a result the standard of reliability is high in spite of the increased speeds at which military aircraft are operating.

NAVAL AVIATION

By William A. Moffett[1]

The fiscal year 1932 has been an important one in the history of naval aviation. The close of the previous year saw the completion of the Navy's five-year building program, and left the Navy with a complement of modern aircraft with which to carry out its missions and maneuvers.

The early part of the year saw the commissioning of the U.S.S. *Akron*, the first fleet airship and aerial airplane carrier, equipped with specially designed high-performance fighting airplanes, and with provisions for their starting, alighting, and housing while the airship is in flight. The U.S.S. *Los Angeles*, after eight years' operation in valuable experimental and training work, has been decommissioned and laid up in the Lakehurst airship dock, in the interest of economy. Increased production of helium and the development of improved tank cars have further reduced the price of helium, so that it is no longer the important item of cost it once was. In addition, experimental work was started in connection with fuel gas for airships, using a K-class non-rigid airship of 320,000 cu ft volume for the purpose. Preliminary work on the Naval Air Station, Sunnyvale, Calif., the Navy's first West Coast airship base, has been actively under way during most of the fiscal year.

Dive and pull-out test results have necessitated a complete overhauling of former assumptions used in structural analysis. Research in this connection with newly developed instruments which record the stress and strains in the airplane structure in action have resulted in the establishment of new criteria which represent much more nearly the actual conditions in the aircraft under consideration than the old ones. A method of conducting basic structural tests on hull sections, which will result in a rational design basis, has been perfected. In addition, series of beam tests and destruction tests on complete airplanes have increased the fund of data available to the airplane designer.

Marked progress has been made in the development and utilization of corrosion-resisting steel in the construction of naval aircraft. It appears that many service difficulties are being eliminated by the use of this material.

The light-weight high-strength aluminum alloys continue to play an important part in naval aviation, and it is particularly gratifying to note the remarkable development in shop practices and maintenance methods made in connection with the use of these materials. Magnesium is also being thoroughly investigated, as it appears to have decided possibilities for use in the fabrication of non-structural parts.

Probably no one thing has aided more to improve the reliability and life of the aluminum alloys in aircraft than the consistent improvements which have been made in protective coatings. As the result of comprehensive study and research conducted at the Naval Aircraft Factory in Philadelphia, new specifications have been prepared which insure the procurement of high-quality durable finishes.

In the aircraft power-plant field, the power output of existing types of engines has been increased about 10 per cent for the same piston displacement. Supercharging is available and is being incorporated where desired. The increased scope and severity of engine tests, together with improved test conditions which simulate more closely flight conditions, have all helped to improve reliability and durability, resulting in a substantial reduction in maintenance costs. The present endurance test includes a 150-hr run. Most of the 1932 special appropriation for high-speed development was spent on power-plant development. During this year the two-row radial engine has been successfully tested in laboratory and flight and put on service test.

A study of aircraft trouble reports has focused attention on "plumbing," since it appears that it, especially in the fuel system, is the chief source of trouble.

Fuel and oil specifications have been revised upward to take advantage of the improvements in the refining art in the United States. In addition, investigations of fuel injection and safety fuels have been undertaken.

Hollow steel propellers have been developed to serviceable standards and are proving satisfactory in service. The variable-pitch propeller, having passed satisfactory tests, is now about to be put into use in service squadrons.

Considerable progress has been made in the development of aircraft instruments. These developments include a compass for scouting planes, an azimuth compass for patrol planes, an extremely sensitive altimeter, an improved octant, an accelerometer for dive bombers and fighting planes, and combined engine-gage units.

Experimental quantities of improved ground-speed indicators and drift sights have been purchased and have been given extensive service tests. Dead-reckoning navigation has been facilitated by improved chart-board equipment and its accuracy increased by the new types of compasses now in use.

The first production dive bombers, a new and distinct type of air arm, were put into service during the year. Several contracts were awarded for two-seat fighters and for two-seat scouting airplanes that embody numerous novel and interesting features. Some of these scouts are of the amphibion type.

The development of suitable radio equipment for aircraft has been pushed, especially in the direction of providing adequate radio for fighting planes and dive bombers. The entire electrical system of naval aircraft has been given more careful

[1] Rear Admiral, U. S. Navy; Chief, Bureau of Aeronautics, Navy Department, Washington, D. C.

study during the past year than ever before. Increased radio sensitivity has demanded more complete shielding of all electrical equipment and wiring. Complete conduit systems have been provided. Engine-driven generators of adequate capacity to handle the power required by both the radio and the electrical system have been developed.

Last winter there was undertaken the first of a series of tests to determine the feasibility of and the difficulties to be encountered in the operation of an aircraft carrier under severe winter conditions. The aircraft carrier U.S.S. *Langley*, with a skeleton complement of airplanes, spent two weeks off the New England coast and carried on routine flight operations.

While the results were very gratifying, these tests have indicated certain lines of development which are now being pursued with a view to improving operations under conditions of severe weather.

Experiments in an attempt to decrease the weight of winter flying suits have been particularly fruitful. Several experimental suits were made and tested under severe operating conditions during the past winter. As a result of these tests, certain minor changes were made in types found most suitable. It has been possible to decrease the weight of these suits 50 per cent, as a result of these studies. Suits have also been made considerably less bulky. A large number of these improved flying suits are being manufactured for service use.

Extensive researches are under way to provide the service with a satisfactory quick-attachable parachute. There appears to be a real need for parachutes of this type, and every effort is being expended in the development of such a parachute. Several types are now undergoing service test. In addition, a parachute with a quick-release harness is being thoroughly studied to determine its suitability for naval usage. Investigations are also under way to determine the suitability of cotton as a substitute for silk in the manufacture of parachutes.

The development of various equipment, including fire extinguishers, life rafts, and oxygen breathing apparatus for high-altitude work, has been proceeding at a most satisfactory rate.

AIR TRANSPORT

By Archibald Black[3]

Apart from the changes in airplane design covered in another section of this report, developments of a business nature represented the most important factors in air transport during the past year. Passenger traffic has continued to increase very substantially despite the unprecedented severity of the general business depression. (See Fig. 3.) The rate of increase, however, was not quite so rapid in the past twelve months as in previous periods. For the first seven months of 1932 the rate of increase in number of passengers was 19.7 per cent over the traffic carried in the same period of 1931, while passenger miles increased 20.8 per cent in the same period. Air mail fell off markedly (see Fig. 4), due almost entirely to the effect of the business depression, but the increase from 5 cents to 8 cents in the minimum rate also had its influence. The poundage of air mail carried in the first seven months of 1932 was 9.6 per cent less than that carried in the same period of the previous year. Air express packages showed a remarkable increase, the poundage carried in the first seven months of 1932 being 68.5 per cent in excess of poundage carried in the same period of the previous year. No change of any consequence took place in miles of route in operation of regularly scheduled services in 1932, but the airplane mileage flown in the first seven months of 1932 increased about 25 per cent over that flown in the same period of the previous year.

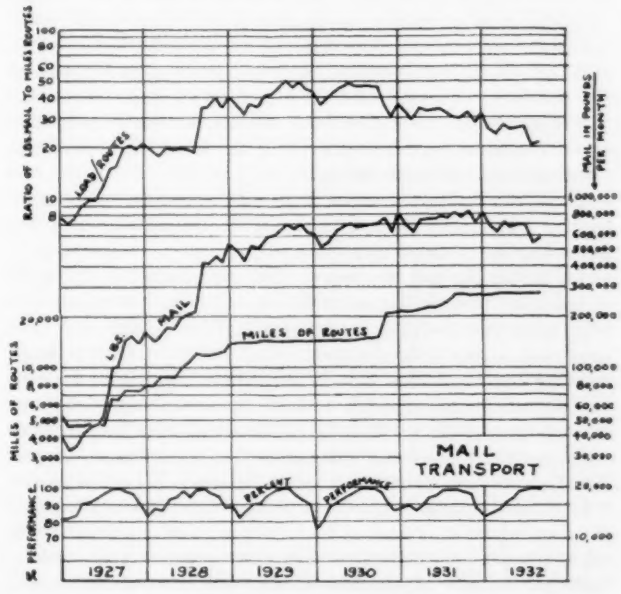

Fig. 4 Chart of Air-Mail Transport

AIRPORTS AND AIR NAVIGATION

By F. C. Hingsburg[4]

Very substantial progress has been made in the development of airports and landing fields since the passage of the Air Commerce Act of 1926. Records of the Aeronautics Branch of the Department of Commerce in Washington reveal that there are available at present in the United States 547 municipal airports, 619 commercial airports, 367 Department of Commerce intermediate landing fields, 64 Army and Navy flying fields, 41 mis-

[4] Aeronautics Branch, Department of Commerce, Washington, D. C.

cellaneous state and private fields, and 459 marked and listed auxiliary or emergency landing fields, a total of 2097. However, many of the airports listed are practically undeveloped in so far as accommodations other than a cleared landing space are concerned.

The principal trend of progress in connection with the operation of airports has been improving operations so as to provide for handling a large increase in the number of arrivals and departures without reduction in safety. At certain times of day a number of arrivals and departures must take place practically simultaneously, and a system must be worked out to handle the traffic at such times with the maximum dispatch as well as the maximum of safety. In this connection traffic control at periods of great traffic congestion is receiving the earnest attention of a large committee of airport and air transport experts. Control by radio communications and visual signals are both being carefully studied with a view to reaching as close as possible an approach to an ideal standard method, with due regard to the fact that variations from the general standard are likely to be required to meet special conditions in various localities.

Considerable attention is being given to passenger convenience. The prospective passenger now arrives at the airport passenger station, where signs and uniformed attendants guide him without confusion through the ticket and baggage preliminaries and invite him to await in a comfortable waiting room the arrival of his ship at a designated embarking gate or canopied gangway. Hangars, workshops, and warm-up lines are generally far removed from this point, and miscellaneous flying is segregated in another section of the airport. Very shortly before the departure time the ship taxies up to the embarkation point, shuts off its engine or engines, and uniformed attendants assist the passenger on board and show him to his seat. The same general procedure takes place upon disembarkation, and throughout it compares very favorably with the handling of traffic at a well-ordered railway terminal.

The system of intermediate fields established and maintained by the Aeronautics Branch of the U. S. Department of Commerce on the Federal airways has undergone considerable revision during the past two years. The increase in size and speed of transport aircraft has necessitated larger and smoother fields with improved facilities. Lighting equipment has also been improved, a recent development being the 36-in. double-beam-rotating beacon. This unit is constructed with two doublet-lens assemblies at opposite ends of the drum-shaped housing and equipped with a 110-volt, 1000-watt airways incandescent lamp, mounted in a lamp changer, with a spare lamp. It projects two beams of light separated by 180 deg. When the beacon is fitted with clear lenses, each beam is of 1,250,000 candlepower. In cases where it is desired to furnish a code characteristic in color, the beacon is operated with clear lenses at three revolutions per minute in synchronization with colored and coded course lights or code beacons.

The Federal airway weather reporting and communications system as described in the Transactions for 1931 has been very comprehensively improved in a number of ways. The number of primary radio broadcasting weather and communications stations has increased to 69. The teletypewriter communications system has been expanded to 13,000 miles with 245 stations. Experimentation with teletypewriter transmission developed the feasibility of transmitting facsimile weather maps to all points reached by this system. To provide the additional service at no increased total expenditure for the system, it was found necessary to purchase the machine component used on the long lines, instead of leasing it. This purchase included 135 page-type machines, making it possible to provide facsimile weather maps at 71 airports and important intermediate fields. Automatic transmission is accomplished by the use of perforated tape functioning in a manner similar to that of the perforated-paper records used in player pianos.

To the system of radio range beacons described in the A.S.M.E. Transactions for 1931 sufficient stations have been added to bring the total to 94. In addition, a few relocations have been necessary. The radio marker beacons which are installed at important points along airways between radio range beacons have been equipped for short-range voice transmission. A further substantial improvement in radio marker beacon installation comprises the installation of loop antennas with higher powered transmitters giving, in addition to the characteristic marker-signal and voice-communication service, radio range signals effective over a radius of from 25 to 50 miles.

There have been promulgated a number of important amendments to the Air Commerce Regulations and revisions in the interpretation of the Air Commerce Regulations governing scheduled operation of interstate passenger air-transport service. These were announced in the Air Commerce Bulletin of May 16, 1932. Of great importance in this connection was the establishment of the "Scheduled Air Transport" pilot rating and the requirement that transport pilots flying airplanes engaged in scheduled operation of interstate air-transport service under a certificate of authority must hold such a rating.

With the announcement of the requirements for the new scheduled air-transport license and the new scheduled air-line operation requirements, interest in the use of the radio range beacon in flying was immediately stimulated. Pilots of all air lines are practicing radio flying diligently in hooded cockpits in order to achieve the new Scheduled Air Transport rating.

AIRSHIPS

By C. P. Burgess[5]

No important new airships have been completed in the year under review, but quiet progress and development have continued. The U.S.S. *Akron* operated on the West Coast for over a month, with no base except an "expeditionary" mooring mast, a short mast of the simplest type with a minimum amount of equipment. On the west-bound flight across the continent, a severe storm and violent squalls were encountered in the mountain passes. The airship successfully won through against the buffeting of the wind squalls and the danger of being cast upon the mountain tops.

The elaborate ground-handling gear at Lakehurst, described in the Progress Report for 1931,[6] has been further developed, and has proved correct in principle, although its early operation was marred by an accident which put the *Akron* out of commission for over two months.

The U.S.S. *Macon*, sister ship to the *Akron*, will be completed early in 1933, and will be based on the new airship station at Sunnyvale, Calif., near San Francisco. This station will be the most perfect and up-to-date airship operating base in the world.

The *Graf Zeppelin* has carried out a regular and almost unnoticed program of round-trip flights between Friedrichshafen and Pernambuco. The schedule for the year calls for ten round trips, and at present, October 10, the ship is keeping up to schedule. The Zeppelin Company is making good progress on the construction of the new airship *LZ-129*, which will be slightly larger than the U.S.S. *Akron*. The ship will be inflated with helium, and propelled by four Diesel engines of 1000 hp each. Several different makes of engines are being considered, but no final decision or choice has yet been made. Loss of weight

[5] Bureau of Aeronautics, Navy Department, Washington, D. C.
[6] See *Mechanical Engineering*, vol. 53, no. 12.

through consumption of fuel in flight will be compensated by valving hydrogen from ballonets suspended inside the helium-gas cells.

AIRPLANE DESIGN AND CONSTRUCTION

By Richard M. Mock[7]

Due to general business conditions and overproduction in previous years, comparatively few new civil airplanes made their appearance in 1932. In recent years there have always been an appreciable number of new airplanes, often of quite progressive design, brought out by individuals and new independent companies. Evidently this decrease in the number of new airplanes of this class was due to difficulties in raising funds. The established manufacturers also produced very few new models for civil use, and many who had no previous military experience tried to develop service planes. It is believed that, due to this, the manufacturers, realizing the limitations of the present civil market and recalling their past over-production, as well as appreciating the experimental costs of a new type, have almost been overreluctant about appropriating funds for new development works and production. Most of the manufacturers have disposed of their previous large inventories.

It has been apparent for some time that in 1933 most of the airplanes built in 1929 or before would be due for replacement. In spite of the fact that this constitutes the greater part of the equipment now in service, very few manufacturers of transport or private planes have built experimental models to be fully developed and ready for limited production in 1933. In the non-transport market used-plane prices are so low as to discourage almost any manufacturer. However, it is felt that there soon will be a definite market for economical and modern non-transport airplanes. In the transport field it is felt that practically all of the planes built in 1929 or before will be replaced. Of course the expected replacement will not be 100 per cent, but it is reasonable to expect, especially in view of the recent increases in air traffic, that some expansion will take place which will also require new equipment. Many manufacturers were slow in realizing this and are now rushing to finish new models to be able to take care of the spring market.

The problems of commercial operators (regular scheduled flying) have been reflected in transport-plane design. More attention than ever was given to the detail design of parts that are apt to give trouble in service and for ease of accessibility and ease of replacement of various units. Airline operators have even gone so far as to draw up detail specifications for man-hours allowed for replacing certain units of the airplane. Though this has tended to reduce operation expenses, it has increased engineering costs, which apparently must be reflected in increased unit cost of the airplane. A great deal of attention on the part of commercial airplane designers has also been given to the reduction of time necessary at an airport for discharging and loading passengers and baggage, refueling, and replacing certain equipment such as batteries. As a result, baggage and accessory compartments are usually accessible from outside the airplane.

As a structural airplane material, duralumin seemed to be increasing in use, and there seemed to be a definite tendency to use it for fuselage construction as well as for movable control surfaces. Material for wing construction seemed to be divided as heretofore except for the tendency away from fabric covering because of the desirability of having a rigid cover on a cantilever wing. There seemed to be a definite preference for a flat dural skin over using it in the corrugated form. Though magnesium alloys were used quite extensively in Europe, both in sheet and in castings, they made little progress in the United States. In spite of the excellent pioneering of the Budd Company with the shot-welding process on stainless steel, it is still only slightly used except on fittings and vital parts which must be especially corrosion resistant. The Boeing "Totem," a monoplane flying boat, has all stainless-steel fittings.

Monocoque fuselage construction in duralumin seems to be increasing in popularity, and as the year comes to a close two new monocoque commercial designs have made their appearance. They are both 600-hp, low-wing, metal-construction transports; namely, the Northrup "Delta" and the plane produced by the American Airplane and Engine Corporation and taken over by the General Aviation Corporation.

In the design of landing gears there seem to be two distinct schools—one that believes that for aerodynamic efficiency the landing gear must be retracted and the other that believes that the retractable gear is an unnecessary extra complication, extra weight, and cost, and that a clean external gear is as efficient and offers less possibility of an accident. The two mentioned planes are examples of this. The former has a streamlined fixed external gear, while the latter retracts the wheel partly into the wing, leaving the lower portion to be covered by movable fairing, producing a bulge below the wing.

More attention than ever was paid to fuselage shape and wing-fuselage interference. Cantilever monoplanes are ever increasing in proportion to biplanes and externally braced monoplanes, and there seems to be a definite tendency to an increase in taper ratio. On single-engine designs the trend seems to be definitely toward the low wing, chiefly because of the ease of retracting the landing gear and the slightly reduced structural weight.

There seemed to be an ever-increasing interest in single-spar cantilever-wing construction, both of the fabric-covered type developed by Stieger in England and the stressed-skin type exploited in Germany. In Germany, Heinkel brought out a low-wing monoplane with a plywood-covered single-spar wing having slots and flaps giving a speed range of 1 to 4.

In general the use of ring cowls on radial engines became quite common both here and abroad. In Europe the Townend ring has been more popular, while here it has been adapted to most old designs, while most new planes have been designed to use a full over-all or N.A.C.A. hood cowl.

There have been a great number of efforts to reduce noise and vibration in airplane cabins. Rubber engine mounts are very common, and practically all cabins are lined with some sound-absorbing and insulating material such as kapok or dry-zero, while one organization uses a mixture of down and feathers. Double windows with an air space in between have also just come into use.

Most cabin planes have windows that cannot be opened by the passengers and have the heating and ventilation system controlled by the pilot or co-pilot. Individual air ducts that can be operated by each passenger, of the type developed by the Fokker Aircraft Corporation, are universally used. Most planes are heated by bringing air in contact with the exhaust manifold, though a Prestone heating system is being used on some new planes under development.

Exhaust collector rings are usual equipment on radial engines, and a few organizations have been experimenting with mufflers. Eastern Air Transport has developed an exhaust muffler that seems to work quite well. One of the new transport planes under development will have geared-down propeller drives to help reduce the propeller noise as well as increase the climb.

Controllable-pitch propellers became more common during the year, especially the mechanically controlled propeller hub of the Smith Engineering Corporation. These should account

[7] Assistant to A. H. G. Fokker, New York, N. Y.

for increased efficiency of multi-engined airplanes with one engine disabled as well as improved climb and take-off on all types.

Aircraft operators have begun to realize that the ultra-fast airplane has the same advantages over the slow airplane as the slow airplane has over fast ground transportation and that a fast airplane can be operated economically. As a result the trend in new designs is for greater speeds, both through surplus in power and improved aerodynamic cleanliness. While a cruising speed of 110 mph was considered excellent a few years ago, at least 140 to 160 mph cruising is now necessary on a modern design, while there are some airplanes already in operation maintaining a schedule cruising of 175 mph.

In the transport field there is a tendency away from the large airplane which a few years ago seemed definitely to be on the horizon. A ten-place plane, operating frequently, seems to be the desire of many operators, though it is felt if they are in operation on an hourly schedule and air traffic increases as it has in the recent past, this size of plane will be too small before it has served its useful life, since it is unlikely to have schedules more frequent than one plane an hour.

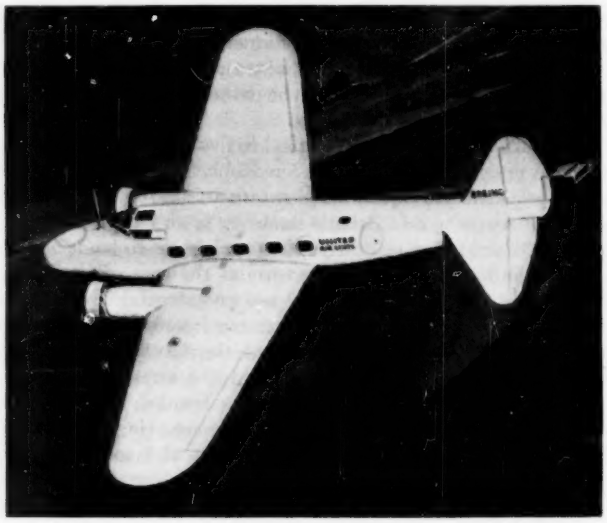

FIG. 5 APPEARANCE, AS PLANNED, OF BOEING 10-PASSENGER HIGH-SPEED TRANSPORT BEING BUILT FOR UNITED AIRLINES

There also seems to be a tendency toward the single-engine transport, since many operators find this type more economical and yet entirely satisfactory for daylight operations over flat country. However, it is believed that if single engines developing more than 700 hp were available, larger single-engine airplanes would be built.

As the year comes to a close a number of experimental single-engine, low-wing, monocoque, ten-place Cyclone- or Hornet-powered transports were being developed. Besides the General Aviation plane and the Northrop "Delta," Lockheed and Vultee in California are developing planes of this type. The Lockheed is expected to cruise at 180 mph and have a high speed of 220 mph with ten people and 500 lb of baggage. In addition there are a few planes of this size and type which are yet in the "secret" stage. Fleet Aircraft, Inc., is continuing production on an improved-model "Fleetster," with Hornet engine. It has a plywood-covered cantilever high wing and a dural monocoque fuselage.

Since landing speeds are not increasing in proportion to top speeds, speed ranges must be improving. As a result the problem of flying controls that are adequate at both maximum and minimum speeds is growing more acute.

Various devices for increasing wing lift have been tested by the N.A.C.A. and are slowly being used in actual construction. The Northrop "Delta" uses split flaps and has floating ailerons above the wing at the trailing edge.

The Boeing Company has developed a servo-rudder which is understood to reduce the load necessary to keep the Boeing tri-motor flying on a straight course with one side engine stopped from 90 lb to 12 lb.

Beech Aircraft has brought out a negative stagger cabin biplane with a split rudder that opens up and acts as an airbrake when both rudder pedals are pushed forward.

The only new multi-engine plane developed and put into production in the United States during 1932 was the Stinson model "U," a ten-passenger tri-motor similar in construction to the original Stinson tri-motor except for a roomier cabin and the addition of a short cantilever lower wing which supports the outboard engines and carries the struts for bracing the upper wing. The stub wing also carries the landing gear. Like the Bellanca Airbus, the stub wing has heat-treated welded-steel-tube spars and contains a compartment for mail or baggage. This load is near the center of gravity and is accessible without disturbing the passengers.

Another passenger transport completed during the year was the 40-passenger Ford mentioned in last year's report. However, as far as can be learned, though this plane was completed in the spring, it was never flown. The design and construction was exceptionally interesting, especially the clean outboard-engine installations, with the engines completely within the wing and driving a propeller mounted in front of the leading edge by means of a shaft.

Boeing, Curtiss-Wright, and Douglas are developing twin-engine retractable-landing-gear transports which, it is understood should be completed about the end of 1932 or early 1933. The Boeing design (see Fig. 5) will be a 10-passenger, low-wing monoplane which is calculated to cruise at 150 mph at sea level with 75 per cent power, and since the engines are supercharged to give sea-level performance at 5000 ft, the cruising speed should be about 155 mph at this altitude. The estimated figures indicate that with full load this plane will be able to maintain 1000 ft altitude with one engine dead and the other developing 75 per cent power. With one engine at full throttle the plane is expected to have a climb from 1000 ft of about 100 fpm.

The Curtiss-Wright transport, or "Condor" as it will be called, is understood to be a sesquiplane with two Cyclone engines located in the leading edge of the lower wing and will carry 15 people and a crew of two, besides 650 lb of mail or baggage. It is expected to cruise at 140 mph.

The Douglas transport will be a low-wing design, powered with two 700 hp Wright Cyclone engines. With 12 passengers and 1000 lb of mail, it is expected to cruise at 165 mph and have a range of 1000 miles.

There were somewhat more new planes produced in the non-transport class during the year. However, most of them were continued refinement of detail. Stinson produced the model "R," which is believed to be the first cabin sport plane with retractable landing gear. (See Fig. 6.) It is like the Stinson "Junior" of previous years, except for the addition of a stub wing for the retractable landing gear and the somewhat roomier fuselage. Besides increasing the width and depth of the fuselage, it was shortened.

Few outstanding features of design in the non-transport class were brought out. One of the commonest refinements was the addition to many of the open-cockpit planes of a demountable transparent cockpit cover for winter flying.

In the flying-boat-amphibion field there were two interesting attempts to reduce the excessive cost of a hull of conventional

construction for a sport plane. Amphibions, Inc., produced a three-place cabin model with a hull having a welded-steel-tube frame with a dural bottom and having the sides and deck covered with waterproof duck. Curtiss-Wright produced an amphibion version of the "Junior" with a special hull of plywood covered with waterproof fabric attached by a gluing process. The hull construction was developed in small-boat manufacture.

Both the plane produced by Amphibions, Inc., and the "F-15" Coast Guard patrol boat built by General Aviation showed the tendency toward having a short hull with a single boom supporting the tail. The "F-15" has an interesting retractable beaching gear that is a permanent unit of the airplane. The wing is of wood, with a stressed birch-plywood covering. Thus the wing adds to the buoyancy of the plane in an emergency. In Germany a novel tailess amphibion design was exhibited with two Diesel engines in the twin hulls driving a single propeller above the wing through a driveshaft.

Among the special planes built for the National Air Races were a number of interesting and efficient designs. Outstanding among these was the "Gee Bee," which broke the world landplane speed record. The short fuselage and extremely small tail surfaces and pilot's cockpit are worthy of notice. Unlike most of the wire-braced low-wing designs, the "Gee Bee" had its wing well above the bottom of the fuselage, tending to eliminate the usual pocket above the rear portion of the wing where it meets the fuselage. Most of the other racers were low-wing, wire-braced designs of about the same proportions as the British racing Moth of 1927. An interesting design feature on one, the Howard racer was the faired tandem-wheeled landing gear, which resembles that on the German G-38, but on a much smaller scale.

FIG. 6 STINSON MODEL "R" FOUR-PLACE CABIN PLANE, LYCOMING ENGINE, WITH RETRACTABLE LANDING GEAR

An exceptionally interesting plane in the cross-country race was built by Claire Vance of California. It consists of a plywood-covered tapered cantilever wing with an engine nacelle in the center. The nacelle is carried back to the trailing edge of the wing, with the pilot's cockpit directly behind the engine. The fully cowled engine is in front of the leading edge of the wing. The tail is supported on two booms. Landing gear is of the external, conventional three-strut type and includes two tail wheels.

In the realm of rotating-wing aircraft there was much activity during the year. The Wilford gyroplane with rigid cantilever blades, described in last year's Progress Report, has been successfully flying for some time. A type of rotor control was developed eliminating the need for ailerons and elevators for lateral and longitudinal control. Since the blades are cantilever, it has been proved feasible to fly on the lower wing alone and let the rotating blades idle without any load, and thus reduce the overall resistance for high-speed flight.

It is understood that in England a type of rotor control has been worked out for the autogiro which consists of a control stick which is really a continuation of the rotor mast down into the cockpit. By rocking the stick from side to side or fore and aft, the masthead, to which the blades are hinged, also moves, producing lateral or longitudinal control.

Both in England and in the United States cabin autogiros were produced. The American machine, built by Pitcairn, is for four people and besides being a cabin type differs from the conventional autogiro in that the lower wing with upturned tips has been replaced by a highly tapered cantilever wing with large dihedral. Two fins and two rudders are used.

AIRCRAFT-ENGINE DEVELOPMENTS

By C. F. Taylor[8]

In reviewing aircraft engine progress for 1932, it seems pertinent to mention some of the more important research work in the general field of internal-combustion engines, on account of its possible future application in the field of aircraft power plants.

Perhaps the outstanding piece of applied research has been the study of the combustion process in the compression-ignition engine, with particular reference to the effect of fuel composition on the "delay period" and on the combustion rate. (See ref. 1 to 5.) The work of Boerlage and Broeze in Holland and the photographic studies of combustion by the National Advisory Committee for Aeronautics are considered particularly significant. This work should have important results in practical application, particularly with regard to control of fuel composition to make possible increased engine output for high-speed compression-ignition engines, with perhaps eventual application to aeronautic work.

The excellent work with regard to the measurement of detonation which has been carried on for some years by the Cooperative Fuel Research Committee has been continued during 1932. Significant results have been obtained relative to the coordination of laboratory tests with actual service conditions. (See ref. 6.)

Research on cycles involving fuel injection with electric ignition has been actively continued during 1932 (ref. 7), and this, together with the development of hydrogenated "safety" fuels, may eventually result in a significant improvement in fire protection for aircraft.

Other significant research that might be mentioned includes work on journal-bearing friction (ref. 8), engine balance (ref. 9), and ring cowling (ref. 10), all of which may have important effects on the design of aircraft power plants.

Under the heading of application, mention should be made of the fact that one of the large air-transport lines has recently put into experimental service an engine using fuel injection into the cylinders, combined with spark ignition. Results to date have been so satisfactory that more extensive application of this type of engine is quite likely.

Engines of the 14-cylinder double-row-radial type, of American manufacture, were put into experimental operation during the year. At least two manufacturers are experimenting with this type of engine.

With regard to conventional engine types, the year was marked by significant increases in the ratio of power output to weight and to piston displacement, especially in the case of air-cooled radials. This was largely accomplished by the use of higher compression ratio, anti-detonating fuels, supercharging, and higher rotative speeds. The progress in this direction was well illustrated by performance records made at the 1932 Cleveland Air Races (ref. 11). As a result of such developments, the power

[8] Professor of Aeronautical Engineering, Massachusetts Institute of Technology, Cambridge, Mass.

and speed rating of most of the more important American air-cooled radial engines has been markedly increased during the year.

Another contributing factor toward the higher power output of the radial engine has been progress in metallurgical technique, particularly with regard to aluminum forgings, notably for pistons, and magnesium castings. There has been a marked increase in the use of such materials for aircraft engines during the year.

AERODYNAMICS

By Elton W. Miller[9]

The most obvious developments in aeronautics during the last year have been the marked increase in the cruising speeds of military and commercial airplanes and the noticeable increase in the safety of flight on air lines. In these developments center the aerodynamic advances of the year. Higher speed is made possible, among other things, by a better understanding of fluid flow about bodies and of the factors affecting the mutual interference and drag of airplane parts. Higher speeds in turn call for a better understanding of structural loading and more rational structural design methods. Considerations of safety in flying require better controllability at low speeds, lower landing speeds, and a solution of the spinning problem. In each of these fields there has been definite progress during the year. Airships and rotating-wing aircraft also have come in for their share of attention.

Interference and Drag. The investigation by Wood of the N.A.C.A. of the relative efficiencies of various wing-nacelle-propeller arrangements has been continued throughout the year, with the result that the designer need no longer be in doubt as to the best position for the nacelle in any particular design, or if practical considerations dictate an arrangement other than the best, he may know how much he is paying for the compromise. This investigation has included variously cowled nacelles for tractor propellers in combination with monoplane wings and biplanes. Tandem propellers and pusher propellers have also been tested in combination with monoplane wings.

The mutual interference of simple bodies has received careful attention by the British; the work of Jacobs, of the N.A.C.A., on the effects of small protuberances on streamline bodies and on airfoils, should prove of assistance in the general "cleaning up" of aircraft. The mutual effects of wings and bodies have been exhaustively studied by Parkin, of the University of Toronto, within the limits of scale of his equipment, and an important contribution in the same direction has been that of Klein, of the California Institute of Technology, on the effects of fillets on wing-fuselage interference.

[9] Chief, Aerodynamics Division, National Advisory Committee for Aeronautics, Langley Field, Hampton, Va.

Cowlings of the N.A.C.A. or of the ring type have been quite generally applied by designers to the air-cooled engine, but more complete information is required to enable the engineer to design the most efficient cowling for each particular case. Whether landing gears should be retracted or merely simplified and made clean seems to be still an open question.

The study of drag and interference is closely related to that of fluid flow about bodies. Deserving of special mention are the studies of flow about bodies of revolution by Millikan and Dryden and about airfoils by Theodorsen. The work of the British and of the N.A.C.A. dealing with flow studies by direct photographic methods should also be mentioned.

Load Factors. The aerodynamic loads actually experienced by military and naval airplanes in maneuvers and by transport airplanes when passing through gusts or vertical currents have been a matter of increasing interest in this country and abroad. The work of Rhode, of the National Advisory Committee for Aeronautics, on the pressure distribution over wings and tail surfaces offers valuable material on which to base the rational determination of load factors. In the same connection a new instrument has been developed by the N.A.C.A. during the year to record acceleration and air speed over a period of time. A number of these instruments are now in use on military and commercial airplanes, and the data being accumulated will doubtless be of great value.

Control at Low Speed. Many accidents in the past point to the need for more effective control at low flying speeds. This need has been appreciated for a long time. The Handley Page tip slot has been widely applied in Great Britain as the answer to this question, but even the British appear more recently to feel that there are possibilities of adequate control by other means. In this country an aversion to complication and to the addition of movable parts may possibly explain the failure to adopt the Handley Page slot.

The N.A.C.A. has attacked the problem by investigating thoroughly and systematically the properties of all existing and some new control devices, in combination with rectangular and tapered wings, and wings with special forms of tip. Some of these combinations seem very promising when properly applied. The results of a number of wind-tunnel tests have been published during the year by Weick and his assistants, and the more promising devices are being tested in flight.

Landing Speeds. As cruising speeds have increased, it has been necessary to investigate means for reducing landing speeds in the interest of general safety. Many devices have been offered for increasing the speed range, such as the Hall high-lift wing, the Zapp flap, and the Fowler variable-area wing. The N.A.C.A. has conducted research throughout the year to the same end, and one of the more promising devices resulting from this investigation is a small fixed auxiliary airfoil ahead of the main wing. Flight tests as well as wind-tunnel tests have been conducted, and the investigation is still in progress. Some of these devices, particularly the latter, have the further advantage of increasing the gliding angle, thus reducing the space necessary for landing after clearing an obstacle. In the same connection, wings of especially low aspect ratio and tailless airplanes appear to offer some advantages.

Spin. Probably no problem of aeronautics has been attended with so much mystery or has received such a large share of attention in all parts of the world as the problem of spinning. Research has been conducted and is still in progress in various laboratories, and there have been contributions by numerous commercial engineers, as by Edmund T. Allen and J. M. Gwinn, Jr. In England a 12-ft vertical tunnel has been constructed and is now in operation, in which models of airplanes may be made to spin and the effects of the controls noted. The N.A.C.A.

now has in operation a vertical tunnel with a special balance on which the moments of various control surfaces may be measured while the model is in a spinning attitude. An investigation in flight has also been continued throughout the year, including the use of smoke to indicate the nature of the flow over the control surfaces.

The solution of the inadvertent spin appears to lie merely in better control and stability at low speed, and a great improvement in control seems now within reach. The control of the voluntary spin appears at present to lie in such design and arrangement of the tail surfaces as will give adequate yawing moments under all circumstances.

Airships. The airship program of the Navy Department has given rise to considerable research work on airships during the past year. Most of this work has been centered around better control of the airship and a better understanding of air flow over the hull. Investigations by Seiferth, of the California Institute of Technology, and Freeman, of the N.A.C.A., on models of the *Akron* have contributed valuable information on these problems, including data of great interest on the boundary layer over the hull. Flight acceptance tests of the *Akron*, in which the Goodyear Zeppelin Corporation and the N.A.C.A. cooperated, have also yielded valuable data.

Rotating-Wing Aircraft. The autogiro offers many attractive features for certain purposes. A number of improvements are being developed, including the change from an open cockpit to a cabin and the elimination of cables on the rotor. The N.A.C.A. is conducting an investigation of the autogiro and has published some of the results during the year. The development of the gyroplane, which differs from the autogiro in that the blades are made to feather instead of flap, indicates another possibility in this type of aircraft.

New Equipment. Of interest in connection with new equipment for aeronautical research, is the dedication during the year of the Guggenheim Airship Institute in Akron. In England, the new compressed-air wind tunnel and a new seaplane channel have been put in operation, and the new 24-ft wind tunnel is understood to be under construction. The newer items of equipment in this country, including the N.A.C.A. tank and the N.A.C.A. full-scale wind tunnel, have been in operation throughout the year, and all have turned out valuable results looking toward more efficient and safer aircraft for the future.

AER-55-2

Lightning Investigation as Applied to the Airplane

By A. O. AUSTIN,[1] BARBERTON, OHIO

The hazard to aircraft from lightning is very small, but has received much attention. Lightning itself has caused but few fatalities, and many cases of trouble have been unjustly charged to it. Once the effect of lightning upon the pilot or plane is recognized, steps can be taken to materially reduce the hazard, if not to eliminate it. Some interesting information has been gathered from tests as to protection for free balloons and planes and other equipment.

WHILE the hazard to airplanes or to any aircraft is very small as compared to many everyday risks, this hazard receives much attention. Although lightning has caused a few fatalities, it would seem that many cases of trouble due to other causes have been unjustly charged to lightning. Once the effect of lightning upon the pilot or plane is recognized, steps can be taken to materially reduce if not eliminate the hazard, although this may be small.

The studies made in the high-voltage laboratory of the Ohio Insulator Company for Ward T. Van Orman in testing out his protection for free balloonists and the series of tests run on planes and other equipment provide some rather interesting information.

Since the tests run in connection with free balloons illustrate certain phases of the subject to better advantage than those upon airplanes, this matter will be treated first.

In running the series of tests, balloon baskets, small-size balloons, and model airplanes, as well as full-size airplanes, were placed between a large electrostatic condenser and the ground on the test field. The condenser may be regarded as a charged cloud, and a discharge taking place between this cloud and the ground can be made to strike the equipment under test. Fig. 1 shows a discharge taking place from this condenser to the ground, the photograph being taken by a synchronized camera.

In general the hazards from lightning may be divided into two classes:

(*a*) Electrical or physical shock that may affect the pilot and passengers

(*b*) Those hazards that damage the plane or aircraft.

It would seem that the hazard due to the direct electrical or physiological effect of lightning upon the pilot or passengers should receive first consideration, rather than the damage to the aircraft. Unfortunately, it is very difficult to obtain information upon this point owing to the variation in the personal element itself and the hazard of making studies that may be exceedingly dangerous. It may be said, however, that as the size of aircraft increases, the direct danger to pilot or passengers tends to decrease, providing ordinary precautions are taken in the design and construction of the aircraft. This is due to the greater distance of the crater or point of contact of the lightning from pilot and passengers.

Hazards to the Plane or Aircraft

These hazards may be classified as follows:

1 Fire hazard due to ignition of combustible material used in the construction of the plane
2 Fire hazard due to ignition of explosive gases
3 Weakening or destruction of metal or other parts due to current in the discharge
4 Breakdown of insulation in the ignition system
5 Backfire or preignition
6 Damage to instruments
7 Damage to rotating parts due to passage of current
8 Sudden change in pressure on adjacent surfaces.

Electrical or Physiological Shock to Pilot or Passengers

The experience of free balloonists throws considerable light upon the hazard due to shock, and upon the means of protection. The fatalities in Belgium and in Pittsburgh of recent years caused Van Orman to give this matter considerable attention.

In the Pittsburgh race Van Orman's balloon was struck by lightning while at an altitude of 3000 ft and was set on fire, and Morton, who was with him in the basket, was killed by the stroke. The No. 26 R.C.A. portable loop radio set, which was between Van Orman and Morton, appeared to be badly damaged. However, an investigation showed that the set was not damaged electrically. Van Orman apparently was conscious for a short time after the stroke. He then lost consciousness and apparently remained in a stunned or dazed condition for five or six hours after the parachuting balloon struck ground.

Wollam and Cooper, in the balloon *City of Cleveland*, had a somewhat similar experience, the stroke of lightning apparently passing over the surface of Cooper's leather jacket or suit, which was wet at the time. The shunt path provided by the suit apparently saved Cooper's life, although he was badly burned by the stroke. Wollam escaped uninjured, and he attempted to lift Cooper and his parachute out of the basket, but was unable to do so. Cooper apparently is the only known person to have suffered a heavy direct stroke and live to tell about it.

These incidents show that a stroke of lightning may be very close to a person without causing any serious injury. Had the pilots been subject to the same conditions while flying an airplane, it is possible that they might have lost control of the plane, causing it to crash.

---

[1] Chief Engineer, Ohio Insulator Company. Mr. Austin was born in Stockton, Calif., on December 28, 1879. He was graduated from Stanford University in 1903, with A.B. in Electrical Engineering. His business and professional history includes the following: 1903–1904, test department of General Electric Company at Schenectady and Pittsfield; 1904, Pacific Gas and Electric Company, in charge of insulator inspection and development; 1905, manager and chief engineer for Lima Insulator Company; 1909, chief engineer for Akron High Potential Porcelain Company, in 1910 changed to Ohio Insulator Company, Barberton, Ohio; 1918, factory manager and chief engineer for Ohio Insulator Company; 1931, vice-president and chief engineer of Ohio Insulator Company and consulting engineer for Ohio Brass Company.

Presented at the Fifth National Aeronautic Meeting, Baltimore, Md., May 12 to 14, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Fig. 2 shows the basket used on the *City of Cleveland* balloon, which was struck while the balloon was at least 5000 ft in the air.

The photograph shows the basket with a dummy in place being subjected to an artificial-lightning discharge. The steel cables from the ring to the basket were not bonded to the reinforcing wires that were used in making up the basket. It is possible that had bonding been carried out, the results might have been quite different.

In the test shown in Fig. 2, the collapse of the electrostatic field caused an induced potential of over 25,000 volts between the dummy and the lower part of the basket. While the energy is not large, the discharge might tend to startle one in a manner similar to the shock one receives in coming in contact with a metal object after picking up a charge in walking over a carpet in cold dry weather.

Fig. 3 shows the metal reinforcing wire fused, due to the discharge of lightning. It will be noticed that the horizontal wire crossing the vertical wire has been burned in two, as well as some of the basket material. An examination of the basket showed a large number of burns where the reinforcing wires crossed each other.

Fig. 4 shows a test on Van Orman's lightning protecting scheme. The protection consists essentially of a cage formed by conductors hanging freely. These conductors are bonded at the top and part way down, but are left entirely free at the bottom so as not to interfere with landing or parachute jumps from the basket. The conductors forming the shunt path are moved outward from the basket a short distance. The cable supporting the basket to the ring has been replaced with rope. It would seem that had this device been used in the flights in Belgium and in Pittsburgh, the fatalities due to direct stroke would have been avoided.

(Photograph taken by synchronized camera, making it possible to photograph discharge in full daylight.)

FIG. 2 BASKET USED ON "CITY OF CLEVELAND," WITH DUMMY IN PLACE BEING SUBJECTED TO ARTIFICIAL LIGHTNING
(Klyndonograph showed 25,000 volts between dummy and basket.)

Apparently there is little difficulty in shunting the main discharge, but there is some question as to how far the discharge should be from the pilot so that he will not be stunned or frightened to the extent of losing control. The baskets in racing balloons are rather small, and any one in the basket must of necessity be very close to any discharge striking the basket. Should the Van Orman cage give the necessary protection for direct hits, it would go to show that the protection to pilot or passengers in an airplane may be easily provided by shunting the discharge a short distance to one side.

DANGER OF DIRECT HIT

Many people believe that a balloon or airplane could not be subject to a lightning stroke while flying, since there is no direct ground connection. Any object, however, that has a greater conductivity than the air or a greater electrostatic-flux carrying capacity will tend to disturb the electrostatic field and will cause a discharge in the immediate vicinity to take a path along the object.

EFFECT OF CONSTRUCTION UPON A STROKE OF LIGHTNING

In running the tests on the Van Orman cage, an attempt was made to protect the balloon. If the gas in the balloon is free from air, lightning will not cause it to explode, although the balloon may be set on fire. If an explosive mixture is present in the balloon, an explosion may take place due to the ignition of the mixture.

Difference Between a Wet and a Dry Balloon

In the study of high-voltage phenomena, particularly those applicable to transmission-line structures using wood, it was believed that there would be a considerable difference between a wet and a dry balloon. The tests were very interesting in this

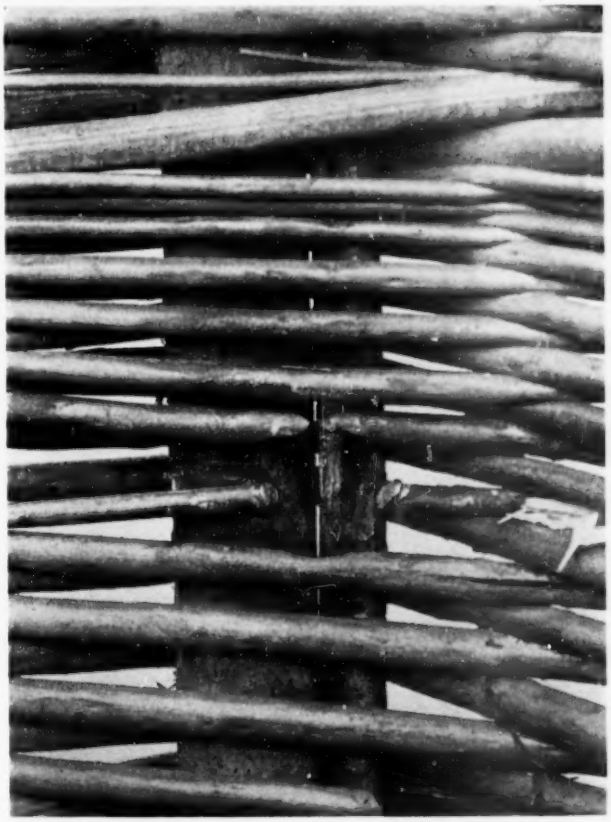

Fig. 3 View of "City of Cleveland" Basket Showing Reinforcing Wire Burned in Two Due to Stroke of Lightning

connection, as they go to show that while there might be a considerable difference in an aircraft that is constructed of metal and one that is primarily of non-conducting material when dry, there would be little difference where the latter was wet. This difference is undoubtedly due to the increase in electrostatic capacity due to the presence of water.

Fig. 5 shows a hydrogen-filled balloon being subjected to an artificial stroke of lightning. The balloon has a conductor attached approximating a long antenna, hanging from the lower side. A number of discharges were applied to the balloon similar to that in Fig. 5. All of these discharges struck the upper part of the conductor attached to the balloon, and then passed from the lower end of this conductor to ground.

As soon as the balloon was wet, however, conditions were entirely changed, the performance being similar to that shown in Fig. 6. The discharges, instead of going directly to the antenna and then to ground, struck the surface of the wet balloon. The discharge in Fig. 6 is apparently passing along the surface, which destroyed the balloon in all cases. The discharge invariably burned the rubber and set the escaping gas on fire. Had the photograph been taken a fraction of a second later, the balloon would have been shown collapsed, the duration of the arc shown in the photograph being less than one-half microsecond.

These tests go to show that there is little or nothing to be gained electrically by the use of non-conducting material in the aircraft structure where the material becomes wet, as the electrical fields set up are not materially different.

A discharge striking conducting material adjacent to inflammable material is likely to set the latter on fire. There are many cases that illustrate this point. Owing to the tendency of a discharge to strike a wet balloon, it was evident that it was necessary to remove the point of contact of any conducting system some distance from the balloon. While this is a distinct disadvantage to racing balloons owing to increased weight, the tests are very interesting as they show the tendency of the wet fabric in diverting or attracting a discharge.

Fig. 7 shows a discharge to ground some few feet distant from a balloon equipped with a cage or lightning rods. In Fig. 8 the balloon has been wet. While there was some tendency for the balloon while dry to attract the arc, the starting point of the discharge was too great, so that the arc struck to ground. In Fig. 8, however, the field set up by the wet balloon was of sufficient magnitude to attract the discharge. The discharge followed the shunt path provided by the conductors of the cage, and then continued from the lower end of the cage to ground. Without the shunt path, the wet balloons were invariably set on fire by the direct stroke. In some cases the fabric seemed to be only slightly damaged. The escaping gas, however, was frequently ignited by the stroke, causing destruction of the balloon unless quickly extinguished.

Probability of a Direct Hit

In the case of free balloons or blimps there would undoubtedly be a considerable difference between the wet and dry conditions

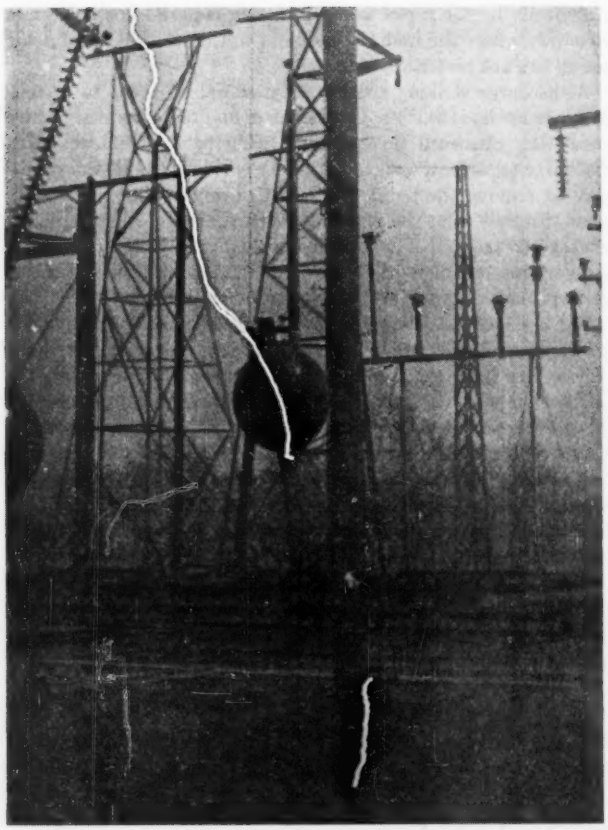

FIG. 5 DRY HYDROGEN BALLOON WITH ANTENNA ATTACHED, SUBJECTED TO LIGHTNING DISCHARGE WITHOUT DAMAGE TO BALLOON
(Discharge passes around the dry balloon to the antenna and then jumps from the end of the antenna to the ground.)

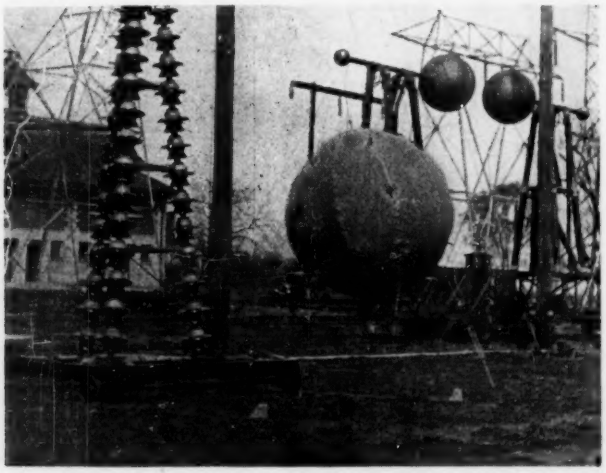

FIG. 7 DISCHARGE TAKING PLACE TO ONE SIDE OF DRY BALLOON EQUIPPED WITH CAGE AND LIGHTNING RODS

in attracting a discharge in the vicinity. In other aircraft as now constructed, however, there would be little difference wet or dry. In the tests on models placed near the path of discharge, it was evident that the path of discharge was diverted an appreciable distance by the presence of the plane. It would seem that the probability of being struck would increase approximately as the square of the greatest linear dimension.

The nature of the electrical field, the polarity of the discharge, and the direction of the axis of the aircraft relative to the general path of discharge are all factors that make it difficult to predict the effect of size in increasing the probability of direct hits. Figs. 9, 10, 11, and 12 show typical discharges to model planes, showing the probable points of contact of the stroke.

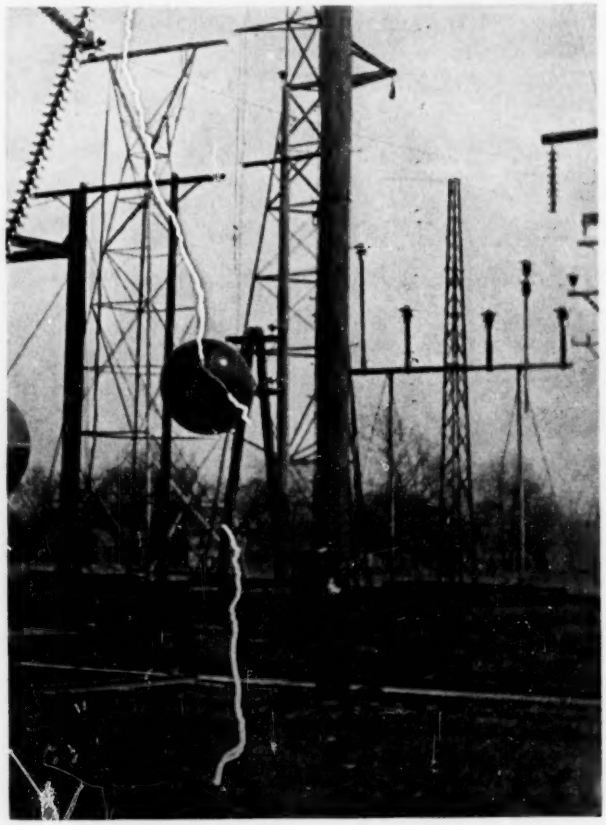

FIG. 6 PHOTOGRAPH SHOWS DISCHARGE TO THE WET BALLOON, CAUSING ITS DESTRUCTION
(The wetting of the surface caused the discharge to go directly to the balloon, burning a path along the surface and setting it on fire.)

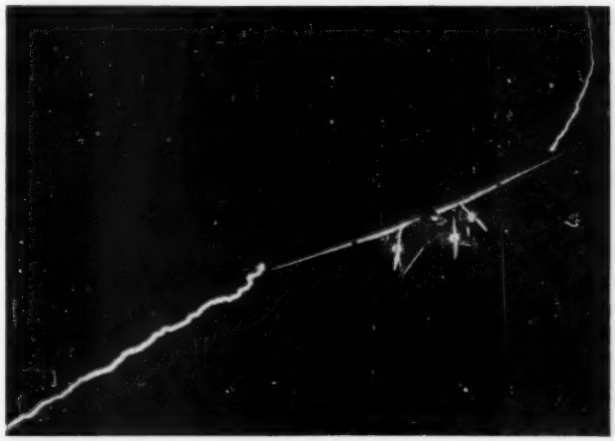

FIG. 10 DISCHARGE ENTERING AND LEAVING FROM WING TIPS

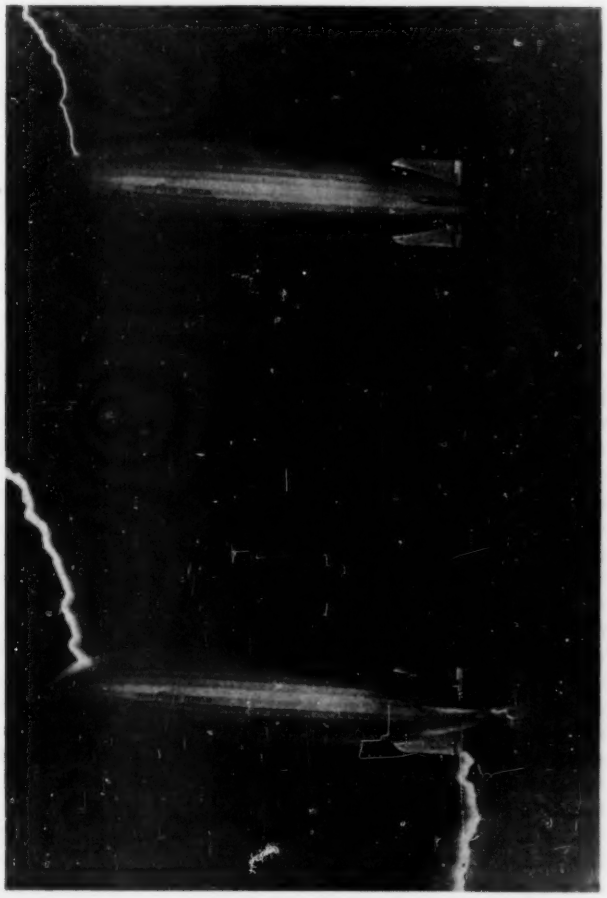

FIG. 13 (UPPER VIEW) DISCHARGE OF LIMITED CAPACITY STRIKING MODEL ZEPPELIN. (LOWER VIEW) HEAVY DISCHARGE STRIKING ZEPPELIN AND CONTINUING TO GROUND

Fig. 13 shows a positive discharge of limited capacity striking a model zeppelin. The discharge was not sufficient to cause the arc to continue to ground, but illustrates the effect of a large body free of ground. Immediately following the first discharge, another discharge was applied of sufficient magnitude to cause a discharge not only to the model zeppelin but from the rudder to ground.

It is interesting to note that in all of the tests the fabric used on the zeppelin and that on the fabric-covered duralumin airplane were not ignited by the discharges. This goes to show that the fire hazard is negligible where a path of high electrical conductivity is provided.

It would seem that the effective increase in size and the use of metal in the present construction of airplanes should do much to minimize the lightning hazard, even though little or no attention is given to protection.

A direct hit to the plane may possibly affect the pilot or passengers in one of the following ways:

(*a*) Direct hit
(*b*) By forming a path for the discharge between conducting objects
(*c*) Shock from induced charge
(*d*) Sudden change in air pressure
(*e*) Severe sound or pressure waves
(*f*) Currents induced in the body by an electromagnetic field
(*g*) Hazard due to the effect of intense light upon the pilot.

While the danger from some of these hazards may be absent in many planes, they can be largely reduced if not eliminated in others by proper attention to details of construction or by applying a protecting scheme that will establish the path of discharge at a distance from the pilot.

(*a*) *Direct Hit.* In general the possibility of a direct hit to the pilot is exceedingly small, even in the low-wing monoplane with open cockpit. The tests showed that the discharges would enter or leave through the propeller or nose, rudder, wing tips, or landing gear. A lightning rod projecting above and to one side of the pilot would insure the diverting of the stroke, even though the pilot's head projected well above the fuselage. In large planes or zeppelins, the points of contact of the stroke would be considerably removed from the pilot or passengers, so that it would appear that the danger from direct stroke may be even less than in the ordinary dwelling during an electrical storm.

(*b*) *By Forming a Path for the Discharge Between Conducting Objects.* A discharge of lightning may carry a current far in excess of that available in any of the laboratories used for the production of artificial lightning. The fused wire in the basket shown in Fig. 2 cannot be duplicated with the heaviest lightning discharges in the laboratory. Records taken at the forest ranger's stations show that a stroke of lightning may be sufficient to fuse a No. 14 copper wire. Tests on aerials have shown that wire of larger size has been fused, all of which indicates currents exceeding several hundred thousand amperes.

The impedance afforded by conductors with this very high rate of discharge will cause a considerable drop in potential. This drop in potential causes the current to divide into multiple paths, the drop in voltage being sufficient to cause the bridging of appreciable air gaps between parallel circuits, even where the difference in the impedance of the metallic paths is not very large. It is therefore essential that the most careful attention be given to bonding between parts to eliminate discharge. In order to lower the impedance (so as to reduce the difference in potential tending to cause discharge) it is well to distribute the conductor in several parallel paths. This reduces the reactance and the voltage drop along the conductor caused by the high rate of discharge.

It is evident that should the pilot come in contact at two points along a conducting member, he is likely to be subject to shock. The thorough bonding, the use of low-impedance multiple paths as far away from the pilot as possible, together with a single point of contact with conducting material, will eliminate the danger of shock from drop in potential due to the passage of exceedingly large currents.

(*c*) *Shock From Induced Charge.* A pilot in an open cockpit may be subjected to an induced charge due to the collapse of the electrostatic field. It would seem that this charge would amount to but little, provided the discharge did not cause the pilot to become frightened so as to lose control. The complete shielding afforded by metal cabin planes completely eliminates the effect of the induced charge due to the collapse of the electrostatic field. The same applies to zeppelins. Conducting parts separated by insulation may discharge across the insulation unless the distance is sufficient to prevent breakdown of the air. Where the area or capacitance of the parts is small, the discharge may be negligible, but as the area or capacitance increases, the discharges may be such as to require the bonding of any isolated metal parts to prevent discharge due to the collapse of the electrostatic field, which may have an appreciable effect although the lightning is some distance from the plane.

(*d*) *Sudden Change in Air Pressure.* The intensity of lightning varies greatly for different strokes. It would follow, however, that the very severe discharge causes a rapid heating of the air and an increase in pressure in the immediate vicinity. The pressure set up where the air is free to expand is not as great as originally supposed. The fact that three balloonists have come through storms where the stroke was within a foot or two of them would indicate that the hazard from this source is not serious, even for the very heaviest discharges where the path can be moved out a few feet from the pilot.

(*e*) *Severe Sound or Pressure Waves.* The effect of the severe sound and pressure waves may be responsible for the shock suffered by pilots and others who have been within a few feet of lightning strokes. The duration of the effect seems to vary considerably with the individual and may cause effects somewhat similar to those suffered from shell shock. Many of the factors producing shell shock are present, although there are others in addition. Fortunately the severity reduces rapidly with distance. It would therefore seem that using a construction that removes the point of contact between lightning and plane well away from the pilot will do much to eliminate any serious effects that may cause the pilot to lose even temporary control. The pilot can, of course, be easily protected from sound or pressure waves by providing a suitable compartment or other sound-absorbing equipment.

(*f*) *Currents Induced in the Body by an Electromagnetic Field.* A stroke of lightning may consist of a single discharge or of several discharges within a very short space of time. The strength of the electromagnetic field will vary directly as the current in the discharge and inversely as the distance. A current of 400,000 amp in a stroke will produce a field of 2620 maxwells at 1-ft distance, 262 maxwells at 10-ft distance, and 131 maxwells at 20-ft distance.

Any change in the electromagnetic field passing through either high- or low-resistance material will induce a voltage and current. The induced voltage and current will depend upon the rate of change in the magnetic field. It is evident that the lines of force passing through a person will induce currents, the action being similar to that in a high-frequency furnace. Several strokes in rapid succession may induce a greater current or potential than a single stroke of higher maximum magnitude but having a slower rate of change.

While it is possible to screen the electrostatic field, it is prac-

tically impossible to effectively screen the electromagnetic field so as to prevent the lines of force passing through objects in the vicinity of the field. The field may be set up by the current of a portion of the discharge in the air or in a conductor in the aircraft. It would seem that the heaviest discharges taking place close to a person may induce enough potential and current to affect the system, or at least to paralyze the nervous system temporarily.

A study of the factors affecting the induced potential and current go to show that the electromagnetic field may be materially reduced by removing the shunt path from the immediate vicinity, and by forming multiple paths around the pilot or passengers so that the field set up by the current in one path tends to neutralize the field set up in the other. The fact that some people have not been affected, although within a few feet of the discharge, would indicate that a reduction of the field strength by an appreciable amount would entirely change conditions and provide protection even for the most severe strokes. Parallel conducting paths on opposite sides can be used to advantage to reduce the effective field strengths caused by heavy discharges.

Further investigation may show that the induced current does not constitute a hazard. The magnitude of the voltage generated and the current induced for heavy strokes in the immediate vicinity, however, would indicate that the possibility of affecting at least the nervous system cannot be ignored without very definite proof to the contrary.

Although little has been accomplished in determining whether the shock or stunning effect is primarily due to electrical causes or to physical conditions similar to those producing shell shock, the same method will improve conditions for either case. This consists primarily in initiating the point of contact of the stroke to the plane as far away from the pilot as possible. Antennas or conductors projecting from the aircraft should therefore be a safeguard rather than a hazard.

(*g*) *Hazard Due to the Effect of Intense Light Upon the Pilot.* The light from a stroke, particularly at night, may have the effect of blinding the pilot when passing through the line of vision. At night the iris is wide open, and it is possible that the ultraviolet light might have some effect upon the pilot from a discharge striking the nose of the plane. In most planes, however, the discharge would be to one side and above or below the direct line of vision. It is believed, however, that the hazard from this source is small. While intense light may have the effect of blinding the pilot for a short time, any serious effect due to ultraviolet light may be easily eliminated by the use of glass in the windows or goggles that would absorb any injurious rays.

While the effect of lightning upon the pilot or passengers undoubtedly causes the greatest and most uncertain hazards, there are other hazards to the plane or aircraft that need careful consideration.

1 *Fire Hazard Due to Ignition of Combustible Material Used in the Construction of the Plane.* The fire hazard to the metal plane is negligible, although intense heat exists at the point of contact with the lightning and the plane. The fire hazard is practically negligible even where material that will support combustion is used. Where an inflammable covering is used in contact with metal, the fire hazard is also apparently negligible. Inflammable material that is readily ignited may be set on fire at the crater. However, the severe rush of air following the stroke has the effect of extinguishing the flame. The discharge being in the nature of an explosion, the rapid expansion of the gases, even in the fabric, apparently absorbs sufficient heat, which, together with the blast of air following the discharge, prevents ignition. This is particularly true where a fabric is used to cover duralumin or other metal. The heat conduction of the metal and the low resistance of the path afforded tend not only to absorb the heat but to reduce the energy dissipated. Heat generated by the discharge through a combustible material so situated that the radiation is cut off constitutes the greatest fire hazard.

Fig. 14 shows the effect of artificial lightning upon the rudder. It will be noticed that the fabric has apparently been exploded at the points of contact, the fibers being torn apart, the effect being similar to that of popping corn.

A rather severe series of tests run on a model zeppelin covered with fabric showed that it was impossible to ignite this fabric with the artificial lightning. The history of zeppelins has also indicated that this danger is small, unless conditions approximate those of the gas-filled free balloons. The framework and outer covering projecting some distance beyond the gas bags affords protection against the ignition of the gas by a direct stroke even where hydrogen is used.

2 *Fire Hazard Due to Ignition of Explosive Gases.* A discharge may take place between conducting surfaces not properly bonded or from isolated tanks or conductors separated from the bonded structure by small air gaps. The discharge may be produced by the release of a bound charge following the collapse of the electrostatic field, or due to the impedance drop in conductors

Fig. 14 Craters or Punctures Produced by Discharges to Rudder

making up the structure, or by the change in the electromagnetic field. These induced discharges are similar to those noticeable in the ordinary dwelling where a discharge takes place between wiring and conduit or fixtures following a stroke of lightning nearby. Should these discharges take place in a pocket of gas, an explosion may result. It is therefore important either to thoroughly ventilate all pockets that may accumulate gas or to adopt a construction so that a discharge cannot take place. Vents or openings for scavenging explosive gases should be protected with a screen similar to that used in a safety lamp.

3 *Weakening or Destruction of Metal Parts Due to Current in the Discharge.* In aircraft having a metal structure there is ample conducting capacity, so that a serious temperature will not be reached in any of the metal parts. However, should the construction be such that the current is confined to small members or to important connections having a high resistance, it is possible that the heating may seriously affect the structure and lower the mechanical strength. This is important, as some of the alloys are materially affected by a temperature far below the fusing point.

While the varnishing of the surfaces and joints, together with the oxidation of the surface, goes to produce a joint of high resistance, it must be remembered that the riveting cuts through the edge and forms a path of low resistance. A number of point contacts formed in this way results in a joint of very low resistance, so that little or no damage need be feared even though the cross-section of metal in good contact is small. Where metal parts simply come in contact or are held a short distance apart, considerable energy may be dissipated in the joint.

It would seem that the greatest hazard due to heavy current affecting the strength of metal parts is that due to control cables or staywires in non-metal planes. Discharges direct to the rudder showed a very appreciable rise of voltage on the control cable, although in the plane that was tested only a small percentage of the current was carried by the control cable, the major part going through the hinge and metal framework.

Fortunately the steel control cables usually have a high impedance compared to metal parts paralleling them. This high impedance tends to prevent a heavy flow of current in the control cables, although a very appreciable voltage may be induced under some conditions. An insulated section placed in the control

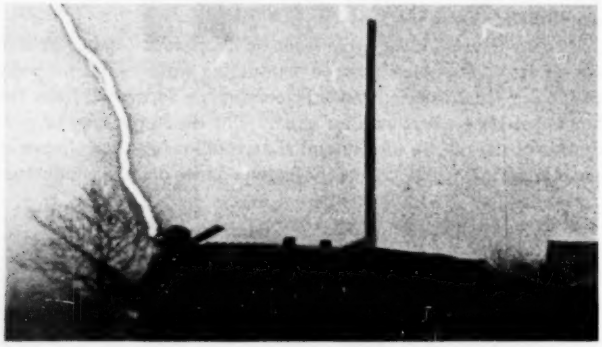

FIG. 15 DIRECT HIT TO IGNITION SYSTEM EXCEEDING 1,500,000 VOLTS

FIG. 16 DISCHARGE TO PROPELLER WHILE IN OPERATION
(Discharge strikes from termination of metal on propeller to ignition system opposite.)

cables can be used to prevent a high induced voltage on the controls, but this method should not be used to take the place of a parallel conducting path. Unless a parallel path is used the insertion of an insulator would tend to cause the discharge to leave the control cable. Should this discharge take place from the cable in place of the fitting, the heat generated at the crater might cause more damage to the cable than if the current were allowed to flow without restriction. The disadvantage of inserting the insulation may be easily offset, however, by providing a shunt between the control cable and any possible point of discharge, which would still permit the insertion of the insulator between the cable and controls.

4 *Breakdown of Insulation in the Ignition System.* Most of the ignition systems are fairly well insulated and have to withstand the relatively high voltages generated in the normal operation of the engine. Care should be taken so that conductors of the ignition system do not form a shunt path. In addition the conductors should be exposed as little as possible. The ignition systems apparently are more immune from trouble than would generally be expected. This seems to be due to the fact that the rise in voltage is limited by the discharging of the spark plug either inside or outside the cylinder.

Fig. 15 shows the ignition system being subjected to a discharge of over 1,500,000 volts. The discharge is striking the spark plug and lead on one of the cylinders. A number of similar discharges apparently had no effect upon the magneto or other parts of the ignition system. A small shield placed over the plug easily diverted the discharge.

5 *Backfire or Preignition.* It is evident that a discharge striking a plug or lead may cause a backfire or cause the engine cylinder to fire out of turn. A series of tests were made with the engine running so that the discharge would strike the propeller or ignition system. The propeller used was wood with a metal shielding which ended some distance from the hub.

Fig. 16 shows a discharge striking the end of the propeller. The discharge is then shown jumping from the metal shielding on the propeller to one of the spark plug terminals, as these happen to end about in line with the end of the shielding. A number of discharges apparently had no effect, although it appeared that the impulse from one cylinder was lost. The effect, however, was so slight as to leave this point in doubt. A small shield placed in front of the rod effectively drew all of the discharges. While the hazard is exceedingly small, it would therefore seem to be good insurance to prevent a discharge of this kind to the ignition system that might break down the insulation of the leads or the magneto.

6 *Damage to Instruments.* During one of the endurance flights at Cleveland the plane was struck by lightning, and the instruments were so damaged that a landing was made. An examination of the instruments did not show any electrical damage due to the conduction of current. There was an indication that the diaphragm in the instrument that was connected to the pitot tube used for determining velocity might have been damaged by the pressure set up. In the tests that were run some time later, it was evident that the pitot tube might be a point of contact for the stroke, in which case sufficient pressure might be set up so as to destroy the rather delicate diaphragm. A sudden air pressure set up by the stroke in any other way might of course have produced the same effect.

Should it appear that there is danger to instruments from the pressure set up, it would be a comparatively easy matter to prevent this by placing a baffle in the line between the pitot tube and the instrument, preferably with a surge chamber between the restriction and the instrument. Other instruments could be enclosed in a comparatively tight chamber having a window.

The electrical fields set up by a heavy discharge in the immediate vicinity may damage magnetic instruments or those in which an induced current may cause a breakdown of insulation. While electrostatic screening is comparatively easy, screening for the electromagnetic field is very difficult, and it would follow that instruments that are likely to be damaged by a strong magnetic field should be so placed that the path of discharge in the frame or surrounding objects is removed as far as possible.

7 *Damage to Rotating Parts Due to Passage of Current.* The damage to rotating parts may be serious where a heavy current must pass through an important bearing. Discharges with currents as high as 100,000 amp showed no appreciable damage on the main bearing or upon ball bearings. Since this discharge lasted for only a fraction of a microsecond, the tests do not prove that damage from this source can be entirely ignored. In general, however, it would seem that a discharge striking a

metal propeller would flash from the shaft to the face of the engine case without causing any damage. However, should the discharge take place in the bearing, it is possible that trouble would result. Owing to the resistance of the bearing, it is comparatively easy to provide a shunt path between the propeller shaft and housing so that the oil film will not be punctured by a discharge.

While the energy stored in the test condenser is of the order of 10,000 watt-sec compared to 10,000,000 watt-sec in the discharge of lightning, it must be remembered that the energy is dissipated almost entirely in heating the air, so that the energy dissipated in a bearing may not be any more with a lightning stroke than that under laboratory conditions, unless the discharge consists of a number in rapid succession liberating a considerable amount of energy.

8 *Sudden Change in Pressure on Adjacent Surfaces.* The sudden change in air pressure following a heavy stroke will probably not exceed that frequently occurring under normal flight. Should a discharge be close to and parallel to a surface, it is possible that a heavy effective pressure may be set up tending to cause a collapse. It is this sudden change in pressure that probably accounts for the tearing of fabric.

It is evident that the larger the spread of the conducting surfaces, the greater will be the danger of a stroke including the airplane in its path to ground or from cloud to cloud. While the use of an aerial extending some distance below the plane will tend to increase the danger of a stroke, it must be remembered that this will at least keep one of the points of contact of the discharge at some distance from the plane. This advantage may more than offset the increased probability of a stroke. The use of a loop set does not change the hazard in any way over that where no radio set is used. The use of a strut or mast extending above the plane for an aerial would seem to be an added protection, as it would tend to keep the point of contact at a distance.

The insertion of a resistance or impedance between the antenna and instrument with a shunt path to the frame of the aircraft will provide ample protection, the protection probably being much more effective than that provided for the ordinary house radio set using an outside aerial.

While hot gas is a good conductor, the question of the engine exhaust forming a conducting path that would tend to carry a stroke to the plane does not seem to be an appreciable hazard. In all of the tests the effect of the exhaust gases could not be noticed. In the many tests made there was no indication that a low resistance or conducting path was created by the hot gases. In fact, it would appear that the dielectric strength of the air was apparently increased by the wind or pressure produced by the propeller. While the gases are conducting for a very short distance from the exhaust, this hot gas is soon cooled by the mixing of the strong air current produced by the propeller, so that no effect upon a discharge can be expected.

Conclusion

In conclusion it may be said that while information is lacking as to the effect upon the person, much can be accomplished to remove the danger of this effect by giving attention to the various factors involved. While the hazard is exceedingly small, it is possible that still further improvements may be effected by taking advantage as opportunities in design and construction present themselves.

Further information upon the effect of shock will doubtless show that the hazard is not very great, although it may appear to be necessary to protect the pilot from sound or other conditions during a storm. Where the pilot has a fear of lightning, it is possible that tests or checks might be devised that would remove this fear.

Anything that will permit the safe landing of the plane or that will provide automatic control while the pilot is stunned would do much to eliminate the hazard that now exists. Owing to the increased reliability of aircraft, less attention will be paid to storms. While this will tend to increase the lightning hazard, it would seem that the present hazards can be more than offset by careful attention to the various factors tending to produce reliability.

AER-55-3

Photogrammetric Measurement of Airplane Landing Speeds

By V. C. FINCH,[1] AUBURN, ALA.

The paper gives a method of airplane landing-speed measurements. Wing loadings have mounted steadily in the past few years, with consequent increase in landing speed. Within the past two years wing areas have been so ruthlessly clipped that some of the 1932 models of conventional commercial airplanes are carrying weight per unit of wing area far in excess of the fastest wartime pursuit airplanes. To fit the government requirement of 65 mph as the limit for passenger-airplane landing with full load in still air, several manufacturers of stock models are assisting in the development of a method of actual measurement of landing speeds. The photogrammetric method gives an accurate and permanent record.

THE question of landing-speed measurement will not down. Wing loadings have mounted steadily since the war, with consequent increase in landing speed, and within the past two years, when economy of airplane operation has been so eagerly sought, wing areas have been clipped and trimmed with such ruthlessness that today some of the 1932 models of conventional commercial airplanes are carrying weight per unit of wing area far in excess of the fastest wartime pursuit planes. Certainly the use of high wing loadings and high landing speeds is conducive to economy and to the high cruising speeds so much desired. Cruising at 125 mph in an airplane with a landing speed of 55 mph costs several times as much per unit of distance and pay load as cruising at the same speed with a plane whose landing speed is in excess of 75 mph. If airplanes had advanced to a stage where forced landings were unknown, and if airplanes were never called on to make a landing at airports other than those with sufficient runway length to gain an A-1-A rating, the tendency toward even higher wing loadings and further economy might be encouraged to go on unchecked toward the final goal, the flying engine.

Unfortunately, under existing conditions, other things being equal, the airplane which lands most slowly is the safest, and the Department of Commerce has therefore set 65 mph as the limit at which a passenger-carrying airplane may land with full load in still air. Faced with the necessity of closely approaching this limit and not desiring to enter into production of stock models exceeding it, several manufacturers have seriously encouraged the development of a method of actual measurement of landing speeds. Their encouragement and their generous cooperation are chiefly responsible for the investigation described in this paper. While the work has been in progress, contacts have revealed that many present-day air-transport operators and even a few private owners are as much interested in the correct landing speeds of their airplanes as they are in the maximum and cruising speeds. Landing speeds obtained by approximate methods of calculation and by uncalibrated air-speed meters are frequently accepted as accurate by purchasers of new airplanes. In general, landing speeds obtained by these methods are appreciably lower than actual landing speeds, and the purchaser who intends to operate from a small field, and to this end selects the airplane of the type desired which is advertised as having the lowest landing speed, is almost invariably disappointed.

Keen competition in the field of airplane sales and the lack of a capable commercial flight-testing organization equipped to make standardized performance tests has led to the advertisement of some very optimistic landing-speed figures. Fig. 1 illustrates these discrepancies. The curve shows the average relation of wing loading to landing speed and is based on the results of the photogrammetric measurements made on airplanes employing medium-lift airfoil sections. The actual landing speeds of airplanes with medium-lift sections should fall on or near this curve. Thirty airplanes with medium-lift sections were selected at random, and their advertised landing speeds are plotted as points on this figure. The range of optimism varies from about 5 mph to nearly 20 mph.

The most common method of measuring airplane-landing speeds used in the past has been by the employment of a calibrated air-speed indicator. Air-speed indicator calibration is accomplished by flying low over a measured course and taking the time of covering the course with a stop-watch. This method has been found subject to the following inaccuracies: (*a*) Deviations in the flight path of the airplane, which are increased in the single-seater sport or pursuit airplane, where the pilot has to handle the stop-watch, sight the markers at beginning and end of the course, read instruments, and record data. (*b*) Air-speed indicator errors, the greatest of which are those caused by faulty pitot-tube installation. If the pitot tube is not parallel with the flight path or is located so close to a wing or strut that it is operating in disturbed air, the air-speed indicator reading will be much lower than the plane's actual air speed. (*c*) Personal errors in pressing stop-watch, sighting markers, etc.

The pitot bomb, suspended below the airplane, eliminates the installation errors, but its position renders it impracticable for determining actual landing speeds.

5	2	26.25	550	41.9	69	42	47.00	10.0	57.00	72	30.05	1.009	56.45	Take-off, tail high
6	High-speed course			519.5	68	190	126.8	9.1	135.9	72	30.05	1.009	134.6	Into wind
7	High-speed course			519.5	68	166	145.0	9.1	135.9	72	30.05	1.009	134.6	With wind

Calibration runs should, for accuracy, be made at or below an altitude of 50 ft. The wind should be parallel to the course and for accurate results should not exceed 14 per cent of the high speed of the airplane. The difficulty and danger of flying low over a measured course at low speeds may be obviated by pacing the airplane which is being tested with a slower airplane

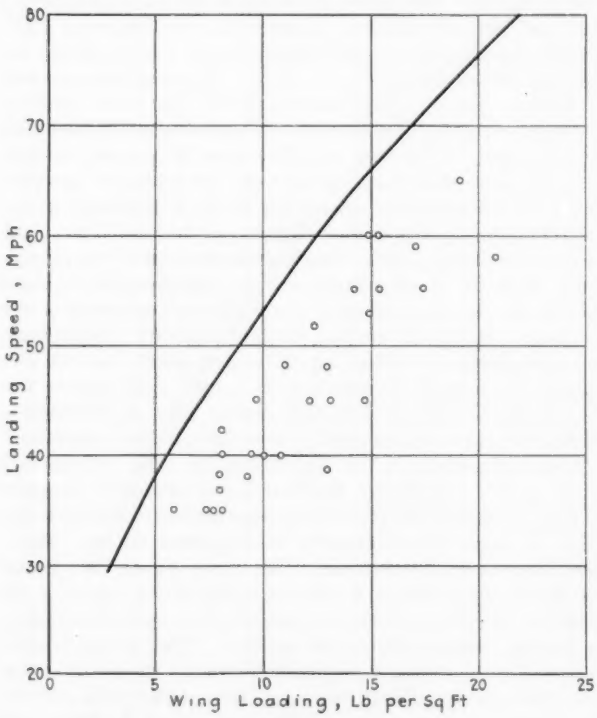

FIG. 1

equipped with a calibrated air-speed meter. The slower airplane should lead the way over the course at a safe altitude. Personal errors are, as stated, at a maximum in single-seater airplanes and are reduced, but not entirely eliminated, when an observer is carried. The air-speed-meter calibration curve is usually continued in a straight line from the lowest accurately observed speeds. True air speeds are obtained from the observed air speeds by correcting for atmospheric pressure and temperature, and for convenience and ready correction of subsequent air-speed-meter readings, they are plotted against indicated air speeds.

Another method which has been used for obtaining landing and take-off speeds (1)[2] consists of attaching an electric recording instrument to the landing wheels which graphically records their rate of revolution while in contact with the ground. From this and the known circumference of the wheel the landing or take-off speed may be readily calculated. This method also has been found subject to large errors from jouncing of the mechanism, partial deflation of the tires, lag of the wheels in landing, and friction.

The form of photogrammetric method of obtaining airplane landing speeds used at the Alabama Polytechnic Institute in tests during the past two years appears to eliminate most of the errors common to the methods described. Its greatest advantage lies in the fact that the pilot is left free to concentrate on landing the airplane. Instrument errors and personal errors are lessened to a great degree, for the reason that all observation is accomplished from the ground. In the tests run and the studies made the primary purpose has been to develop a simple method of landing-speed measurement that could be utilized easily and cheaply by airplane manufacturers and operators. In testing the airplanes submitted for landing-speed measurements, the aeronautical department of the college did not enter into an agreement to furnish certified performance data, but out of courtesy to the manufacturers submitting planes and in the desire to develop an accurate method, experienced engineering observers of the faculty performed the actual tests with graduate aeronautical engineering students assisting. The results of most of the tests were treated as confidential.

The data in Table 1 were obtained with a 16-mm motion-picture camera with standard lens and the expenditure of only 100 ft, or one loading of film. Economy of the process is further promoted by reversing the film in development from negative to positive, thus eliminating the expense of making a negative and taking positive prints from it. The small camera and film are not expensive and are entirely suitable for this work. The 16-mm film is particularly suited to the steady high camera speeds necessary for the slow-motion photography used because of the fact that this size gives 40 frames or pictures per foot of film as against 16 frames per foot of standard 30-mm film. This allows a lower film velocity through the shutter for a given number of frames per second and consequently gives greater accuracy in speed analysis.

The normal speed of motion picture cameras is 16 frames per second, and on the small cameras this speed is governed by a spring motor which maintains a surprisingly accurate rate. The camera used in obtaining the data in Table 1 has two speeds, the normal rate of 16 frames per second and the slow-motion rate of 68 frames per second.

The arrangement of the apparatus used is shown in Fig. 2. The camera is set up on a tripod at a distance that permits six standards to show in each frame on the film. These standards are $^3/_4$ in. by $^3/_4$ in. and are accurately located 2 ft apart, in a line parallel to the direction of the wind. The distance to the camera on a line perpendicular to the line of standards was for this particular "set-up" 26 ft 3 in. This distance will vary with the class of lens used and with the number of standards it is desired to show in the pictures. The distance from the camera to the path of the plane in landing and the spacing of the standards must be accurately known in order that the distance traveled by the airplane in its path between standards may be calculated. Assuming a distance from the camera to the path of the plane of 390 ft, we have, with 2 ft between standards, $26.25 : 2 = 390 : x$, or $x = 29.71$ ft.

[2] Numbers in parentheses relate to references at the end of the paper.

Briefly, the procedure for obtaining landing speeds is as follows: The set-up of the apparatus is made and checked, and white lines are laid down, as shown in Fig. 2. The plane is signaled to land, and the landing is made into the wind and parallel to the lines laid off on the field, which are parallel to the line of standards and the direction of the wind. These lines assist the pilot in landing directly into the wind and aid the observers in identifying the marks made by the wheels and tail skid when they take measurement Y for each landing. The character of the landing is noted, and readings are taken on anemometer, barometer, and thermometer. The time is noted, and later these three readings are checked with those of the recording instruments in the aerological tower of the airport. It is necessary for the plane to land at a point within the angle of the camera, and for this reason two white lines intersecting at the camera and passing through the bases of the end standards are projected out across the landing runway. A landing at any point between these boundary lines is satisfactory, providing the path of the plane is parallel to the wind direction. The camera is started just before the airplane enters the range, and the airplane is photographed as it passes across the range. Before stopping the camera after each landing, a close-up of a stop-watch is taken for 5 sec or more to give a check on the camera speed. A seconds pendulum swinging in front of the lens is used as an additional check. A slate with a number on it is then photographed to identify the film for future reference.

After the film is developed, it is run in a projector to check the observer's notes on the character of landings and take-offs. The slow-motion views are very interesting. The slightest motion of the control surfaces and the telescoping of the shock absorber unit as the plane comes in contact with the ground are plainly visible. After projection, the counting of the frames is accomplished under a magnifying lens. This enlargement assists in determining the exact frame where the landing or take-off occurred. In landing, the tail skid strikes the ground, and dust usually shows in the frame where the initial contact is made. If this point of contact is between the two standards, a count of the frames between the standards (i.e., from the frame in which the nose of the plane passes the first standard to that frame in which it passes the second standard) is used to obtain the correct ground speed. If the point of contact is in line with a standard, a similar count of frames is made from the frame in which the nose passes the preceding standard to that in which it passes the following standard. Equally accurate results can be obtained in the latter case if the length of the airplane is known and the number of frames counted from the time the propeller hub passes the reference point (the standard) until the tip of the rudder passes the same point. Camera speed is readily obtained from the stop-watch dial and the seconds pendulum as shown on the film. With the frame count thus made for the previously computed distance x, which the airplane travels between markers, the ground speed is computed from the following formula:

$$0.6818 \frac{(x \text{ times camera in frames per second})}{\text{frames counted for distance}} = \text{airplane speed in mph}$$

The wind velocity as taken from the anemometer is added to this, giving observed air speed. The observed air speed is corrected to standard atmosphere by dividing by the density factor $\sqrt{\rho_o}/\sqrt{\rho}$ obtained from $\rho/\rho_o = 17.32\ (\rho \text{ in. Hg})/T\ °\text{F} + 459.4°$. The standard atmosphere is an arbitrary variation of temperature, pressure, and density, given in Reference 2. Standard air, at 29.92 in. pressure, and 59 F or 518.4 abs, has a density of 0.0764 lb per cu ft as a basis for comparing performance.

Measurements of the take-off speeds and maximum speeds of the airplanes submitted for landing-speed measurements were also made with the 16-mm camera. The same arrangement of apparatus is used for measuring take-off speeds that is used for measuring landing speeds. In measuring take-off speeds, the airplane starts at a point estimated to be the correct distance outside the camera angle to allow the airplane to leave the ground at a point within the angle. This distance will vary with the speed of the wind, and usually several preliminary trials will be necessary before a normal take-off will be made within the camera angle. The observers note the character of the take-off and record the data previously mentioned for landing-speed measurements.

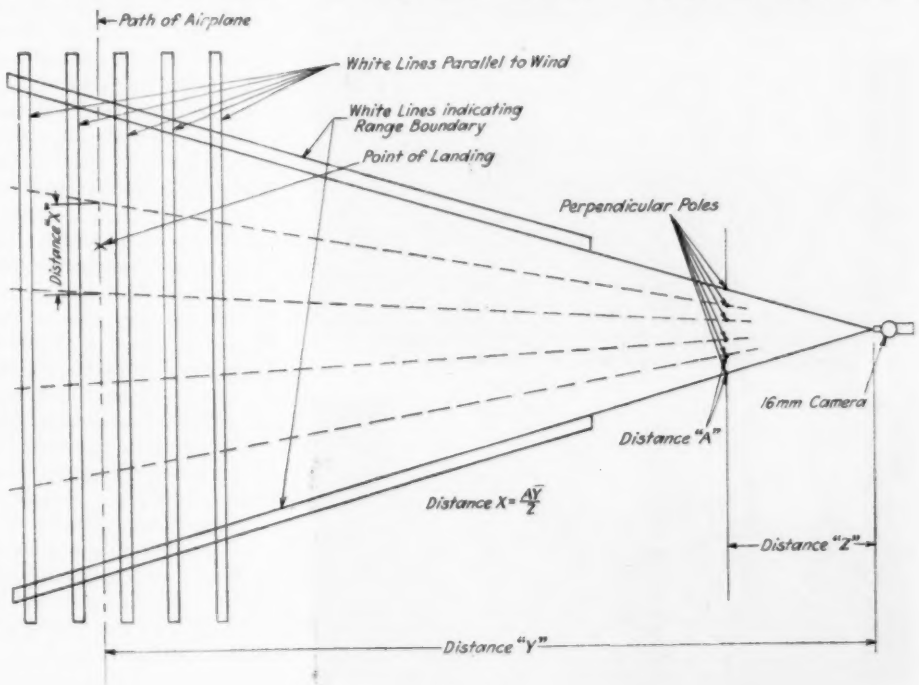

FIG. 2

The measurement of take-off speeds has not been stressed, as length of take-off run and rate of climb are figures that are easily obtainable and are considered more vital to the airplane operator than the rate of speed at which the airplane leaves the ground. The performance requirements for take-off imposed by the Department of Commerce on a landplane are that it shall take off within 1000 ft at sea level in still air with full load, and that the climb in feet during the first minute after take-off shall be at least eight times the theoretical stalling speed in mph, but it must in no case be less than 300 ft.

For maximum-speed tests the camera is secured in the airplane, focusing down at right-angles to the thrust line. The plane is flown level at full throttle over a measured distance, first into the wind and then with the wind. A course parallel

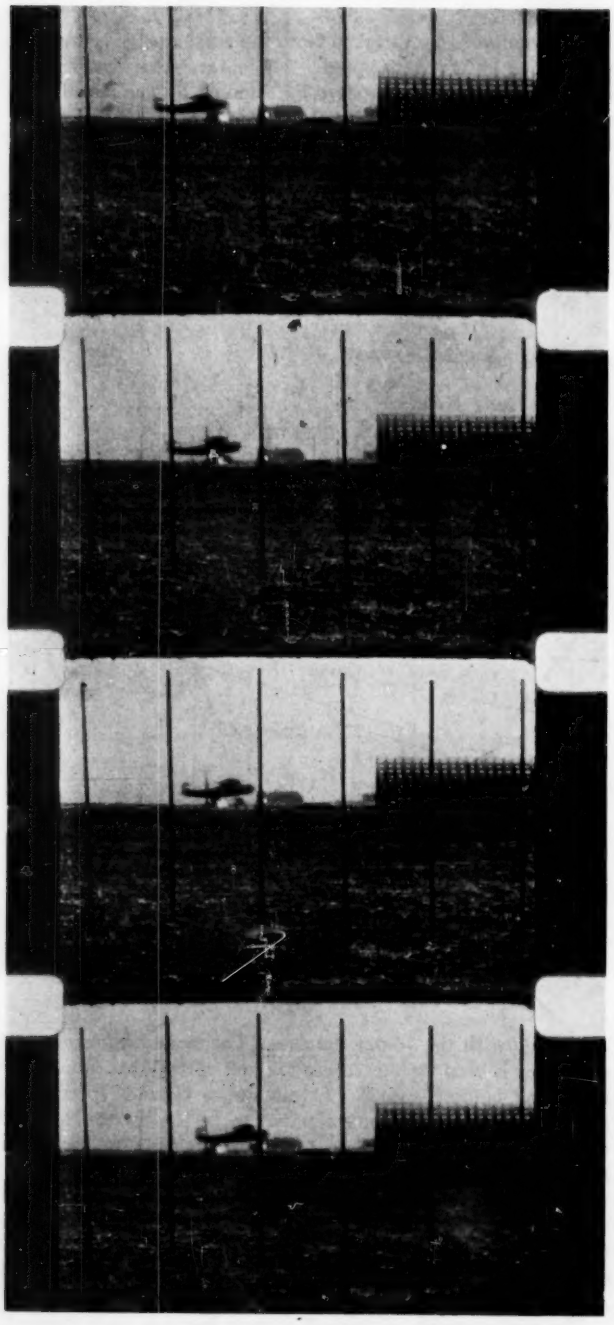

FIG. 3

with the wind direction and about 500 ft in length over level ground is adequate. This test requires careful piloting, and a number of runs must be averaged to insure accuracy. A sensitive level-flight indicator is of considerable aid to the pilot in making this maximum-speed test. Runs are observed from the ground, and where there is any deviation from level flight, the run is eliminated from the computation. The difference between the average of the speed in both up-wind and down-wind directions and the speed in either direction equals the wind velocity. A comparison of the wind velocity obtained in this manner with the anemometer reading gives a check on the accuracy with which level flight has been maintained. In this high-speed test the camera is started before the line marking the beginning of the measured course comes in range and is stopped when the line marking the end of the course is out of range. The pilot must fly at a constant altitude (50 ft has been used in our tests) and at a horizontal distance from the markers that will permit them to fall within the camera angle as mounted in the airplane.

An alternative method of measuring high speed is exactly similar to that used for measuring landing or take-off speeds with the camera placed low, and, if necessary, somewhat closer to the standards. An objection to this method is that the measuring course is very short and that piloting errors are therefore magnified. With a longer course, errors in piloting are usually noticed by the pilot and are slightly over-corrected. Thus they tend to compensate each other. Outlying markers at a distance of about 500 yd from the standards should be established over which the pilot must pass in level flight.

Photogrammetric measurements of maximum speeds have been found to compare closely with speeds obtained by timed runs over a 2-mile course, but these close comparisons were found in tests where the pilot making the photogrammetric runs conscientiously tried to fly at a constant level over the course. The majority of the maximum speeds found by the photogrammetric method were high because of the fact that on one or more of the runs the pilot, inadvertently or otherwise, would start across the short course at a greater altitude than that at which he was flying when he reached the end of the course. This almost imperceptible "downhill" flying has occurred very frequently in the maximum-speed tests, and for this reason photogrammetric measurements of maximum speeds are not recommended. Runs over a 2-mile course timed with a stop watch appear to offer better conditions for accuracy and should be employed for maximum-speed measurement whenever possible.

The important application of this form of the photogrammetric method of obtaining airplane speeds is in the measurement of landing speeds. It gives an accurate and permanent record which with careful checking can be certified as being correct within 1 per cent.

Discussion

A. M. PRIDE.[3] The method presented is of considerable value in that it provides a complete history of the landing operation and enables the observer to study rebound, changes in attitude,

[3] Lieutenant-Commander, U. S. Navy, Naval Air Station, Hampton Roads, Va.

etc., as well as to obtain a continuous record of speed. One of the first requisites for accuracy seems to be an exact knowledge of the distance from the camera to the airplane, and experience along these lines leads to skepticism as to the dependence that can be placed on a pilot's ability to fly parallel to the indicated lines. A positive means for determining the path of the airplane is probably necessary, and a trailing rod that will scratch the ground suggests itself.

Several years ago, in measuring airplane speeds in landing on board a carrier, by means of a camera that was fixed normal to the airplane's path, it was found that an error of about 2 per cent occurred due to blur in the image on the film. It is possible that a similar condition would occur with this method if photographic material capable of "stopping" very rapid motion with sharp definition were not used. It is suggested that the requirement for this class of material be stressed.

Timing by counting frames with a spring-motored camera is considered highly satisfactory, since experience involving a great many measurements and check measurements in which photographs of split-second watches were made in connection with the landings on board ship, mentioned above, has indicated that the maximum time error is less than 2 per cent, and this with ordinary aerial camera guns and commercial hand-held cameras selected at random. If the equipment were to be selected especially for uniformity of film motion, the error could undoubtedly be reduced to less than 1 per cent.

In any measurements of this nature, the complication of errors due to rotation of the airplane as the tail rises or falls must be accounted for if a high degree of accuracy is to be obtained. Since by "speed" it is assumed that the velocity of the center of gravity is meant, it is obvious that measurements referred to any other part of the airplane are not directly applicable, if pitching occurs. The superposition of the effect of rotational velocity on the lineal velocity obtained in such a case is difficult, and it is suggested that the center of gravity be marked on the fuselage and that all measurements be taken directly from this mark. Due allowance must be made for the lateral distance from the fore-and-aft center line to the side of the fuselage.

C. F. Taylor.[4] The value of the paper would be enhanced by data showing the degree of accuracy of the readings. A table might be given of the readings and the computed landing speeds for a large number of landings by two or three different pilots with a given airplane, other conditions being held as nearly the same as possible for the whole group of tests. Such a table would reveal the amount of error to be expected in using this method.

Pressure in Airships

By W. A. KLIKOFF,[1] DETROIT, MICH.

The use of pressure in the so-called "pressure airships" and the methods used for maintenance of pressure are described. The effects of "gas head" and of excess internal pressures are considered as design factors, showing the advantages derived from a strength standpoint. It is pointed out that, by utilizing the pressure, the low factors of safety used by airship designers for critical loading conditions can be eliminated, and the ultimate design of the pressure rigid airship is discussed. Recognizing the disadvantages of manual control of pressure employed in the present airships, it is emphasized that pressure control can be made perfectly automatic if pressure regulators used in the modern power-plant installations are adopted for airship-pressure control. The proposed pressure control system for large metalclad airships is described. To utilize the advantages of pressure as a design factor, the materials used in the present rigid airships should be more efficiently disposed around the cross-section, again pointing to ultimate metalclad design.

THE type of lighter-than-air craft whose shape is maintained solely by internal pressure is often called the "pressure airship." In this type of airship the contraction and expansion of the gas with changes of atmospheric conditions are compensated for by the air-filled ballonets. The internal air pressure is maintained by blowing air in the ballonets, thus raising the pressure slightly above atmospheric. The air pressure acts on the movable ballonet diaphragm, thereby increasing the pressure in the gas container and producing tension in the outer cover.

For purposes of analysis this tension is usually considered as having two components: longitudinal, acting in the direction of the ship's axis, and transverse (or hoop), acting in the plane perpendicular to it If airships had been made as perfect spheres, then the longitudinal component of pressure would be equal to the transverse, but as long as aerodynamic requirements dictate a slender, elongated shape with much larger radius of curvature in the longitudinal direction than in the transverse, the longitudinal component of pressure becomes smaller than the transverse. Each one of these components performs a well-defined function. The transverse component of tension retains the shape of the cross-section, which will be circular in the case of an airship subjected only to internal air and gas pressure and loads distributed uniformly around the circumference. The longitudinal component of tension, due to pressure, maintains the longitudinal shape of an airship. When the airship is built of materials that cannot resist compression loads, such as the non-rigid airship, this longitudinal tension component should be always of such magnitude that the tension due to it exceeds the compression imposed by either static or aerodynamic loads acting on the hull. This consideration determines the value of the internal pressure to be used in the hull.

It may appear that the internal pressure should be of considerable magnitude to resist these loads, but actually, due to large cross-sectional areas, the pressure required in the case of non-rigid airships is, in general, of the magnitude of $1^1/_2$ in. H_2O, or approximately only 0.37 per cent higher than the standard atmospheric pressure. Such a small pressure can be very easily maintained mechanically, but is also easily subjected to atmospheric variations.

This small increase of pressure corresponds approximately to only 2 F change in temperature and 0.11 in. Hg change in pressure, or 100 ft change in altitude. This comparison shows the sensitiveness of pressure to outside atmospheric conditions and the necessity for careful handling.

Maintenance of Pressure

The excess of pressure is handled by automatic valves which tend to release the air from the ballonets in case of gas expansion, and at the present time they have reached such a degree of development that no particular attention is attached to this phase of the problem. The capacity of the valves is usually designed for the maximum desirable rate of ascent, and the valves are set in such a manner that the air valves open first and the gas valves follow, so as to preserve gas as much as possible. Manual control of the valves is provided to take care of the possible failure of the automatic features.

The means of supplying internal pressure have not reached such a degree of perfection as the means of releasing it, and at the present time are rather cumbersome. In non-rigid types the pressure is usually maintained by scoops which are lowered manually in the slipstream of the propellers. This manual control has the disadvantage of constant attention on the part of the pilot. The drop in pressure to or below atmospheric will cause the collapse of the envelope and the necessity of abandoning the forward speed, and will put the airship at the mercy of the winds like a free balloon. The maintenance of too high a pressure produces high tensions in the fabric envelope, causing a more rapid deterioration.

The semi-rigid airship was evolved to relieve the tension load in the fabric, and part of its ability to withstand outside bending moments is achieved by the introduction of a rigid keel capable of carrying a very high percentage of the bending load.

In the case of semi-rigid airships the pressure is often maintained by means of dynamic scoops which are located in such places on the hull that they automatically scoop up air in the case of forward motion, producing higher internal pressures in case of higher speeds. This arrangement has the disadvantage that if the scoops are not properly located they may be blanketed

[1] Aeronautical Engineer, Metalclad Airship Corporation, successor to Aircraft Development Corporation. Mem. A.S.M.E. W. A. Klikoff was born December 29, 1898, in Sebastopol, Russia, and arrived in the United States in 1919. He was graduated from the Massachusetts Institute of Technology in 1923 with S.B. in Naval Architecture and Marine Engineering. Since 1924 Mr. Klikoff has been connected, as an aeronautical engineer in lighter-than-air work, with the Aircraft Development Corporation and the Metalclad Airship Corporation and, in heavier-than-air work, with the Verville Aircraft Company and the Detroit Aircraft Corporation. Mr. Klikoff participated in the National Balloon Races from 1927 to 1930. From 1930 to 1932 he lectured on aerostatics at the University of Detroit.

Presented at the Fifth National Aeronautic Meeting, Baltimore, Md., May 12 to 14, 1931, of The American Society of Mechanical Engineers

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

somewhat in some of the maneuvers, reducing the delivery of air. In addition the scoops become inoperative when the forward speed of the airship drops to zero. In this case the pilot has to rely on mechanical blowers, which should always be ready to be started for this purpose. In the hangar or when maneuvering on the field, the blowers are the only means of maintaining pressure. Being manually controlled, they require constant attention. These factors tend to make the maintenance and operation of the present fabric-covered pressure airships troublesome.

The opinion is often expressed that rigid airships are independent of pressure. This opinion is erroneous, because the rigid airships are not independent of pressure. They tend to fly only under such conditions that pressure inside is near atmospheric, and a series of openings are provided to keep the internal pressure as close as possible to atmospheric. Failure to do so may lead to disaster. Some of the rigid airships tend to utilize the effect of pressure for the support of fabric or other purposes. For instance, the latest British airship, the *R-101*, was normally operated under slight positive pressure to reduce flapping of the fabric covering. Openings in the envelope were provided to satisfy these conditions.

Pressure as a Design Factor

The question arises, if pressure is such a cumbersome factor and one requiring so much attention, why use it at all? Why not eliminate it entirely and build airships perfectly independent of pressure? The answer is that internal pressure is always present, even in the case of the conventional rigid airships, where it is often not used to any advantage and with the present types of design may constitute even a liability. The pressure that is referred to in this case is the gas-head pressure. The pressure within a gas container increases due to the difference of the densities of air and gas. This property of gas is called "gas head," which is exactly similar to the "water head" in hydraulics, but of an opposite sign.

If h represents the head of gas measured upward and k the unit lift of gas, the pressure due to gas head becomes evidently kh. This pressure produces a constant longitudinal force, which in the case of a fully inflated circular airship is $k\pi r^2 h$, where r = the radius of cross-section.

The pressure due to gas head increases toward the top of the airship; therefore the resultant of this longitudinal force acts above the center line, which usually coincides with the neutral axis of the airship. Consequently, it will tend to produce a hogging bending moment, which for a fully inflated ship is equal to $k\pi r^3 h/4$.

The values of longitudinal forces and bending moments for sections not completely filled can be found in textbooks on airships.

This hogging bending moment and this longitudinal force due to gas-head pressure are present in all airships. In rigid airships there exists another factor due to gas pressure. Whereas in non-rigid types the transverse component of pressure produces uniform transverse tension in the covering, in rigid airships this transverse component acts as a side load on longitudinals, complicating their design by loading them with side load combined with direct stresses due to bending of the whole airship. This loading condition of longitudinals tends to explain why gas pressure is often called a liability in the case of conventional rigid airships.

The present large airships reach such large proportions that the gas-pressure factor is becoming of primary importance. The diameter of modern airships has already reached 132 ft. In this case the pressure due to gas head at the top of the hull at the maximum section becomes, for a helium-filled ship, 8.20 lb per sq ft, or 1.57 in. H_2O. The total longitudinal force becomes 57,000 lb, and the hogging moment due to it 950,000 ft-lb.

These gas-head pressures due to the properties of lifting gas produce forces and moments reaching such magnitudes that the airship designer should undoubtedly try to utilize them as much as possible to his advantage. The longitudinal force is the most helpful one because it tends to produce a uniform tension throughout the structure, and all materials used in airships can carry much higher tensile loads than compression loads. It will be of interest to study the help that could be derived from the longitudinal tension on the hull due to pressure.

Consider an airship whose cross-sectional area of metal used is A, which is distributed uniformly around the cross-section; then the moment of inertia of this cross-section is $Ar^2/2$. If this airship is subjected to a certain longitudinal force P and bending moment M, then the maximum compressive longitudinal stress will equal

$$S = \frac{P}{A} - \frac{2Mr}{Ar^2}$$

Assuming, as in the case of the non-rigid airship, that the outer covering is incapable of carrying any compressive loads or limiting the value of stress $S = 0$, then solving the equation, we obtain the critical value of bending moment in relation to longitudinal force $M/P = r/2$. If the non-rigid airship is full of gas and is subjected to pressure due to gas head only, then the relation of gas-pressure bending moment to longitudinal force due to gas pressure is:

$$\frac{M}{P} = \frac{kr^4}{4kr^3} = \frac{r}{4}$$

or the value of the hogging bending moment can be doubled before compressive loads will occur in the fabric, and the airship could carry a sagging bending moment equal to three times the gas-pressure moment without having any longitudinal folds in the fabric.

Introducing an internal pressure higher than the pressure due to gas head, such a rigidity of the hull can be obtained that a very severe bending moment can be carried by the hull, which is exactly the practice followed in non-rigid airships.

It will be of interest to arrive at actual figures to determine what is the value of the internal pressure required in modern airships to resist bending moments. Take, for instance, the case of the British airship *R-101*, which was destroyed with great loss of life in France. During the inquiry of causes of this disaster, and previous to that, the designers released more reliable information about this airship than about any others recently built.

This airship was 732 ft long, 132 ft in diameter, and had an air displacement equal to 5,600,000 cu ft. The arbitrary value of the maximum aerodynamic bending moment to which this size of airship would be subjected is:[2]

$$M = 0.02 \frac{\rho}{2} V^2 (\text{vol})^{2/3} L$$

or at 75 mph at sea level,

$$M = 0.0000237 \times 110^2 \times 31{,}000 \times 732 = 6{,}640{,}000 \text{ ft-lb.}$$

Assuming that the gas-pressure bending moment resists all the static loads, then to counterbalance the effect of this aerodynamic bending moment the longitudinal force due to internal air pressure should be:

$$P = p\pi r^2 = \frac{M}{r} \times 2$$

and internal pressure

$$p = \frac{6{,}640{,}000 \times 2}{3.14 \times 663} = 14.7 \text{ lb per sq ft} = 2.82 \text{ in. } H_2O$$

[2] Technical Report No. 325, National Advisory Committee for Aeronautics.

It can be noticed that by increasing the internal pressure only 180 per cent above the pressure that already is present on the top of the ship due to gas head, all the compressive stresses which would appear in the hull due to the action of this severe aerodynamic bending moment will be eliminated. This computation does not mean that all the stresses will be eliminated—they will appear on the tension side, but as long as the materials used for the present airships have such properties that they can resist tension from 50 to 100 per cent better than compression, the advantage of utilizing the internal pressure can clearly be seen.

The fact that materials should be utilized always on the side on which they are most efficient has long been recognized by the structural engineer, who in suspension bridges utilizes the high tensile value of the cables and in concrete structures utilizes the high compressive value of concrete.

Design Conditions and Factors of Safety

In the present design of rigid airships a rather peculiar system of factors of safety is adopted. Factors of safety of 4 and higher are used for static loads, but when the aerodynamic loads are superimposed, then the designers do not increase the structure in proportion to the increase of load, but increase the structural strength only to some extent which causes decreasing of the factors of safety. This practice is justified by the fact that conditions of superimposing both types of loading occur less often and the effects of higher loads on the structure will be less. For this reason airship designers are satisfied to drop their factors of safety to as low as 2, and sometimes even smaller for the worst loading conditions. This method of design may give the operating personnel a false sense of security, making them overconfident in the strength of airships under normal flying conditions, and in case of emergency they may treat the airship without due caution, causing perhaps a breakage of structure and severe disaster. Several airship accidents were traced to this cause by some of the experts.

It must be kept in mind that the nature and magnitude of gusts and other aerodynamic forces are not completely known and probably never will be definitely known, just as in shipbuilding the forces due to the impact of waves are just approximated from the results of years of experience. Airships while floating in a fluid have the advantage of being more easily analyzed for aerodynamic loads due to the fact that air is a more perfect fluid than water, but air has a peculiarity of having very steep rising and descending currents which may not be visible to the eye of the pilot.

Therefore a somewhat more logical system of airship design would be not to design the airship for too high a factor of safety for average conditions and too low for an extreme condition, but to design an airship, for instance, for the following conditions:

1 Adopt a reasonable factor of safety for the worst static conditions, combined with certain usually encounterable aerodynamic loads.

2 Provide enough compressive strength in the airship to be able to carry these loads safely.

3 In flight when the airship is subjected to severe aerodynamic loads, provide the excess strength and maintain the same factors of safety by introducing certain other positive factors of strength; for instance, one which is the most readily obtainable, pressure.

The operating personnel will then know that when the airship is operating under internal pressure the compressive strength is not endangered, the loads are taken through materials in tension, which are known to have much higher strength value than in

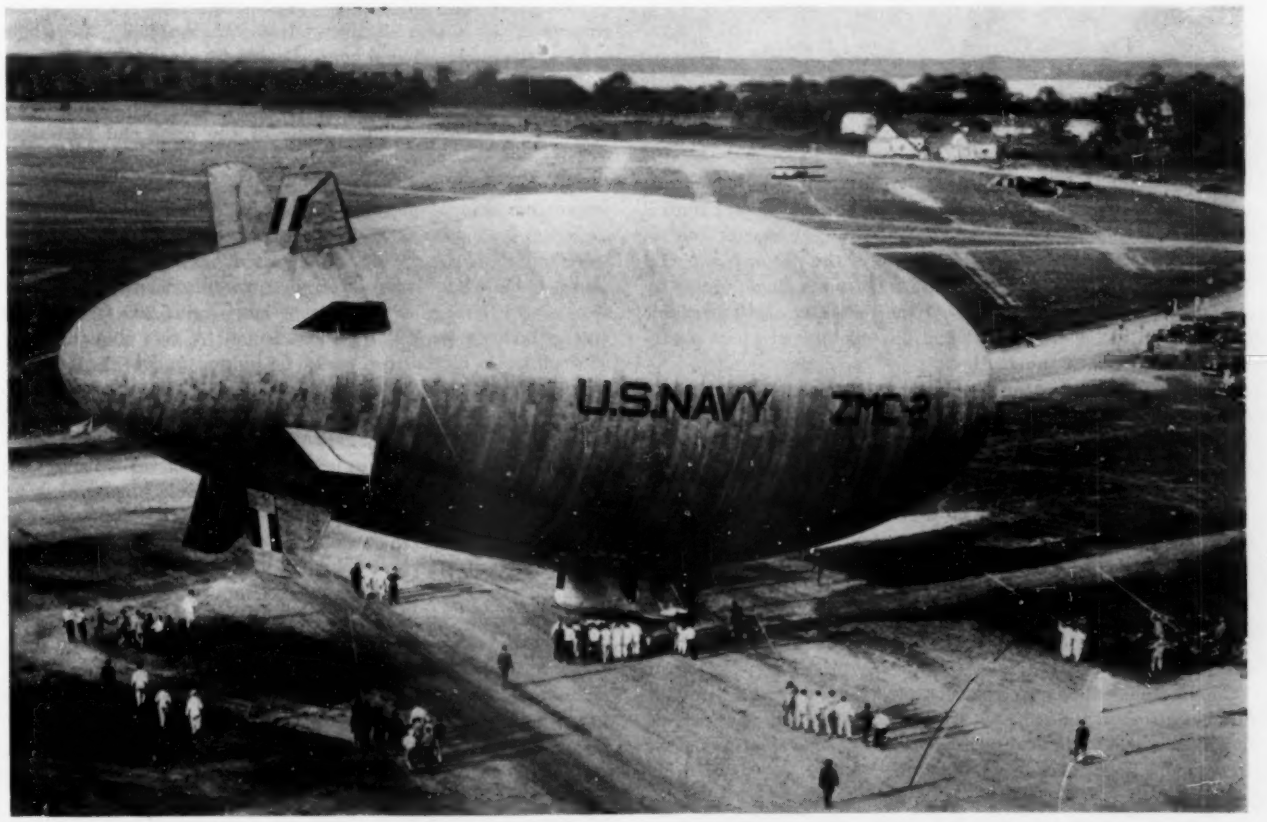

Fig. 1 First Successful Pressure Rigid Metalclad Airship

compression, and the airship can be safely flown through any atmospheric disturbance and can withstand any maneuvers.

When the pressure system is not functioning for some reason or other, then the operator knows that the airship is not strong enough to withstand severe loads and should be handled carefully. It should be slowed down, like an ocean liner partially disabled at sea, no excessive maneuvers should be made, and aerological disturbances should be avoided if possible.

If the pressure system is designed with the required amount of care, then the last condition should really never occur in the life of the ship.

Pressure Rigid Airship

The designers of the large metalclad airship have always kept in mind the policy that the system of design just outlined is a more logical one and have always considered it as an ultimate goal of metalclad airship design and development.[3]

As was mentioned previously, conventional pressure airships are so dependent on the pressure that a drop in pressure means a loss of shape and inability to proceed at a forward speed, thus transferring the airship to the free-balloon class.

This condition is undesirable, and it should be the aim of designers of pressure airships to design the airships in such a manner that they can maintain their shape and proceed at slow speeds at atmospheric internal pressure, using the internal pressure as an auxiliary means of extra strength and rigidity in case of flying at high speeds.

The question arises as to the possibility of controlling the internal pressure. All the disadvantages of the pressure supply system as used in present airships can be eliminated easily if airship designers would only try to follow in the footsteps of the mechanical engineer, who has already solved the problem of pressure control very admirably in power-plant installations.

Pressure Control in Power Plants

It is seldom realized to what extent the control of power plants has been taken out of the class of the uncertain human element by the automatic regulator. In a typical automatically controlled power-plant installation, the regulators control the fuel feed, air supply, furnace pressure, and forced- and induced-draft fans. All of these regulators are connected to a master control panel, from which they can be controlled. The master control panel is thus the central control station of the power plant, and the operator can control the whole plant from a single source by simply adjusting the setting of all the regulators. Remarkable decreases in fuel consumption and an economy of plant operation are achieved by this method.

Sometimes the regulators are called upon to regulate accurately pressure and pressure differentials to within an error of 0.001 in. of water column and in other instances to regulate the steam pressures running into hundreds of pounds to within a limit of a few pounds.

Automatic combustion control is used in the most modern and large power plants, such as the Brooklyn Edison Company's station, Hell Gate Station, Detroit Edison Company's stations, and Bethlehem Steel Company's power plants. The application of automatic control is not limited to power stations, but it also is applied to coke ovens, open-hearth furnaces, and blast furnaces.

The mechanical engineer has accepted the automatic regulator and is using it in the industry and is relying on it in complicated installation where slight disarrangement of the system will cause tremendous losses and disorganization.

[3] R. H. Upson, "Metalclad Rigid Airship Development," delivered before the S.A.E., February, 1926, gives the original ideas on internal pressure control as applied to metalclad airships.

Application of Pressure Control to Airships

The airship engineer, by taking one item out of the complicated power-plant-control system and installing it in the airship, may solve the whole problem of pressure control on airships. This item, the pressure regulator, can be designed to a range of accuracies exceeding considerably the airship requirements and would tend to make the control of pressure entirely automatic.

Several automatic pressure regulators could be installed in such a manner that a drop of internal pressure would cause either the immediate opening of the propeller scoops, in case of flight under power, or would start the blower motor, which would be kept constantly in warm condition ready to start. It might even be desirable to provide a regulator which in case of failure of the pressure system would switch off some of the engines, thus reducing the speed of the airship to a point safely allowable for operation without pressure.

The operating personnel, with automatic pressure regulators installed, would set the regulators at a certain selected value of internal pressure. The regulators would take care of the variation of pressure by operating pressure-supplying units. All of these pressure-supplying units could be connected to the control car, and any change in their position would then be shown by a signal on the board installed in the control car. Thus all the elements of the internal pressure-control system could be checked periodically by releasing the pressure and observing the functioning through the signals. Any uncertainty of the system could be immediately adjusted so as to have the whole system in perfect condition in case of emergency.

Proposed Pressure Control in Metalclad Airships

It is recognized by the designers of large metalclad airships that the pressure system should approach perfection as closely as possible and that automatic pressure regulators should be incorporated as a part of the system. Undoubtedly the whole body of the airship should be made airtight.

This can be attained by providing all the means of access with doors that are pressure-tight. This is not considered a difficult engineering problem. Then some of the crew and passenger quarters, as well as corridors and means of access to the structure, could be placed in the hull in the air space, which under certain conditions would be under slight pressure. This also can be easily achieved, and the small internal pressure inside of the airship of, say, 3 in. water would not be uncomfortable, because this slight increase in the atmospheric pressure corresponds to a change of altitude of only about 200 ft, and the human body is known to be unaffected by this change. The whole interior of the ship could be lighted and be kept under slight pressure when necessary.

If the pressure rises above the design value, then an excess of it could be released by the air valves, the design of which would be very similar to the valves used at the present time.

If the pressure drops, then some means should be provided for its replenishment. The main pressure-supplying units would undoubtedly be the dynamic scoops, which are really inward-opening valves, located at several points on the hull where the external dynamic pressure due to the forward motion of the airship will exceed the internal pressure required for the longitudinal strength. The design of dynamic scoops is a very simple problem, and they would normally be used as the only pressure-supplying units. Their action can be made perfectly automatic, and with increase of speed, air at higher pressures would be supplied.

In case it should be desirable to supply more constant pressure, irrespective of changes of speeds or in case of descents under power, when a large quantity of air must be supplied, the propeller scoops located in the slipstream of the propeller can be used. It is proposed to control these scoops by automatic pressure regu-

lators. If the amount of air supplied by the dynamic scoops proves to be insufficient, then the pressure inside of the hull would drop, and the automatic pressure regulators influenced by this drop of pressure would open the propeller scoops.

Mechanical blowers also should be installed to supply air for rapid descent without forward speed and for ground handling. The blowers should always be kept in such condition that they can be started at short notice and develop the maximum pressure. The blowers also would be controlled by the automatic pressure regulators, which would start them when the system of dynamic and propeller scoops might prove to be inadequate under extreme conditions.

In case of complete failure of the pressure system, recourse might be had to the present rigid arrangement, i.e., opening of certain apertures in the hull, tending to maintain inside pressure equal to atmospheric. Then the airship would assume the same condition as when maintained in the hangar and also would be able to fly at reduced speeds, as previously mentioned.

Manual control of all the pressure-control items could be provided also as an auxiliary to the automatic control.

It can be clearly seen that the proposed installation would take out of the hands of the operating personnel all necessity for constant attention to the pressure system except for routine checking and inspection, and would remove the most important objection to the use of internal pressure as a strength factor in airships.

Types of Airship Structures

After considering pressure as a factor in airship design, it may be desirable to review the types of structures used in the present airships. It must be admitted that the present rigid airship structure is very similar to the familiar airplane wired-frame system used in the wartime days. The airplane fuselage built according to this system had four longerons acting as major structural members, braced by shear wires and covered by doped fabric, which, to produce a shape of low resistance, was supported by fairing strips. Only the longerons and shear wires acted as structural members, the remainder of the cross-section being added only for streamline effect.

The present rigid airship employs a very similar arrangement, except that it even complicates it by adding the gas cells and the gas-cell wiring. Therefore, if all the elements of the cross-section of the rigid airship are considered, it will be found that a large percentage of the total weight is not efficiently utilized from a strength standpoint, but serves auxiliary functions such as gas holding and preserving exterior shape.

Assuming a certain rigid airship and applying to it an arbitrary value of bending moment, it will be found that the stresses on the tension and compression side will be equal, and for comparison it may be assumed that the factor of safety is 4 on the compression side and 7 on the tension side. Suppose the longitudinal force is now introduced of such magnitude that it eliminates all compression loads, then there will be zero stress on the compression side, but on the tension side the factor of safety will drop to 3.5.

From this consideration alone it appears that it is not advantageous to utilize the effect of pressure on rigid airships. This is due to the fact already mentioned that rigid airships do not utilize all the materials disposed around the circumference as load-carrying factors. If all the materials employed could be utilized, then the cross-sectional area available for load-carrying purposes would be increased and the unit tensile stresses would drop. That is exactly the principle used in non-rigid airships, where the whole cross-section acts as a load-carrying member. This statement is proved by the fact that theoretically in non-rigid airships the same overall efficiency can be reached as in rigid airships. The proper utilization of the cross-sectional area, although handicapped by inability to carry any compressive loads, can be made as efficient as the rigid system of design.

It would appear that the most efficient system of design should utilize the compressive and tensile ability of the cross-section to the utmost advantage. Taking the case of the airship just considered, the most advantageous value of internal pressure will be such that the factors of safety on the compression and tension side are equal, or 5.5 for the loading aforementioned. It will be hard to balance the pressure exactly at this point, but this investigation points to an ultimate design of airship that will tend to utilize completely the whole value of the cross-section as a stress-carrying member capable of carrying high tensile loads as well as certain compression loads.

As has been mentioned, the ultimate metalclad airship design would try to approach these requirements. In it the high transverse stresses due to pressure, which are so detrimental to fabric non-rigid airships, are easily carried by monocoque metal covering. The hull of such a ship also may be sufficiently reinforced in the longitudinal direction to carry appreciable compressive loads. The perfection of this method of construction, employing the proper combination of internal structure with stressed skin covering, will produce the very efficient large-size airship capable of the high speed essential to commercial application.

Conclusion

It cannot be denied that pressure is one of the major factors in airships. It is always present as a gas-pressure force. It is a question whether it would be advisable to utilize the pressure as a strength factor or to try to combat its effects as much as possible. So long as airships are built of materials that are more efficient in tension than in compression, and pressure provides a factor which allows carrying all the stresses on the tension side, then it is certainly advantageous to utilize pressure as a strength factor. This can be accomplished by raising the internal pressure higher than the already-present gas-head-pressure value.

The question of control of internal pressure can be solved by an application of the modern methods of control already adopted by mechanical engineers.

It is undeniable that from a safety standpoint airships should be built not fully dependent on pressure. The ultimate airship must be designed to be rigid enough at atmospheric pressure for maintenance in the hangar and for slow-speed flying and to utilize the pressure only as a positive factor of excess strength to withstand extreme loading conditions. Such an airship in counterbalancing the excessive external loads by internal pressure coincides with the logic of Count Zeppelin, who many years ago said, "The forces of nature cannot be eliminated, but they may be balanced one against the other"—to serve man's needs.

AER-55-5

Air Compression With Temperatures Above Adiabatic, With Special Reference to Airplane Superchargers

By SANFORD A. MOSS,[1] WEST LYNN, MASS.

In compressing air or other gases by means of reciprocating or centrifugal compressors of comparatively large size, with large cooling areas and often water-jacketed, an appreciable amount of heat is removed which helps to decrease the power input. This cooling, however, is by no means essential, and under many circumstances decrease of power for compression by cooling is not very great. Furthermore, conditions are often encountered which make cooling inadvisable. In the present paper the author outlines the mathematical theory to be used when due consideration of all of the circumstances indicates that a compressor with a small amount of cooling is the most advantageous.

COMPRESSION of air or other gases originally was accomplished by means of reciprocating or centrifugal compressors of comparatively large size and with large cooling areas, often water-jacketed. An appreciable amount of heat was removed during compression, which helped to decrease the power input. The usual mathematical treatment of compression implies such possibility of appreciable cooling. However, this cooling is by no means essential. The upper curve of Fig. 5 shows that, under many circumstances, decrease of power for compression by cooling is not very great. Frequently conditions are encountered which make cooling inadvisable.

Figs. 1–4 give examples where consideration of all of the circumstances has led to selection of machines without water jackets. The machines shown in Figs. 1, 2, and 3 have rotational speeds from 14,000 to 33,000 rpm in order to decrease the overall size of the casing. This results in a casing area so small that there is relatively little cooling, even with use of radiating fins. The requirements regarding weight and space are such that multi-stage compressors are not desirable, and there must be appreciable pressure rise in a single stage. Pressure ratios of 1.5 to 2.0 with air are quite common, and machines have been built with a pressure ratio as high as 4.0. With air at sea-level inlet pressure, this gives discharge pressures of from 7.5 to 15, and in the extreme case 45 lb per sq in. gage, in one stage. Fig. 4 shows a larger unit of 13,000 hp capacity for quite a different service, but to which the same mathematical considerations apply, on account of the final air temperatures, which are arranged to give the best heat balance for the plant.

It is the purpose of this paper to outline the mathematical theory to be used when consideration of all of the circumstances indicates that a compressor with a small amount of cooling is most advantageous. As explained in detail in the Appendix, all of the losses of compression, as well as the theoretical power for compression, are added to the fluid and finally appear as heat causing temperature rise. Usually there is removal of heat due to whatever cooling may occur with the casing area used. However, this is comparatively small as compared with the heat added, for the compressors here considered, so that the temperatures are above the theoretical ones for adiabatic compression instead of below them. With some superchargers there is even unavoidable addition of heat from adjacent hot engine parts, or from the nozzle box in an exhaust-gas-turbine supercharger.

The type of compression here discussed may be called "hyperadiabatic" compression as opposed to the "subadiabatic" compression supposed to occur in some types of compressors. (As an actual fact, there often have been illusions regarding the amount of heat removed when subadiabatic compression is expected. Many an indicator card of a reciprocating compressor shows a compression line well below the adiabatic and approaching the isothermal line, not due to efficient cooling but to piston and valve leakage during compression.)

The removal or addition of heat during compression changes the volume of the fluid being compressed. The power for compression depends largely on the actual volume, so that, as already mentioned, fluid compressed to a given pressure will require somewhat more power if the volume is increased during compression than if it is decreased. Therefore the power depends directly on the temperatures which occur during compression, and these depend directly on the facilities or lack of facilities for removing heat. This is an entirely separate consideration from the shaft efficiency e with which the compression is carried on. If compression with certain existing temperatures attained no matter how and requiring addition or removal of a definite amount of heat, were carried on without losses of any kind, there would be needed P_n the theoretical power for compression with existing temperatures, values for which are given in the compressor formulas of Table 1. This amount of power is therefore the criterion for a perfect compressor operating with the existing temperatures. An actual compressor with definite losses and a resulting shaft efficiency e will require a greater amount of power. However, the standard on which the efficiency is to be based is this theoretical power for compression with

Dr. Moss began his engineering career by serving a four years' apprenticeship as a machinist in San Francisco, Calif., afterward spending some years as a draftsman. He entered the University of California and was graduated from the College of Engineering in 1896, afterward receiving a Master's Degree from the University of California and a Doctor's Degree from Cornell University. This college work was interspersed with professional work as a draftsman and engineer. He became associated with the General Electric Company in 1903 and has since been engaged on mechanical engineering research work connected with gas turbines, steam turbines, centrifugal compressors, and superchargers for internal-combustion engines. He has been granted a number of patents for apparatus produced by the General Electric Company.

Presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

existing temperatures, or theoretical power for hyperadiabatic compression, and not the power for adiabatic or isothermal compression. In order to ascertain whether or not a given compressor is good or bad, from the point of view of efficiency, we must therefore find the actual temperatures which occur during compression regardless of the manner in which these temperatures are attained, which fixes P_n, the theoretical power when these temperatures exist. Of course, the losses which occur during the compression, the theoretical power for hyperadiabatic compression, the amounts of heat removed by casing cooling, and

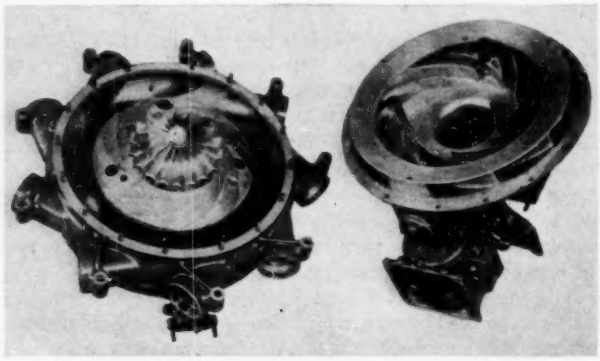

FIG. 1 BUILT-IN GEARED SUPERCHARGER IN PRATT & WHITNEY RADIAL AIR-COOLED AIRPLANE ENGINE. SPEED, 14,000 to 33,000 RPM

added by hot engine parts or the like, are all factors in determining the temperatures during compression. However, as far as the power for hyperadiabatic compression is concerned, the way in which the temperatures are attained is immaterial, as they are fixed by considerations external to the compressor itself and largely independent of it. The temperatures having been fixed, there results a theoretical power for hyperadiabatic compression which is the standard by which the compressor must be judged. To state this matter in another way, the compressor handles fluid with certain volumes, corresponding to certain existing temperatures, and the power which is theoretically required to handle fluid with such volumes is the criterion on which to base the shaft efficiency, not the power for adiabatic or isothermal compression, where the volumes would be less than in the existing case.

However, if it is desired to determine the effect of a change in internal design of a given type of compressor, the amount of cooling remaining fixed, the theoretical power for adiabatic compression would be a logical standard on which to base the comparison. This gives a somewhat better idea of the relative merits of two designs under such conditions, since the losses are added as heat and the shaft efficiency based on existing temperatures would not sufficiently penalize the more inefficient machine. The ratio of theoretical adiabatic power to shaft power is called adiabatic shaft efficiency.

Furthermore, while for most purposes the shaft efficiency rather than the adiabatic shaft efficiency is of importance to the designer, the latter may be of interest from a commercial standpoint. If the user of a compressor does not need high temperature of the discharged fluid, he wishes a machine which will deliver a given pressure with a low power input, and whether a gain comes from better cooling or improved design is immaterial to him. The adiabatic shaft efficiency is a measure of the combined gain due to both factors.

This matter of computation of power for existing temperatures is well known, on the basis of an equation of the compression curve, $pv^n = c$. The general formula for theoretical power for compression with such compression curve with the general exponent n often has been given in the exact form presented later. It usually has been applied to the case here called subadiabatic compression where n lies between 1.00 and k or c_p/c_v. However, the same formula is shown to apply to the case of hyperadiabatic compression with n greater than the adiabatic value k or c_p/c_v. Hence the theoretical power for compression with existing temperatures is the same thing that has been called theoretical power for polytropic compression, or theoretical power for compression with exponent n. For the present case, with temperatures above adiabatic, whence n is greater than k, it is called the theoretical power for hyperadiabatic compression.

There are therefore two entirely independent variables which fix the performance of a hyperadiabatic compressor, one relating to the heat removal and the temperatures which occur during the compression and which fix the theoretical power for hyperadiabatic compression, and the other relating to the shaft efficiency with which the actual power input is applied to supply this theoretical power for hyperadiabatic compression. It is always understood, as already mentioned, that all of the losses due to the fact that the shaft efficiency is less than 1.00, are added to the fluid and so form one element in the heat which is added during compression and which contributes to fix the temperatures during compression. The bearing friction is always negligible for the compressors here considered. Sometimes the fluid passes around the bearings and absorbs their losses. In any case, bearing loss not absorbed by the fluid is neglected.

The ratio of the theoretical power for hyperadiabatic compression to the actual shaft input is defined as the shaft efficiency, denoted by the symbol e. The better the blade and diffuser

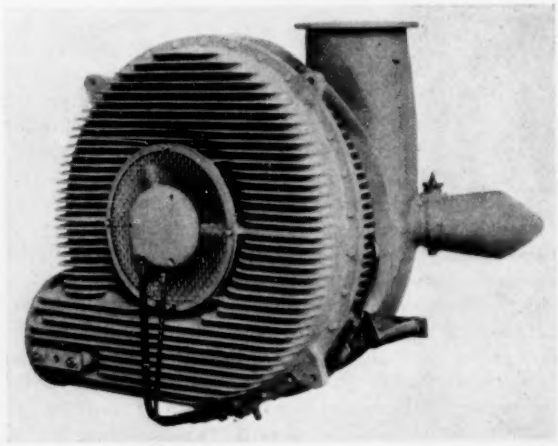

FIG. 2 EXHAUST-DRIVEN SUPERCHARGER USED BY U. S. ARMY AIR CORPS

angles, shapes, and passages, and the less the rotation losses, the greater the value of e.

The temperatures during compression may be taken account of in several ways. The most common one is the use of the value of the exponent n in the relation between pressure and volume during compression, $pv^n = c$. As is well known, n is 1 for isothermal compression, about 1.4 for adiabatic compression, and 1.4 to 1.7 for the hyperadiabatic compression here discussed. Another way in which the temperatures during compression may be taken account of is by the value of the ratio, called e_n, of the theoretical power for hyperadiabatic compression, P_n, to the net power added in the form of heat during compression, causing the temperature rise, P_T. This net power P_T is the shaft power P_s which gives the gross power added in the form of heat, minus the power P_R corresponding to cooling. Of course, the power corresponding to any addition of heat from hot engine

parts or the like also must be counted. This ratio e_n is called the exponential efficiency, and a very simple mathematical expression for it is deduced later

$$e_n = \frac{P_n}{P_T} = \frac{(k-1)/k}{(n-1)/n}$$

e_n is a direct function of n and the relation between the two is shown graphically by the lower curve of Fig. 5. The value of e_n occurs frequently in the mathematics of hyperadiabatic compression, and this is the principal reason why it is given a name.

If the cooling during compression is such as to give adiabatic temperatures, P_n becomes P_k, the theoretical power for adiabatic compression. P_T, the power corresponding to the temperature rise of the fluid, also becomes P_k since we have adiabatic temperatures. Therefore, for cooling to adiabatic temperatures, e_n becomes 1.00. For no cooling at all, P_T becomes P_s, the shaft power, and e_n becomes e, the shaft efficiency. The exponential efficiency e_n therefore varies from 1.00 with cooling to adiabatic temperatures, to e with no cooling, and the actual intermediate values in any given case denote how much cooling is accomplished. e is about 0.70 for a usual case, with a maximum of about 0.75 when circumstances are favorable, and values down to about 0.65 when compromises have to be made in the design. These are therefore the values of e_n with no cooling. In designing a hyperadiabatic compressor for a given pressure rise and flow, values for e_n or n between the adiabatic case and the case for no cooling may be estimated from experience. There can be no general relation between speed, capacity, etc. which serves to fix e_n or n, since they depend primarily upon the heat dissipated from the casing. Values may be computed by finding a tentative value of P_s, and a tentative value of P_R from an estimate of the casing temperature and Robinson's paper mentioned later. Then

$$e_n = \frac{e}{1 - P_R/P_s}$$

and

$$n = \frac{e_n}{e_n - (k-1)/k}$$

P_R need not be known very exactly to give a good value of e_n. A second approximation may be made if desirable by using the first value for e_n to compute n, P_n, P_s, and T_1, from which a second estimate of the casing temperature may be made and a second value of P_R computed.

Various other functions of n or e_n give other aspects of the amount of cooling, and some of these are listed in line IV, column 3, of Table 1. However, no matter how we express the amount of cooling which occurs during compression, there are two entirely independent variables, one such as the exponential efficiency e_n, giving the amount of heat removal or addition with given losses, and in some way fixing the temperatures and hence P_n the theoretical power for hyperadiabatic compression; and the other, the shaft efficiency e, fixing the efficiency with which the shaft input P_s is applied to supply this theoretical power P_n. Of course, the higher the exponential efficiency e_n, indicating better cooling, the lower will be P_n, but for given temperatures P_n has a given value which is the ideal so far as shaft efficiency is concerned. It is by keeping clearly in mind these two distinct variables e and e_n that we shall best be able to attain the best values for each of them, and so obtain the best compressor. The shaft efficiency e is to be made as great as possible by properly propor-

TABLE 1 COMPRESSOR FORMULAS WITH SPECIAL REFERENCE TO HYPERADIABATIC COMPRESSION

(The values are for any perfect gas unless otherwise specified)

Formula	(1) Isothermal Compression. Cooling which removes theoretical power for compression as well as losses so that there is no addition of heat	(2) Adiabatic Compression. Cooling which exactly removes losses, or perfect compression without loss	(3) Hyperadiabatic Compression with cooling or addition of heat. The temperatures are above adiabatic and below or above those of the next column according to the amount of cooling or addition of heat	(4) Hyperadiabatic Compression without cooling or external addition of heat. The temperatures are those due to addition of heat corresponding to entire shaft power which includes theoretical power for hyperadiabatic compression as well as losses due to a given shaft efficiency e. This is the case where the surface is so small in comparison with the power that cooling or addition of external heat is negligible. For the case where such cooling or addition is comparatively small, the given formulas may be used as approximations
I—Theoretical power for compression with existing temperatures, expressed as horsepower	$P = 0.004364 p_2 q_2 \times (\log_e p_1 - \log_e p_2)$ $(0.004364 = 144/33000)$	$P_k = \dfrac{0.004364 p_2 q_2 Y}{(k-1)/k}$ For air and other diatomic gases this becomes $P_k = 0.01542 p_2 q_2 Y$	$P_n = 0.004364 \dfrac{T_1 - T_2}{T_2} \dfrac{p_2 q_2}{(n-1)/n}$ For a design where e, n, and e_n are known, $P_s = P_n/e$. For a test, P_s may be observed or may be found from the computed power P_T corresponding to the temperature rise and the computed casing cooling P_R, by the following formula: $P_T = 0.004364 \dfrac{(T_1 - T_2)}{T_2} \dfrac{p_2 q_2}{(k-1)/k}$ $P_s = P_T + P_R$ n and e_n are found from the observed temperatures and the formulas below Then $e = P_n/P_s$	$P_n = 0.004364 \dfrac{T_1 - T_2}{T_2} \dfrac{p_2 q_2}{(n-1)/n}$ $P_T = 0.004364 \dfrac{T_1 - T_2}{T_2} \dfrac{p_2 q_2}{(k-1)/k} = P_s$ For a design e is known and the temperatures are computed from the formula for e below. For a test the temperatures are observed
II—Theoretical energy for compression, ft-lb per lb of fluid	$w = J c_p T_2 \dfrac{(k-1)}{k} \times (\log_e p_1 - \log_e p_2)$	$w_k = J c_p T_2 Y$	$w_n = J c_p e_n (T_1 - T_2)$	$w_n = J c_p e_n (T_1 - T_2)$
III—Relations between initial temperature T_2 and final temperature T_1 abs F	$T_1 = T_2$	$T_1 = T_k$ = final temperature with adiabatic compression $\dfrac{T_k}{T_2} = \left(\dfrac{p_1}{p_2}\right)^{(k-1)/k} = Y + 1$	$\dfrac{T_1}{T_2} = \left(\dfrac{p_1}{p_2}\right)^{(n-1)/n} = Y_n + 1$ $\log T_1 - \log T_2 = \dfrac{n-1}{n} (\log p_1 - \log p_2)$ $n = \dfrac{1}{1-(n-1)/n} = \dfrac{e_n}{e_n - (k-1)/k}$ For a design n is known and T_1 is computed. For a test T_1 is observed and n is computed	Use formulas of preceding column. For a design, e is known and $(n-1)/n$ is computed from the formula for e below. Then T_1/T_2 and Y_n may be computed from the formulas of the preceding column. For a test $(n-1)/n$ is computed from the temperatures and the formulas of the preceding column and e is computed from the formula below

IV—Efficiencies and ratios

Exponential efficiency = $\dfrac{P_n}{P_T} = \dfrac{(k-1)/k}{(n-1)/n}$

$= \dfrac{k-1}{k}\dfrac{\log p_1 - \log p_2}{\log T_1 - \log T_2}$

Formulas for P_k and T_k in column 2.

Adiabatic power = Theo. power with exist. temps. $\dfrac{P_k}{P_n} = \dfrac{1}{e_n}\dfrac{Y}{Y_n} = \dfrac{1}{e_n}\dfrac{T_k - T_2}{T_1 - T_2}$

Adiabatic temp. rise = Existing temp. rise $\dfrac{Y}{Y_n} = \dfrac{T_k - T_2}{T_1 - T_2} = \dfrac{T_k/T_2 - 1}{T_1/T_2 - 1}$

Adiabatic power = Shaft power $= e e_k = \dfrac{P_k}{P_s}$

Fraction of shaft power removed by cooling = $\dfrac{P_s - P_T}{P_s} = 1 - \dfrac{e}{e_n}$

Fraction of eddy and friction losses removed by cooling = $\dfrac{P_R}{P_L} = \dfrac{P_s - P_T}{P_s - P_n} = \dfrac{1 - e/e_n}{1 - e}$

For a design, $e_n = \dfrac{e}{1 - P_R/P_s}$

Shaft efficiency = $e = \dfrac{P_n}{P_s} = \dfrac{(k-1)/k}{(n-1)/n}$

$= \dfrac{k-1}{k}\dfrac{\log p_1 - \log p_2}{\log T_1 - \log T_2}$

$n = \dfrac{e}{e - 1 + 1/k}$

e is given by e_n of the preceding column. Use formulas of preceding column, substituting e for e_n

tioning vanes, areas, angles, and other items of the design. The cooling is to be made as great as possible to decrease the theoretical power for hyperadiabatic compression, as well as to decrease the final temperature in case it is desirable to have the final fluid as cool as convenient. In case of a supercharger some temperature rise assists vaporization, but after this, the cooler the air, the greater the amount of charge forced into the engine cylinder. It is easily possible for a supercharger to nearly defeat the purpose for which it is installed if the final temperature is so high that the weight of charge in the given volume of the cylinder displacement is unduly decreased. This occurs if the efficiency is unduly low, and if heat is added instead of being removed during compression. Therefore the supercharger casing should be separated as far as possible from the engine crankcase or parts heated by hot oil, and protected by baffles from radiation from a hot nozzle box. Cooling fins, as shown in Fig. 2, should be provided, and whatever arrangements are possible should be made for circulation around these fins.

In case the compressor speed and power input are so great and the casing area so small that the cooling is a negligible percentage, we have the case of column 4 of Table 1, with no cooling or heating, so that the power P_T corresponding to the temperature rise gives the shaft power P_s, and the exponential efficiency e_n has its minimum value, which is the shaft efficiency e. A test of such a compressor with measurement of temperatures and pressures only thus gives the value of shaft efficiency without necessity for power measurement. This sort of test is so simple that it has been used in cases where appreciable dissipation of heat from the casing makes it improper, and shaft efficiency has been computed from a test on the basis that the shaft power was given by the temperature rise of the air, when really the latter was appreciably less, owing to heat dissipation from the casing. This amounts to using our exponential efficiency e_n as if it were shaft efficiency for this case. An example of the error is shown in Fig. 7 where some points have a shaft efficiency of 0.70 and an exponential efficiency of 0.78. If the value of 0.78 is supposed to be the shaft efficiency, the compressor is given much more credit than it deserves. A demonstration of the fallacy of neglecting heat dissipation from the casing is the fact that some centrifugal compressors whose efficiency was computed by temperature rise, operated at no load without much increase of the casing temperature. In this case the entire shaft power at no load, about 20 per cent of the full-load power, was dissipated from the casing because there was no flow of fluid. An amount of power of the same order of magnitude was of course dissipated at full load, and there was therefore appreciable heat dissipation. However, owing to the use of high speeds, casings of small area cannot safely dissipate the no-load power, and machines of the type of Figs. 2 and 3 become unduly heated if operated at no load by completely closing the inlet for any length of time.

The shaft power P_s for a test may be accurately computed by adding the power P_R removed by cooling, computed by methods outlined by Robinson,[2] to the power P_T shown by the measured temperatures of the air.

Fig. 7 shows the application of the preceding principles to a test at sea level of a particular airplane supercharger. Test I was first made with the entire casing covered with heat-insulating lagging so as to make the heat dissipated from the casing negligible, as in column 4 of Table 1. Then $e = e_n$, and the shaft power and shaft efficiency are given by measurement of the temperature rise of the air. This method of measurement of shaft power and shaft efficiency has been used in a number of cases and has been found to be trustworthy when the temperature rise is great enough so that it may be determined with accuracy. The lagging was then removed and the run marked IV (Fig. 7) made with usual cooling. The interior of the machine was the same as in test I, so that the shaft efficiency was the same for both tests and was given by e_n for Test I.

Fig. 7 shows values for the various efficiencies and factors. It is to be noted that the maximum cooling which can be provided gives an appreciable decrease of temperature rise, but does not do very much toward decreasing P_n, the power for hyperadiabatic compression. However, all of the cooling has been done which seems possible with the small, compact machine which the conditions demand. The power actually delivered during the test at the larger volumes is 117 hp with a casing of 20 in. outside diameter which does not permit of an appreciable percentage of cooling.

Notation for Formulas

v = specific volume

p_1 = high pressure, lb per sq in. abs. This is the final pressure for a compressor

p_2 = low pressure, lb per sq in. abs. This is the initial pressure for a compressor

[2] "Heat-Balance Method of Testing Centrifugal Compressors," Trans. A.S.M.E., vol. 47 (1925), p. 1179.

T_1 = high or final temperature, abs F
T_2 = low or initial temperature, abs F
T_k = high or final temperature for adiabatic compression
q_2 = flow, cu ft per min at inlet conditions p_2, T_2
k = c_p/c_v = ratio of specific heats. $(k-1)/k$ is taken as 0.283 for air and perfect diatomic gases
n = exponent in $pv^n = c$
Y = $(p_1/p_2)^{(k-1)\ k} - 1$
Y_n = $(p_1/p_2)^{(n-1)/n} - 1$
P_s = shaft horsepower

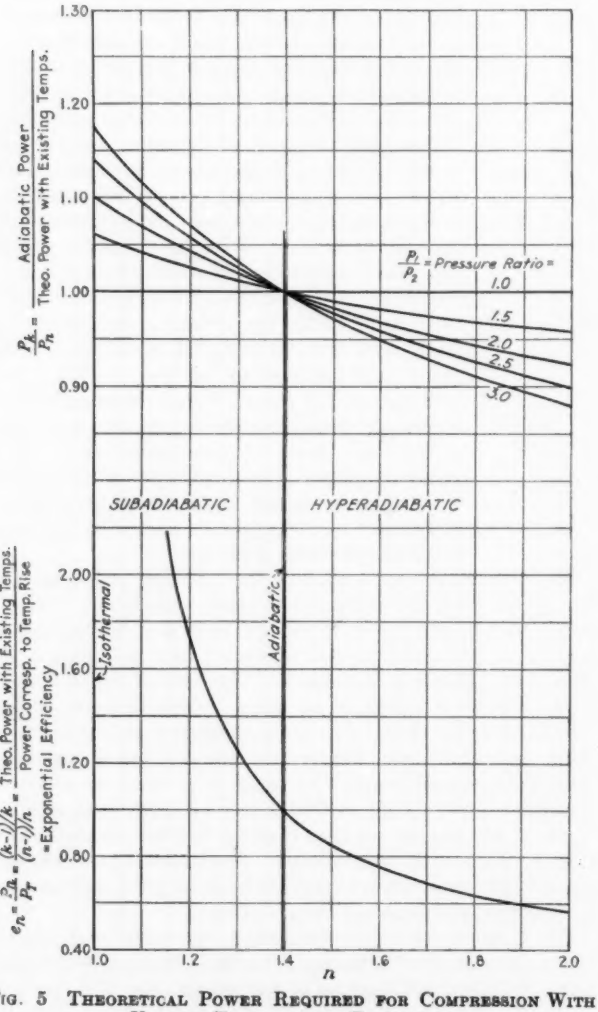

FIG. 5 THEORETICAL POWER REQUIRED FOR COMPRESSION WITH VARIOUS TEMPERATURE CONDITIONS

P_n = theoretical power for hyperadiabatic compression or compression with existing temperatures or with exponent n, expressed as horsepower
P_R = cooling or radiation from the compressor casing, expressed as horsepower. It may be computed from the temperature and area of the casing if there is no possibility of addition of heat as from hot engine parts, nozzle box, etc.
P_k = power for adiabatic compression
P_L = eddy and friction losses of compressor, as horsepower
P_T = horsepower corresponding to temperature rise of the air
w_n = theoretical energy for compression with existing temperatures, ft-lb per lb of fluid
w_k = energy for adiabatic compression
e = P_n/P_s = shaft efficiency
e_n = $\dfrac{P_n}{P_T} = \dfrac{(k-1)/k}{(n-1)/n}$ = exponential efficiency. This is the ratio of differential temperature increments, being that for adiabatic temperatures divided by that for existing temperatures. It also comes out as the ratio of the theoretical power for hyperadiabatic compression to the power corresponding to the temperature rise
e_k = adiabatic power divided by theoretical power for hyperadiabatic compression. $e_k = w_k/w_n = P_k/P_n$
η = hydraulic efficiency, or ratio of theoretical energy for hyperadiabatic compression required for the pressure produced, to the theoretical energy added to the fluid by virtue of the wheel angles and speed.

In order to determine the size of an impeller to produce a given pressure, there must be known from experience the hydraulic efficiency η, which is the ratio of w_n the theoretical energy for hyperadiabatic compression to the theoretical energy input for a given wheel speed. The latter expression has the form KV^2/g, where V is the peripheral speed of the impeller in feet per second, and K is a constant dependent upon the directions of the fluid, in space at the impeller inlet, and relative to the impeller at the exit. The values of w_n given by Formula II are to be inserted in the relation

$$\frac{KV^2}{g} = \frac{w_n}{\eta}$$

In a usual supercharger, the fluid enters the impeller with its absolute velocity in space in a direction normal to the surface of the inlet edges of the impeller vanes, and the vanes at impeller exit give the fluid a velocity relative to the impeller which is normal to the surface of the exit edges of the impeller vanes. For this case $K = 1.00$ in the above equation. Under some circumstances the fluid at the impeller exit does not follow

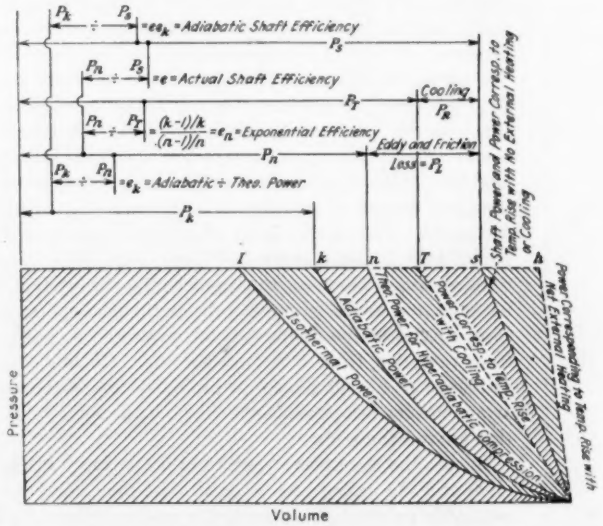

FIG. 6 PRESSURE-VOLUME DIAGRAM FOR VARIOUS TYPES OF COMPRESSION

(This figure is purely diagrammatic and not drawn to scale. Dimension lines refer to area of diagram included between the two sloping or vertical lines indicated. The area between k and n shows the extra power which must be supplied because the cooling provided is not sufficient to give adiabatic temperature.)

the blade angle, and a factor from experience must be introduced to take account of this effect, called "slip." Sometimes it is most convenient to refer to w_k, the adiabatic energy. Both

purposes may be accomplished at once by using another factor from experience, defined as follows:

$$\text{Compression coefficient} = \frac{w_h}{V^2/g}$$

Appendix

DEDUCTION OF FORMULAS

SUPPOSE a pound of fluid passing from a region A, such as the atmosphere, through a region C, such as a compressor, where mechanical energy, heat, etc. may be transferred, and into a region D, such as the discharge pipe of the compressor; with conditions p_2, v_2, and T_2 at the junction of A and C and p, v, T at the junction of C and D. Let $U - U_2$ ft-lb be the change in the molecular energy resident in the fluid from A to D. The passage from A to C means that energy 144 p_2v_2 is added to C by A, and similarly energy 144 pv is added by C to D. Hence the net energy added to the fluid during its passage through C is

$$(U + 144\,pv) - (U_2 + 144\,p_2v_2)$$

Of this added energy, only a portion $U - U_2$ remains in the fluid, and the remainder is added to the external universe, but nevertheless the whole expression represents energy which must be added when the fluid passes through C. The value in each parenthesis, counted above some suitable zero, is well known as the "total heat" or "enthalpy" for any fluid. Air and similar gases, for engineering purposes, may be treated thermodynamically as perfect gases. For these it is well known that no energy is involved when the molecules are brought closer together as at the higher pressure, since even then they are so far apart that their mutual attraction is negligible. Hence a given weight of gas at a given temperature contains a given amount of internal energy, regardless of the pressure. It follows that the heat equivalent of all of the mechanical energy actually added to the fluid causes temperature rise just as if it were added directly as heat without causing any change of pressure. Energy in ft-lb per lb added to cause temperature rise of fluid in a closed vessel is expressed by

$$J\,c_v(T - T_2)$$

and this is therefore the value of $(U - U_2)$ for a perfect gas. By substituting this value in the above expression and also making use of the well-known relations for a perfect gas, 144 $pv = RT$, and $c_p - c_v = R/J$ (which is really the statement that the internal energy depends on the temperature only), we have as the value of the above expression for the energy which must be added to the fluid either as heat or mechanical energy as it passes through the compressor

$$w_T = Jc_p\,(T - T_2) \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The mechanical energy for compression is applied to the fluid in a centrifugal compressor in a way somewhat different from what it is in a reciprocating compressor, although of course the result is the same. At any point in the compression, the volume v passes from a region of pressure p to a region of pressure $p + dp$. The mechanical energy in ft-lb per lb which must be supplied by the compressing machine to accomplish this is 144 vdp.

The total energy for compression from p_2 to p, therefore, is

$$w_n = 144 \int_{p_2}^{p} vdp \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

This is obviously the area of the pressure-volume diagram, Fig. 6, and vdp is the area of a differential horizontal strip. Such a diagram is also the "indicator card" for a reciprocating compressor. If the energy added to the fluid as given by [1] is the exact amount of the mechanical energy given by [2], so that no heat as such is added or taken away, we have what is called

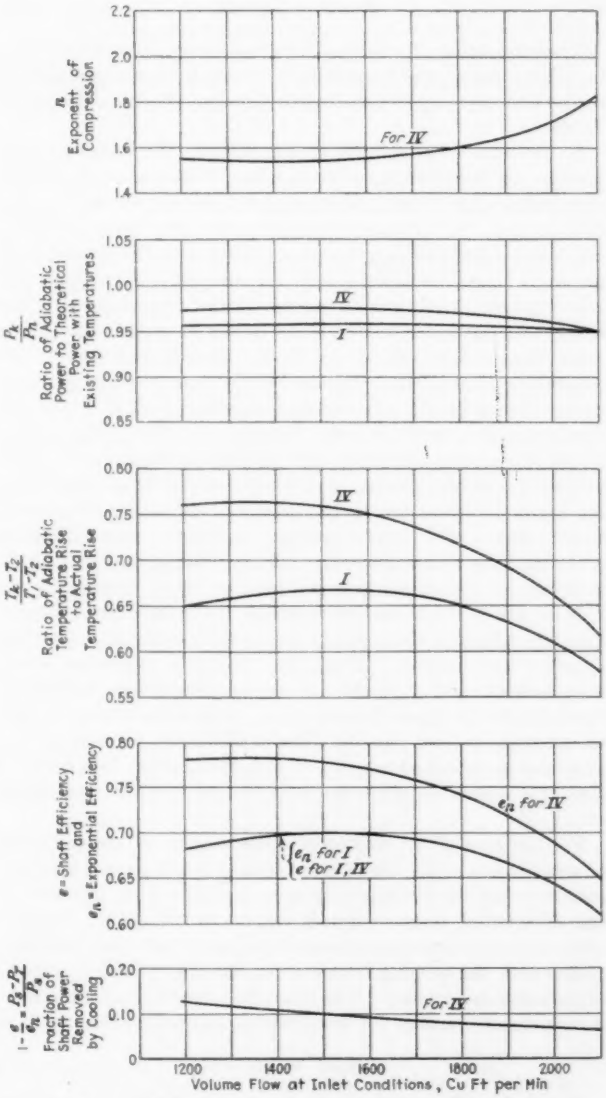

FIG. 7 EFFICIENCIES FROM SUPERCHARGER TESTS
(I—Casing lagged with asbestos. IV—Casing bare and cooled.)

"adiabatic compression," defined by the equality between [1] and [2]

$$Jc_p\,(T - T_2) = 144 \int_{p_2}^{p} vdp \quad \ldots\ldots\ldots\ldots [3]$$

Such a thermodynamic change, without external addition or subtraction of heat, is called adiabatic in the general case of expansion where there may or may not be some internal transformation of mechanical energy into heat, as by energy loss due to fluid friction. The particular case of adiabatic expansion with no internal transformation of mechanical energy into heat is called "isentropic," and this term could properly be used for the same type of compression, which is the present case. However, the reverse of the general case of adiabatic expansion would be compression with internal transformation of heat into mechanical

energy, which is not possible. Hence adiabatic compression can only be isentropic compression. As the term "adiabatic" is very widely used, the author will adhere to it. Equation [3] gives as the differential equation for adiabatic compression

$$Jc_v dT = 144\, vdp \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

The integration of this equation gives the well-known relations between pressure and temperature for adiabatic compression (of course also applying to isentropic expansion) given in column 2 of Table 1.

In the case of a centrifugal compressor, the losses of compression are due to eddies at blade inlets, friction along the blades of impeller and diffuser, and rotational friction of the impeller in its casing. All of these, which may be called hydraulic losses, are added as heat, causing temperature rise of the fluid being compressed. Since the useful energy for compression, $\int vdp$, is also added as heat, it follows that in a centrifugal compressor all of the energy corresponding to the shaft power P_s finally appears to cause temperature rise of the fluid. That is, the energy corresponding to the losses plus the energy shown by [2] gives the energy shown by [1]. In the mathematical work it is assumed that there is a constant ratio between the differential energy added to cause compression, the differential heat added or removed by external sources, and the differential heat added from the hydraulic losses during compression. Of course, this is not strictly true. The heat removals, additions, and efficiencies probably have values somewhat different during that part of the compression occurring along the impeller from those along the diffuser, etc. The losses due to eddies at the impeller or diffuser inlet are added at these points rather than uniformly along the impeller and diffuser. There are no data regarding these irregularities, and it would not be mathematically feasible to take account of them if there were. Hence the observed final temperature is used and the differential energy changes due to all causes are assumed to proceed proportionately. It is believed that this procedure gives the final results without appreciable error.

For the case of hyperadiabatic compression, where the losses of compression minus the effect of cooling give a greater temperature rise than for the adiabatic case, we define e_n as the ratio of the differential temperature increment which would occur if there were adiabatic compression, to the increment which actually occurs with the existing temperature conditions, taking account of the losses and cooling. The adiabatic increment corresponds to the mechanical energy for compression, 144 vdp, so that we have

$$e_n Jc_v dT = 144\, vdp \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

This is the differential equation for hyperadiabatic compression corresponding to Equation [4] for adiabatic compression. The integration is readily performed and gives

$$p_1 v_1^n = p_2 v_2^n \qquad \text{and} \qquad \frac{T_1}{T_2} = \left(\frac{p_1}{p_2}\right)^{(n-1)/n}$$

where n is defined by the relation

$$e_n = \frac{(k-1)/k}{(n-1)/n}$$

This assumption of a constant ratio e_n of adiabatic to existing differential temperature increments therefore gives final results identical with the well-known formulas for polytropic compression with exponent n. The energy for hyperadiabatic compression comes out

$$w_n = 144 \int_{p_2}^{p_1} vdp = e_n Jc_p (T_1 - T_2)$$

The energy corresponding to the temperature rise is

$$w_T = Jc_p (T_1 - T_2)$$

It follows that

$$\frac{w_n}{w_T} = \frac{P_n}{P_T} = e_n$$

which gives a definition of e_n which may be used instead of the original one. From the relations above given may be deduced the various relations of column 3 of Table 1. If there is no cooling, P_T becomes P_s and e_n becomes P_n/P_s, which is defined as the shaft efficiency e. This gives the formulas in the last column of the table.

In the transformations involved in the various formulas there is often used the well-known relation

$$c_p - c_v = c_p(k-1)/k = R/J = \frac{144pv}{JT}$$

where R is the constant in the relation $144pv = RT$ with p in pounds per square inch. The fundamental constants should be selected so that they are reputable in view of modern experimental work, as well as to exactly satisfy this equation.[3]

Discussion

C. F. Taylor.[4] The writer is glad that Dr. Moss has presented the theory of air compression under high-temperature conditions in such a clear and useful form. While this theory has been well known, this is the first time that the writer has seen it presented for publication in a form so convenient for the engineer.

There is one point to which attention might be called, and that is that all the calculations and formulas are based on the assumption that the initial volume of air, per unit time, remains constant.

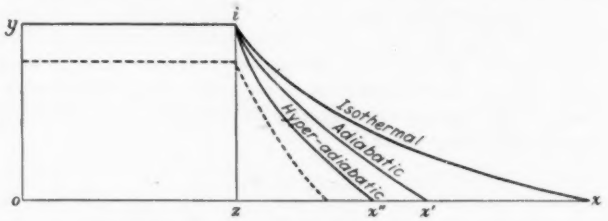

Fig. 8

In the case of the internal-combustion engine, however, it is the final volume rather than the initial volume which is held constant, assuming the engine speed not to vary.

Referring to Fig. 8, let us assume that the cylinder volume of the engine per unit time is represented by the length *o-z*. The power for isothermal compression would be represented by the area *o-x-i-y*. Now if the temperature increases during the compression process, and we compress to the same final pressure, the initial volume must change in order to attain the same final volume. In such a case the power for compression is reduced, and is represented by the areas *o-x'-i-y* and *o-x''-i-y* for adiabatic and hyper-adiabatic compressions, respectively. Thus the increase in compression temperature actually reduces the power absorbed by the supercharger, under the usual conditions obtaining in the internal-combustion engine. As a matter of fact, the case is usually even more exaggerated, because when the temperature of the air delivered to the engine increases, the pressure to which supercharging may be carried is often reduced on account of deto-

[3] "Engineering Computations for Air and Gases," by S. A. Moss and C. W. Smith, Trans. A.S.M.E., vol. 52 (1930), paper APM-52-8.

[4] Professor, Massachusetts Institute of Technology, Cambridge, Mass.

nation. The actual compression diagram under such conditions would be represented by the dotted line of Fig. 8.

The power for compressing a given *weight* of air to a given pressure, increases with increase in compression temperature, as the author states. From Fig. 8, however, we can easily see that in the case of supercharging the internal-combustion engine the weight of air decreases as the compression temperature increases, to such an extent that the power required by the supercharger goes down rather than up.

In the case of a blast furnace, a constant weight of air is required. This means a constant initial volume, and Fig. 6 would be representative of such an application except that the final pressure would vary with the varying resistance to flow of the furnace charge.

For most commercial uses of compressed air, such as for driving small tools, the requirement is a constant pressure after the air has been stored and cooled practically to its initial temperature. In this case, Fig. 6 would apply.

The Mooring and Ground Handling of a Rigid Airship[1]

By C. E. ROSENDAHL,[2] LAKEHURST, N. J.

Problems in mooring and handling rigid airships are treated. Differences of opinion resulting from the relatively limited airship operating experience are discussed. Prediction is made that successful mooring and handling of rigid airships will center around the low mast. When the problems of airship terminals reach a satisfactory status, as it is asserted they soon will, it will be found that extremely important contributions will have been made by the airship personnel and engineering talent of the United States.

EVERY successful type of carrier requires extensive auxiliary facilities to permit it to serve usefully and efficiently. Such facilities have seldom been anticipated or originally conceived with the carrier, but are achieved through progressive development after extensive and sometimes expensive practical experience has been gained. Even a hasty glance at the histories of railroads, steamships, and automobiles reveals the multitude of essential auxiliaries such as servicing stations, roundhouses, repair shops, elaborate signal systems, communications, tunnels, drydocks, wharves, bridges, fleets of tugs, and so on, of fundamental and indispensable need. Furthermore, automobiles and railroads have required hundreds of thousands of miles of elaborately prepared paths for their use. In other similar essentials and except for the matter of prepared paths, aircraft, and particularly airships, are at present in the status analogous to that of other successful carriers in their pioneering days when their auxiliaries were just being found necessary and accordingly began to be developed. The greatest need today in the airship project is that of providing mooring and ground-handling equipment commensurate with the ships themselves.

It is to be regretted that the development of mooring and handling methods and equipment did not proceed apace of airships themselves, as probably no other single factor has been so effective in retarding the airship project as the lack of adequate and efficient terminal facilities. This is not an occasion for citing the reasons why such development has lagged, but suffice it to say the situation has been realized in this country from the start of rigid-airship operation here; and as a result of determined steps along this line, highly improved equipment is now in use and further continuous progress is being made. It is the opinion of those of us who have been and are now engaged in the operation of rigid airships that the attainment of the full potentialities of this remarkable carrier is dependent on and will be materially expedited principally by the solution of the mooring and handling problems. Most important of all, it is our conviction also that these problems are not at all insurmountable, but are capable of solution upon the expenditure of suitable effort.

In taking up airship operation in this country we were forced to begin with inherited methods of operation, and naturally were largely dependent on manual methods for the landing and ground-handling of our ships. The several years of operation of the *Shenandoah* and the *Los Angeles* taught us much. With only one active airship, progress has necessarily been slow, but we are now more fully cognizant of the requirements and specifications for more generally applicable mooring and handling methods. We have produced a mechanical handling system for the *Los Angeles* whereby that ship has been handled in and out of the Lakehurst shed with as few as 60 men. Further improvements are necessary and are on their way to early realization.

Likewise we have realized the weak points in the construction details of past airships which have impeded the application of mechanical-handling methods to them. Future ships will incorporate features for making ready application of improved handling equipment. The old manual methods, however, involve the basic fundamentals and have been valuable in impressing the principles involved. These manual methods will probably for some time continue to be available for emergency or last-resort use just as hand-steering equipment is still available in surface vessels. Modern airships are of such size as to preclude regular dependence upon man power for ground handling, and if a suitable mechanical equivalent is not found, it will be very difficult indeed for the airship project to succeed.

The main problems involved in providing adequate airship terminals (exclusive of repair facilities) may be classed under three headings:

(1) Landing the airship from flight by mechanical means
(2) Servicing the ship and mooring it out in the open
(3) Housing and unhousing the ship when necessary, by mechanical means that will reduce the danger and increase the utility of the operation; this includes moving the ship between the mooring location and the dock.

I shall endeavor to point out briefly some of the fundamentals of the remaining problems and then how I believe we can meet them practically.

[2] Lieutenant Commander, U. S. Navy, in command of U.S.S. *Akron*, home port Naval Air Station, Lakehurst, N. J. (NOTE: Early in 1932, Lieut.-Com. C. E. Rosendahl was transferred to sea duty on the battleship *West Virginia*.) The author was born on May 15, 1892. He was graduated from the U. S. Naval Academy in June, 1914; served in various line officers' billets in the Navy continuously; in April, 1923, volunteered for airship duty and began training in that branch at the Naval Air Station, Lakehurst, N. J.; was a member of the original crew of U.S.S. *Shenandoah* and a survivor of her loss in September, 1925; then became executive officer of U.S.S. *Los Angeles*, becoming commanding officer of U.S.S. *Los Angeles* in May, 1926, and retaining that command for three years; then became commander, Rigid Airship Training and Experimental Squadron, for a year; about one year in Bureau of Aeronautics, Navy Department; flew trials of U.S.S. *Akron* and became first commanding officer of that ship, relinquishing that command in June, 1932; made first transatlantic crossing of *Graf Zeppelin* in October, 1928, as U. S. Navy observer; made world flight of *Graf Zeppelin* in August, 1929.

Presented at the Fifth National Aeronautic Meeting, Baltimore, Md., May 12 to 14, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

In the development of the improved equipment, we have kept in mind the desirability of combining in each item as many functions as possible and of keeping the number of items small, if such could be done without materially complicating the units involved. While such an objective might at first seem a little ambitious, consideration of the matter shows it to be largely practicable. Experience has shown that a mooring mast having certain essential characteristics can be made to serve as the nucleus for all such systems and equipment.

As is generally known, the mooring mast or tower is a post-war product devised by the British. The main factor contributing to its conception was the vital need for servicing and mooring out airships in the open when weather or other conditions made it impossible to house them. There exists also the additional need for having outlying servicing stations which are not so pretentious or expensive as those possessing hangar and repair facilities, etc. In other words, airships require not only navy yards or docking yards, but harbors as well. The facilities at airship harbors are those comparable to wharves, moorings, and anchorages for surface vessels, including fueling, watering, and provisioning arrangements. For an airship, these will consist of a mooring mast and certain servicing facilities that can be conveniently grouped around it.

During the temporary cessation in the British airship program their progress in mooring masts also was retarded somewhat; but with the revival of their airship activities an elaboration of the original tower was produced, and several examples of this design were constructed throughout the British Empire. During the British inactivity, the U. S. Navy made great progress in mooring masts and expanded their use very materially. The mooring mast is established as a permanent factor in airship operation.

Three general types of masts or mooring towers are recognized:

(*a*) The high mast or tower
(*b*) The low or "stub" mast
(*c*) The mobile mast.

"Semi-portable" and "expeditionary" masts of either the high or stub varieties have been put into use after quick erection at outlying places. The "floating" mast and base, as represented by the installation on the airship tender *Patoka*, have been in use for a number of years.

The low or stub mast is a U. S. Navy development. The high tower is the type developed and still used by the British. No high masts have been erected in the United States for several years, and it is the author's opinion that the high mast is being superseded by the stub mast and is rapidly going out of style. The stub mast is a very versatile member of the airship project, and the principal concern of this paper is with it. To show the trend leading to the stub mast, it is necessary to describe briefly the present means employed for securing a rigid airship to a mast.

The longitudinal members of a ship's structure come together in a strong bow-cap, in which is secured an axial steel tube housing a strong spindle mounted in bearings. A steel mooring cone is mounted on the outboard end of the spindle and hinged by an athwartship pin. At the top of the mooring mast, a steel cup that is the counterpart of the ship's cone is mounted on a radial bearing. When the ship is secured to the mast, the cone is locked in the rotary mast cup, and the ship has three degrees of freedom: she can swing around the mast in the horizontal plane like a weather vane in response to fluctuations in the direction of the wind; her stern can oscillate vertically about the hinge pin of her mooring cone; and she can roll about her longitudinal axis. The original type of mooring mast was of such height that contemporary ships were permitted a downward angle of 12 to 15 deg before the stern was in danger of striking the ground. With modern airships, this freedom would require a structure some 250 ft high. Restriction of the vertical motion of the stern, particularly upward, presented an exceedingly interesting problem. In a wind of appreciable velocity, some dynamic control at the mast is available from the flow of air past the ship's surfaces, and a certain amount of static control, although somewhat sluggish at times, is possible by use of ballast. Due to fluctuations in wind direction, to rapid atmospheric temperature changes, and to gusts and vertical air currents, a ship moored to a high mast is in motion about the mast much of the time and must be "flown" while so moored.

Vertical movement of the stern, under certain conditions, has assumed dangerous proportions. Various efforts at automatic ballasting and trimming have been suggested and some tried, the principle being to permit easy horizontal movement of the ship in azimuth, but to check the vertical oscillations by automatically adding weight during the tendency to rise and by reducing the weight when the ship tends to fall. A seemingly ideal form of tail drag (or automatic weight) is a suspended chain branching into parts and each successive part branching out again, to increase the weight increment with increase of upward angle of the stern. The most practical type consists of one or more sets of heavy wheels that tow on the ground in horizontal motion, but add their restraining weight as the ship tends to lift. For use at the mast of the *Patoka* a string of partially filled floating drums of water serves quite well. However, any form of drag yet devised for use at a high mast has considerable surface friction, with the result that there often occurs a tendency (which can be of dangerous proportions) to "spring" the stern downward. The use of several individual drags presents difficulty in their attachment and detachment under the gusty conditions in which they are most needed.

During the passage of wind shifts in barometric depressions that are sometimes as great as 180 deg in direction, and often accompanied by considerable and almost instantaneous drops in temperature, there may be danger for the ship which is moored at a high mast in adjusting herself to the new wind direction, due to having a temporary false buoyancy caused by lag of her gas-temperature changes and to vertical currents and gusts. Although it might be expected that storm conditions, if any, would be those that would put a moored ship through dangerous contortions, another situation of quite different characteristics actually caused concern over this on at least one occasion. On a peaceful day when the barometric gradient was weak and the wind consequently light and variable, the *Los Angeles* lay moored to the high mast at Lakehurst. Secured to her stern, as had been customary in several years' operations, was a tail drag consisting of chain and heavy wheels weighing altogether about 2500 lb. The mean wind direction had been northwesterly. Early in the afternoon and without warning except for a series of dust whirls seen approaching a short distance away, the sea breeze with noticeably colder air came sweeping in from a southeasterly direction. With this breeze striking the ship directly from astern, and with the buoyancy augmented temporarily by the sudden immersion of the ship in the colder air, the stern began to rise and continued to almost a vertical position. Just before reaching the top of the arc, the ship began to turn about her longitudinal axis and into the new wind direction. Shortly she came to rest on an even keel without any injury to personnel and with practically no damage whatsoever to herself. As a matter of fact, she could have flown at once in total safety. Although this was the most remarkable demonstration of unsuspected strength ever staged by an airship, it can hardly be called a desirable stunt for repetition. I can conceive of storm conditions that might not treat a ship at the high mast so considerately. This performance corroborated our previous views as to this fault

of the high-mast mooring-out system. It is my opinion that proposed elaborate tail drags and automatic ballasting systems cannot adequately correct this fault of the high mast without introducing complications and perhaps other dangers.

While this incident spurred us on to develop the lower type of mast that would permit full control of the stern movement, there were also other important contributory reasons. Included in these are the knowledge that wind velocities nearer the ground are frequently much less than those at the level of the so-called "high" masts; the fact that gustiness is greater a few hundred feet off the ground than at the surface; and that while vertical currents often exist at the level of the high mast they cannot blow into or out of the ground. The lower position should therefore be relatively safer.

The stub-mast equipment, in general, consists of a mast structure carrying a cup into which the nose of the ship is secured and a stern carriage to which the after part of the ship is attached. A path of some sort for the stern carriage is involved. The simplest form of stub mast consists merely of a wood or steel pole carrying on top, above a small operator's platform, an ordinary mast cup. The heel of the mast may be so hinged as to permit lowering it. Suitable steadying guys and erecting gear are provided. Servicing connections for such needs as electricity, fuel, water, and helium are located at the base of the mast. It is interesting to note that the Germans, who for many years had no mooring-mast convictions, adopted this low type as their first mooring-mast venture.

At outlying stub masts, up to the present, the ship has used a pneumatic wheel and a tail drag at the stern. However, at more complete bases we have employed a circular standard-gage railroad track about the mast and a holding-down carriage fitted to this track by means of rollers which prevent its motion up or down. Suitable means have been devised for the attachment of the rear car of the ship to this holding-down carriage. The latter is so installed that in an emergency a take-off is possible by automatically disconnecting from the stern carriage when the ship is free forward; yet under normal conditions the ship responds to fluctuations in wind direction freely, while the stern is positively restrained from vertical oscillations. At first it was believed that any upward vertical load should not be taken by the car itself, and hence the track was made to resist the expected vertical load. However, it has been found by experimentation that it is safe to make the holding-down carriage itself of such weight as to resist most of the tendency toward lifting vertically. Early criticism directed at this restricted stern movement pointed out that the high friction expected from such a device would retard and deprive the ship dangerously of a freedom of movement in azimuth that it should be allowed. Actual experience has shown this fear to be unfounded.

It has been pointed out that the use of a path or track of fixed radius around the stub mast will necessitate such a path for each of the various sizes of airships that might at some time desire to moor there. While this may be true, it is not considered of any serious consequence. The matter of variable height to accommodate ships of various diameters is readily taken care of by incorporating an extensible feature in the mast. A remaining consideration of equal importance is that of standardizing mooring cones and mast cups, and international negotiations bearing on this matter have been under way for some time.

For the moored ship, the low riding position at the stub mast undoubtedly possesses marked superiority over the high mast. However, to the inexperienced or to those who have not studied the matter, there may at first appear to be certain disadvantages connected with mooring or riding to the short mast. Actually, however, in my opinion, the principal feature pointed out by such persons as a disadvantage of the low mast represents a shortcoming common to both types as they exist today. The introduction of the stub mast merely called closer attention to it.

The gist of the mooring operation is of course the pulling of the ship's cone into the corresponding cup at the top of the mast. To accomplish this, the airship about to moor proceeds into the wind to a point to leeward of the mast and drops to the ground the end of a steel cable fastened to a swivel in the ship's cone. This cable is then coupled to a similar cable that has been led from a winch at the base of the mast, up through the mast, and out of the cup to the ground. Operation of the winch in winding in this coupled cable pulls the nose of the ship into the cup. As the wind is seldom steady in direction and velocity, additional wires become necessary. A steel cable called a "yaw" or nose-steadying wire is led from each side of the ship's nose to the ground, these two cables being then coupled to corresponding wires that are led out on the ground at an angle of 60 deg on either side of the wind direction. When at the proper length, these wires prevent lateral motion of the ship and also keep her from overriding and fouling the top of the mast during the mooring operation. The ship is thus held at the apex of a pyramid of wires, the buoyancy of the ship providing an upward force to make the wires taut, the ship's engines and the wind preventing undue forward momentum, and the yaw wires preventing lateral displacement and overriding. We thus establish in space at the ship's nose as rigid a point as we can with wires; with the ship fast to it we then transfer this point to the mast top.

In the past, the anchorages for the ground yaw wires have been fixed, but the use of a rigid track around the mast will make the introduction of floating yaw-wire anchorages easily feasible. This is another advantage of the stub-mast stern-track system that can be well understood when it is realized that if, during the mooring operation, the wind changes direction to any considerable extent, there is danger of having the wires foul the hull of the ship and also of diminishing their usefulness if their anchorages cannot be readily corrected to the new wind direction. Also it has happened on occasions that the wind direction at the levels of approach for landing is diametrically or widely divergent from that on the surface, so that the ship approaching into her own wind direction actually spirals down as she approaches nearer to the surface.

As indicated earlier, the introduction of the stub mooring mast called attention to an important shortcoming in the method heretofore used in mooring rigid airships. Some people believe that due to the lesser height of the low mast there would be additional danger to the ship while mooring because of the closer presence of the ground. This has resulted in considerable attention being directed toward obtaining better vertical control of the ship during the mooring operation. While the necessity for such control may be seen more readily in connection with the short mast, nevertheless an analysis of the whole problem shows unmistakably that adequate vertical control is a necessity at any mooring mast regardless of its height. Since it has been my fortune to make or attempt to make moorings under bad conditions as well as good, my own experience has pointed out forcefully that the mooring system as employed in the past will not suffice. By "bad" conditions is not meant merely high wind velocities, for a steady high wind would facilitate the mooring. It is the gusty irregular wind, involving lateral and vertical disturbances, that complicates the operation.

The mooring operation has been considerably improved by the adoption of higher speed and more responsive winches and of distant control of the mooring winches from the operating platform. However, no mooring method has been able satisfactorily to overcome purely vertical gusts or the vertical components of gusts that would tend to drive the ship downward during the mooring operation. To make either the high or low mast sufficiently

serviceable, it will be necessary to take care of these vertical fluctuations by an addition to the present mooring system. It is only the buoyancy of the ship that now provides the present upward force and makes a fairly rigid pyramid of the mooring wires. In itself, this has been found to be insufficient. There are several other ways of providing a sufficient force, and included among them are the following:

(1) Inclination of the ship to obtain upward dynamic effect
(2) Use of ship's propellers
(3) Vertical thrust from propellers
(4) Excess buoyancy by ballasting
(5) Addition of new means to provide upward force.

Each of these will be discussed briefly, as they apply to one of the very important remaining mooring problems; and frequently engineers in other lines are able to recommend, from the symptoms, cures that their parts of the engineering world may be able to supply.

Every one knows that airplanes and airships obtain lift from air speed and the inclination of their surfaces. An airship such as the *Los Angeles* can, at top speed, obtain a dynamic lift of between 4 and 5 tons. However, since this lift varies as the square of the air velocity, it will be seen that the dynamic lift falls off rapidly at low or moderate speeds, or rather, does not amount to much until quite high velocities are reached. While no one challenges the fact that there is some slight advantage in maintaining the bow-up, stern-down inclination during the mooring operation, nevertheless its value, in my opinion, is highly overrated. American airships have made a great majority of the moorings that have been made in the world, and these operations have generally been made on an even keel or even at a slightly stern-up inclination. Reference to the dynamic-lift curves for an airship will show that a high wind velocity is required before the dynamic effect obtainable from a few degrees of inclination amounts to any considerable quantity. Actually, some of the most trying conditions for mooring are found in winds with a velocity of only 20 to 25 miles, or even less, with gusts considerably higher, and the dynamic effect at such air speed is of course small. British mooring doctrine is based on the approach to the mast with the ship trimmed bow up, so that downward gusts would have to overcome this slight dynamic lift to cause downward motion of the bow.

It is not a simple practical matter to keep a ship trimmed stern down throughout a mooring; for one thing, passage of air strata of different temperatures may alter the buoyancy temporarily, but compensation for such changes must be made at once and not postponed. Next, while we do not know the exact structure of a downward gust, it does represent the resultant air flow. Coming from above, rather than its normal horizontal flow which produces the dynamic lift on the inclined ship, it would appear that the downward flow of air in the gust not only deprives the ship of the dynamic effect at the time it is needed, but actually tends to drive it downward in addition.

In the American stub-mast mooring it is of course not possible to maintain the stern-down attitude during the entire operation. As a result there is one school of thought that has advocated the construction of a telescopic mast so that the actual mooring operation might be conducted at a sufficient altitude to allow the stern-down inclination, and then by telescoping the mast obtain the advantages of riding to the stub mast. However, in view of the slight assistance to be expected from the inclination and the resultant dynamic lift, this proposition represents practically negligible advantage and has the considerable disadvantage of complicating for all uses an otherwise simple mooring mast. It overlooks entirely the fact that the high mast in itself lacks any vertical control that the low mast does not possess. It is therefore my opinion that the building of a telescopic mast to secure the stern-down inclination or for any other reason now apparent is not warranted.

The use of the ship's rudders and elevators to counteract the effect of lateral and vertical gusts while mooring is generally of little value. The use of these movable surfaces during the mooring operation in gusty conditions is generally sluggish and tardy, and on the whole unprofitable. Human instinct is not able to detect or interpret gusts sufficiently in advance to prevent their effects; it is difficult also to know when to shift the controls to counteract for the opposite gusts. Furthermore, it must be remembered that in trying to lift the bow by means of the horizontal rudders to counteract a downward movement of the bow, the whole ship moves bodily downward for a short period. One must draw the deduction therefore that the use of the elevators to counteract vertical gusts during the mooring operation is generally too limited to be of any practical value.

The *U.S.S. Akron* is equipped with propeller mountings which enable the ship to obtain vertical thrust both in the upward and downward directions. It would appear that, among other virtues, this vertical thrust might be of considerable value in overcoming vertical gusts; experience may substantiate this. However, from the suddenness with which gusts strike and from the relative sluggishness of human reactions, I believe the use of vertical thrust during the mooring operation in gusty weather will be a ticklish procedure.

One school of thought proposes to obtain the necessary upward vertical force from excess static buoyancy by the generous use of ballast. In my opinion this has definite limitations, although under ordinary conditions, such as those in which possibly 90 per cent of all airship moorings of the past have been made, the buoyancy of the ship itself suffices. It is probable that in 75 per cent of the moorings to be expected, even in wider operation, a reasonable amount of buoyancy and the normal method of mooring as we know it today would suffice. It is the other 25 per cent, however, that must be provided for, and in order to be able to use the corrective measures when they are required under these severe conditions, the system used daily should be a complete one. Nature seldom, if ever, guarantees that the good conditions at the beginning of a mooring will not rapidly degenerate into unsuitable ones before its completion. Although a ship equipped with water-recovery apparatus will, at the end of a long flight, have a great amount of water ballast available for dropping to obtain excess buoyancy, such buoyancy adds materially to the load on the mooring winches, which would have to be made considerably more powerful than would otherwise normally be required. Also it is not to be expected that all ships will be equipped with water recovery. I recall the arrival of the *Graf Zeppelin* at Lakehurst from her South American flight in 1930 when the sole useful ballast, either liquid fuel or water, was represented by one bag of emergency ballast dropped during her spectacular but "heavy" landing. The *Graf Zeppelin*, under the conditions, could not have made a safe mooring to a mast.

Should a very light ship be required to discontinue her efforts to moor due to failure of mooring wires or other equipment, as has been experienced, or for other reasons, the resultant loss of helium in order to land her later might be a very expensive item in ships of modern sizes. The place in the ship at which we desire the upward resistance to vertical gusts is at the bow. If ballast is dropped throughout the length of the ship, she will assume the normal stern-up attitude of a light ship; this, according to the doctrine of the high-mast proponents, is undesirable. It is ordinarily a difficult matter to determine, in variable conditions, just how light the ship should be during the mooring operation. It is perfectly apparent that the force required to overcome momentum is considerably greater than that required to prevent

the acquiring of momentum. It may therefore be seen that a ship could easily get into a state of excessive buoyancy.

In my opinion the foregoing features are not sufficient remedies to care for the matter under consideration. I regret that my deduction involves additional equipment in an operation which, within its limited usefulness, has heretofore been marked by great simplicity, but at this time I can see no other method for solving the problem than with additional equipment. To the anxious airship captain who has been helped out of a tight place by this added gear but once, the up-to-date combination required will forever after appear sweetly simple. It might be recalled that the mobile mast had its scoffers, but today no airship operator wishes to handle his ship without it. We must incorporate in the mooring system a mechanical provision which is effective at all times after connecting to it, for resisting undesirable downward movement and not one which we attempt to use intermittently after the accumulation of downward momentum. This provision we have already made to a considerable degree in the similar matter of lateral yawing, where we do not wait for the ship to acquire a yawing motion before attempting to apply a counteracting force. The yaw wires are put into complete operation at the earliest possible moment. Likewise, for vertical yawing we must make advance provision. The pyramid of wires that we establish in our mooring must have added to it an additional upward force. If it cannot be applied directly at the bow, then it should be as near as possible to that point.

There are two possibilities in this connection: one is the application of the force from below and the other from above. There have been numerous suggestions as to how to put these ideas into practical execution: glorified buffer bags approximating small balloons have been suggested; collapsible ladders and platforms providing an adjustable rigid connection with the earth have been proposed; one wag has even suggested the use of a stream of water against the bottom of the ship. Unfortunately, such proposals for utilizing the force from beneath the ship do not appear to be practicable.

On the other hand, it has been proposed that there be established above the top of the mast a point from which there can be led downward to the nose of the ship an additional wire kept under a reasonable degree of tension. This wire would thus supply continuous resistance to the ship's acquiring undesirable downward movement under the influence of gusts. In other words, I propose to increase the rigidity of the apex of the pyramid or the point in space formed by the wires at the ship's nose, by continuous mechanical assistance, and not by various means of fluctuating values. In my opinion this does present a practicable solution.

The ideal mooring system would be that in which the airship could be transferred immediately from her free-flight condition into her moored status without an intervening period. There appears to be no practicable way in sight at the present for accomplishing this ideal, and we must therefore reconcile ourselves to a transition period and make every effort to reduce this transition period to an absolute minimum. Certain practice abroad has been to let the ship rise on about a thousand feet of main cable before beginning to haul her down. It has been my experience that dangling on a single cable under gusty conditions is without a doubt one of the most annoying times in the life of an airship captain. American practice is based on high-speed winches and low approaches, so that the slack in the mooring wires may, immediately after the coupling to the ground wires, be whipped into the taut condition with the least possible delay. The ship is much more secure once she is on three taut mooring cables.

If we are to incorporate the vertical wire from a point above the ship, it would be desirable to make that point as high as possible. There seems, however, to be a feeling of apprehension over the possible danger to the ship from the presence of such a superstructure above the mast. This apprehension I do not share, as the proper method of supplying the force from above would not include the erection of the superstructure in its mooring position until after the ship had been secured to her yaw guys and was thereby restrained from overriding the mast structure. The superstructure or topmast for providing the point above must not project to leeward beyond the center of the mast, must be capable of quick erection and quick removal, and must be provided with adequate motion in the horizontal plane so that in shifting winds it may be kept opposite the ship at all times.

A stub mooring mast for a ship the size of the *Akron* will be about 80 ft high. It has been calculated to be perfectly feasible to build a structure capable of furnishing a point 200 ft above the ground for the desired vertical control, of sufficient strength for the loads expected, and still easily and readily erected and removed. Its motion in azimuth also is an entirely feasible matter. At the present time it appears to me that this is the best solution yet offered, and in the absence of something better we shall no doubt try it practically.

There is an additional phase of the mooring operation that requires correction. It has already been pointed out that the anchorages for the ground yaw wires must be mobile and that this can be easily accomplished. The remaining feature is the introduction of a method for equalization of the tensions of the yaw wires. It can readily be seen that a gust striking on the starboard side of an airship whose starboard yaw guy is of fixed length and of an unyielding tension would tend to drive the ship downward on the yaw guy as a radius. In so doing, the leeward yaw wire would become slack. Upon the dying out of the gust and the attempt of the ship to return to its previous position or, as normally happens, upon the impact of a gust from the other side, the impact load on the unyielding yaw wire might assume great proportions. As a matter of fact, yaw guys have been parted in such a manner.

It is therefore apparent that we must provide a means of maintaining the two yaw wires automatically at even tensions. This may be done in effect by veering slightly on one and reeling in on the other. Actually it is possible to devise a means for adjusting these lengths without using the winches for that purpose. The main point to be gained is never to allow slack in either yaw wire or, as a matter of fact, in any of the mooring wires.

To sum up the improved mooring operation, we may expect to find it follow these lines:

- The mooring will be made to a mobile stub mast accurately centered and firmly anchored within the circular railroad track for the stern carriage
- The mooring winches will be located at the mooring site in such a way as not to impede movement of the mobile mast
- At least four wires will be used—that is, a main cable, two yaw guys, and the fourth wire or its equivalent for vertical control
- Yaw-guy anchorages will be made mobile so as to maintain continuously the proper angle relative to the ship's structure in shifting wind conditions
- There will be incorporated a practical means for automatically maintaining yaw-guy equalization
- The approach of the ship will be made on approximately an even keel until the latter part of the operation, when a stern-up attitude will be assumed
- After the bow has been secured to the mast, the stern will be hauled down into its stern carriage by means of a cable and a winch.

I fully expect that the mooring operation to the stub mast will eventually be accomplished more easily, more economically, and more safely than can be done at the most elaborate high mast in use today.

The next important phase of our problem of adequate terminal facilities for a rigid airship involves the servicing of the ship and its mooring out under the wide range of weather conditions to be expected. Experience in the United States has pointed out that there are definite advantages in riding to the short mast with the stern restricted from vertical motion. As a matter of fact, I do not know any one in the American airship operating personnel who would shed tears at the abolition of the high mooring mast, and I confidently believe the high mast will pass out of style quickly upon successful attainment at the stub mast of the items pointed out.

Before going into the relative merits of the two masts, I wish to comment on one of the commonly alleged disadvantages of the stub mast. Proponents of the high mast point out that in case of a breakaway or a forced departure from the mast, the airship might be expected to have a better chance from the taller structure. With the importance of this feature or this idea I do not agree. In the first place, it is difficult to conceive of a modern airship breaking away from a modern mast. The British *R-101* rode out a gale in which the wind reached gusts of over 60 miles an hour over an extended period, and in which the maximum gust attained a velocity of 83 miles per hour. I believe any airship captain would hesitate to make a deliberate departure from a mooring mast of either type under average gale conditions. In any event, if he did make such a decision, he would have to depend on a very considerable static buoyancy to get his ship safely into the air. I do not believe that the hundred-foot difference or so in the mast height under those conditions would count very much. The mast structure itself is the main obstacle in the path of the ship and is at the same relative height whether it is a high or a stub mast. I cannot help wondering how an airship employing several tail drags simultaneously, as has been done with a recent ship at a high mast, would free itself of them in a breakaway or a storm take-off. It is the storm condition in which the tail drags are generally the most urgently needed. Furthermore, they would be needed up to the very instant of departure. It would appear to be a difficult task indeed to rid the ship of several tail drags simultaneously and instantly, and also to have any but the roughest idea of the buoyant condition of the ship under storm conditions with several tail drags attached. Depending on generous use of ballast and upon vertical thrust from propellers, and upon the freedom from tail drags that are not automatically and instantly detachable, I believe that in a forced departure the stub mast is equally as safe as the high type. It is a real emergency in any case, and must be met by gaining altitude with reference primarily to the mooring mast, whether high or low.

Comment on other relative features of the two types of masts would seem in order. Following are my comments:

(1) *Cost.* A modern high-mast installation costs several times as much as the most elaborate or complete stub-mast installation now under consideration. Even without added equipment for what I consider satisfactory vertical control, a recent high mast on this continent is said to have cost about $375,000. With necessary vertical control incorporated, the cost of the high mast should be materially greater than this figure. The cost of including vertical control of whatever type at the stub mast is proportionately much less than at the high mast.

(2) *Complication.* The top hamper of the most recent high masts is decidedly more complicated than our stub masts, even of the mobile type. Vertical control added to a high mast is decidedly more of a complication there than to the low mast.

(3) *Other Utility.* The high mast cannot be used for docking and handling purposes and requires an added "transporter" mast, if a mobile mast is to be used as the nucleus of a mechanical docking system. The stub mast can easily be made a mobile unit at a reasonable cost, thereby performing an additional very important function. Transition of an airship from a high mast to a "transporter" mast for docking is an added operation and may be a hazardous one. No such added features are involved in the use of the mobile stub mast.

(4) *Care of Ship While Moored Out.* While moored out at a high mast an airship is continuously being "flown," and consequently the strain on the crew is greater than at the low mast. Absence of vertical motion of the stern at the stub mast is a decided advantage as well as a safety factor in ordinary conditions, and particularly in wind shifts, rapid temperature drops, and gusty conditions. Large quantities of water are required at a high mast for continuous ballasting. At some locations this necessary water is difficult to obtain in the quantities required. With the stern supported at the stub mast, far less care is required in the case of rain or snow loads that might be great enough or sudden enough to force the stern to the ground at the high mast. Absence of tail drags at the low mast removes a great liability and a source of trouble.

(5) *Servicing and Loading.* Much more easily accomplished at stub mast, where loads can come aboard from the ground at logical points throughout the ship. At the high mast all loads and personnel come to the top of the mast via elevator and must be brought on board through the bow hatch.

(6) *Repairs.* More extensive repairs are possible at the low mast; ordinary repairs and replacements are more readily accomplished there than at the high mast.

(7) *Adaptability to Larger Ships.* Cost and size of stub masts for larger ships do not increase as rapidly as would be the case with high masts for the same ships. High mast is more easily standardized for various sizes of ships. A set of stern carriage tracks for each length of ship would probably be required at a stub mast. None is required at the high mast. Tail drag paths are required at high masts, but not at the low. More level terrain is required at the low mast.

(8) *Safety of Ship on Emergency Take-off.* Previously discussed.

(9) *Wind Velocities.* Generally markedly less at the low mast. Therefore the ship moored there should be safer.

(10) *Stresses.* Moored to the low mast, the stresses during riding are probably greater than at the high mast, but it is believed that they are entirely within safe limits.

(11) *Stern Weighing Device.* At the stub mast it is possible to incorporate a stern weighing device that, with the similar bow device, allows ready and continuous knowledge of the static condition of the ship. At the high mast it is difficult, if not impossible, to know the static condition under other than the best conditions.

(12) *Mooring Crew.* At the high mast 10 to 12 men have sufficed thus far. With vertical control added, this number may have to be increased to 16 or 18 men. No stub mast has yet been equipped for a full mechanical mooring, and therefore the number of men required by the present temporary combined manual and mechanical system cannot be fairly compared with the 10 to 12 men in the high-mast crew. With proper mechanical aids at the stub mast comparable to those at the high, it is probable that only 4 to 6 more men will be required at the low mast. This will include any extras that may be found necessary in the provision of mobile yaw-guy anchorages at the low mast. When vertical control is included in each type, the same difference of 4 to 6 men will probably obtain, but actually no more highly trained specialists are needed at the low mast than at the high.

(13) *Mobile Yaw-Guy Anchorages.* They are necessary at either type, but cannot be incorporated in the present high-mast

scheme without considerable added equipment. They are readily applicable on the stern carriage path already provided at the low mast.

(14) *Ease and Safety of Mooring and Unmooring.* This is discussed at several places in this paper. In my opinion there will be greater ease of mooring to the low mast, when corrected as indicated to be necessary, than to the present high mast. The safety of mooring will then be at least as great as to the high mast, even if the latter is provided with ertical control. In unmooring from either type, the mast structure itself is at the same height relative to the ship, and in either case is an obstacle to be hurdled. In an emergency the moored airship can be released from the low mast with more safety than is possible at the high mast due to the tail drags required.

(15) *Menace to Flying Activities.* The high mast is much more of a danger to airplane operations than is a low mast, particularly of the mobile type, which may be moved out of the way, or the expeditionary type, which may be lowered by its hinged heel.

The next phase of this paper involves that of housing and unhousing the airship mechanically. It is now realized that hangar design can be an important factor in this consideration. The shape of the building itself and of its doors, if not carefully determined, can give rise to very undesirable and even dangerous air-flow conditions at and in the vicinity of the shed and the handling point. Much more attention is being paid to this point today, and we may expect improvement in the housing operation because of the attention to aerodynamic design details of hangars.

Another interesting need in this connection is for a thorough analysis of gusts and gust structure. No one today has a satisfactory working knowledge of this feature, but undoubtedly more complete knowledge of this point could assist materially in our handling problem. We must know what nature is trying to do to us. There ought to be cheaper ways than learning from full-scale tests.

Ideas vary as to how far we should go in strengthening the airships themselves for mechanical handling and housing and unhousing. With the wind parallel to the hangar axis, it is a comparatively simple matter, dependent to some extent on the vertical loads that the ship's structure can safely withstand. In a beam or cross wind, the enormous loads on the full area of the airship hull make it a more difficult problem. In such a case there is involved not only the vertical strength but the beam strength of the ship as well. The principle of the revolving shed is still correct, but we hope it will prove much cheaper and sufficiently satisfactory to utilize a fixed shed and to revolve the ship itself into the necessary direction. Judicious selection of sites with a prevailing wind of marked directional constancy is a great natural factor of assistance.

It may be interesting to know that it was the vertical strength of the *Los Angeles'* structure aft that determined the maximum wind velocity in which that ship could be handled in and out of the shed. As a matter of fact, it was necessary to supply bracing equipment at the stern of the ship for use on handling occasions. With the mobile mooring mast and certain equipment for resisting the side-wind load, applied only around the stern, it is possible to handle the *Los Angeles* in a cross-hangar wind of 17 miles per hour. Meteorological records show that even at Lakehurst, where there is a high frequency of severe conditions, on 93 per cent of the days of the year there are periods of two or more hours a day during which the wind velocity drops to less than 20 miles per hour. Therefore any method that will enable us to handle the ship in a 20-mile cross-hangar wind would be highly acceptable, for with a safe mooring-out system it would not be necessary to wait very long for the opportunity of docking if required. However, as a result of extensive experience we have provided sufficient strength in the *Akron* and in her handling equipment to permit housing and unhousing that ship in a cross-hangar wind velocity as high as 26 miles per hour. While it is still felt necessary to have docks for airships, there is no doubt that the day is coming when airships will be capable of staying out over extended periods and will not have to resort to "dry docking" in a shed except infrequently.

By the simple expedient of making the stub mooring mast mobile, we have obtained the fundamental unit for a satisfactory mechanical-handling system. It seems firmly established that future handling systems will continue to be premised on the use of a mobile mast. At Lakehurst there has been in operation for a considerable time a triangular mobile mast 60 ft to a side, weighing about a hundred tons and mounted on crawlers. It has proved highly satisfactory. There are of course refinements yet to be made in the mast, such as the incorporation of its own propulsion plant. The crawler mast has proved entirely satisfactory and, in my opinion, has some very forceful advantages over a similar mast mounted on trucks to run on railroad tracks. However, in order to try several promising ideas, there has been constructed a second mobile mast that will operate on rails. Competitive use of the two types should develop any advantages of either, but there is no reason to believe today that the crawler type will be surpassed in its attainment of the necessary degree of practicability.

In the movement of the ship from its mooring point to the vicinity of the dock for housing, or vice versa, it is necessary to have at the after part of the ship a point of contact with the ground. Formerly men on the hand rails of the after car kept this part of the ship under control during its movement over the ground. This same function is now accomplished much more satisfactorily by the use of a large pneumatic wheel secured to the stern and capable of easy castering. This wheel is capable of high vertical loads as well as ready change of direction and affords smooth rolling contact since the ship is kept "heavy" so that the wheel ordinarily cannot lift off the ground. As an additional precaution, a tail drag is also employed at the stern. Whether this castering device continues to be a single wheel or blossoms out into a multi-wheeled unit is unimportant. The necessity and correctness of such a device have been definitely established.

Under cross-hangar wind conditions there is required apparatus for hauling the ship up against the wind into the direction parallel to the hangar for entering. Conversely, in undocking under such conditions, the ship must be kept under control while the stern is being allowed to swing into the wind direction after clearing the hangar. There are several ways of providing mechanical power for pulling the ship up against the wind or for restraining it. The idea that immediately suggests itself is that of having tractors attached by lines to the ship pull it into position. There are several reasons why this tractor scheme is not a practicable idea. One is that the pull from the tractors of today, due to their means of traction and their methods of changing direction over the ground, is extremely irregular and even dangerous to the hull of a ship. Another reason is that tractors are not built in commercial sizes that provide sufficient drawbar pull for our purpose. For example, a drawbar pull of 63,000 lb will be required in the case of the *Akron* for this purpose. There is a method of hauling up and controlling the stern based on the use of straight lengths of track at right angles to the hangar axis. Another method employs a circular track in the immediate vicinity of the hangar. While both straight- and circular-track ideas have advantages and disadvantages, it has been decided to experiment first with the circular-track idea.

There will be required a hauling-up circle at each end of the hangar. From the mooring site at which the ship was landed from flight, the mobile mooring mast will cast off its anchorage and proceed with the ship to the center of the hauling-up circle.

While the ship is still headed into the wind, a huge steel beam specifically designed for this purpose will be moved by a locomotive along the circular track to a point under the lower fin of the *Akron*, and there the ship will be attached to the beam. To the extremities of the beam, which is about 164 ft long, there will be run lines from both sides of the ship. The locomotive will then tow this stern-handling beam into the direction for entering the shed, pivoting the ship at her nose about the mobile mast, then stationary at the center of the circle. When the stern-handling beam has reached the rails parallel to the hangar, its second set of trucks will be dropped to the handling rails. The locomotive will be detached from the beam and moved off clear on the hauling-up circle. The mobile mast will then get under way and move the ship into the shed. No attempt is made to provide the stern-handling beam with its own motive power, as it may not be necessary, and it would probably be a difficult matter to synchronize the power of the mobile mast with that of the motorized beam to prevent any possible "accordion" effect on the ship. For the *Los Angeles* the mechanical-handling gear at the stern of the ship is towed by cables to the ship itself, and it is believed that a similar arrangement of equivalent cables from the stern-handling beam to the structure of the *Akron* will prove satisfactory for the latter ship.

Differences in airship construction make themselves felt in this handling problem at this point. In a ship not designed for mechanical handling, it was necessary to apply the loads at carefully selected points and always in proper directions relative to the structure. Although satisfactory means were found, nevertheless this feature complicated the design of the mechanical-handling equipment for the *Los Angeles*. For the *Akron*, with its differences in structural design and construction, the matter is not such a difficult one. Instead of having to maintain the pull always normal to the ship's length, as is the case with the *Los Angeles*, it will be safe to pull on the main frames of the *Akron* at a considerable angle. This allows on each side the leading of a wire from each of several frames near the stern of the ship to one point at a central location abreast the after part of the structure. This results in the necessity for providing but one movable docking point on each side of the stern of the ship instead of the four points now required on the *Los Angeles*, for resisting beam-wind loads. The net result is beneficial, for the length of the handling gear aft runs athwartship rather than fore and aft.

There have been various suggestions as to other ways of handling large airships mechanically, and a number of them possess merit. Among these is the suggestion to employ a mobile mast at the stern as well as at the bow. Another proposes, in addition to the bow mast, one or more mobile masts or their equivalent along each side of the after portion of the ship. By the time these individual units have been connected up and synchronized, the project almost invariably reaches the proportions and characteristics of a huge cradle or raft similar to that proposed several years ago in this country and more recently in another adaptation abroad. In our efforts we have endeavored to avoid the necessity for equipment of such magnitude. We confidently expect that the use of the mobile mast at the bow, together with the stern-handling beam at the after part of the ship, will prove completely satisfactory for handling such large and modern ships as the *Akron*.[3]

In conclusion, it is my opinion that the problems of supplying the remaining essentials in the mooring and handling project for rigid airships will be met successfully in due course of time. In the absence of more widespread airship operating experience there is naturally room for some differences of opinion in practical solutions to problems. So no doubt the high-mast school of thought will continue to have patronage. However, as may have been surmised from this paper, my own experience so far tells me that the successful mooring and handling of rigid airships will center about the low mast.

The aeronautical world moves rapidly. New developments will continue if we can arouse the proper interest in the project. Although the fundamentals remain the same, no man is safe in making his suggestions as to their applications to aeronautical matters too final and fixed in the present pioneering state of the art. However, the opinions and ideas I have expressed herein are those I hold today in the light of all the information and experience that I have been able to gather.

When the problems of airship terminals reach a satisfactory status, as they soon will, I am sure it will be found that extremely important contributions will have been made by the airship personnel and engineering talent of the United States.

---

J., for handling the *Akron*, see paper on "Mechanical Equipment for Handling Large Rigid Airships," by Lieut. C. M. Bolster (CC), U. S. N., at Sixth National A.S.M.E. Technical Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932.

AER-55-7

Heating and Ventilating of Cabin Airplanes

By M. GOULD BEARD,[1] FARMINGDALE, N. Y.

Comfort for airplane passengers is being seriously considered, and aeronautical engineers are designing features for the airplane cabin that follow closely the comforts of railroad drawing-room cars and the facilities of the larger motor coaches. The adaptation is easily made, with alterations in weight and size. Heating and ventilating systems are replacing the rudimentary provisions of the past. The paper states the problems of heating and ventilating of cabin airplanes, gives available data, describes methods in use or attempted, and urges the mechanical and aeronautical branches of the profession to join in solving the problems.

THE airplane is rapidly establishing itself as the vehicle for fast transportation. Its mechanical reliability is beginning to compare favorably with any of the longer-established means of transportation. Aeronautical engineers all over the world are concentrating on obtaining the maximum efficiency in performance for this carrier of commerce. Intense effort is being applied to make the airplane reliable in all kinds of weather. It is only recently, however, that the comfort of passengers has been seriously considered, as is evident by looking through the cabins of transport planes built as recently as 1930.

Since the air lines have taken up passenger transportation in earnest, far-sighted aeronautical engineers have concentrated on building models suited especially for this work and have designed into the plane as many of the comforts of travel already existing in railroad drawing-room cars and in large motor coaches as could be readily adapted to the airplane. Modification of these appliances is always necessary, particularly as to weight and often as to size, to make them usable in airplanes, but in general the adaptation is easily made. Such phases as heating and ventilating have been left with only rudimentary provisions until recently. The expansion of the air lines, calling for planes suitable for passenger carrying, put into the minds of some engineers the necessity of designing really efficient heating and ventilating systems. Thus far these problems have been tackled by aeronautical engineers within the industry. To get the best results the industry will have to utilize the training and experience in the mechanical branch of the engineering profession. The main object of this paper is to state the problems of heating and ventilating of cabin airplanes, to give whatever data are available, and to describe methods in use or being attempted, with a view to bringing together the mechanical and aeronautical branches of the profession on these problems.

The basic principles of heating and ventilating are well known, and courses in these subjects are in the catalogs of all colleges of engineering. The application of these principles to the airplane require a knowledge of:

1 The physical conditions that are encountered in flight, such as temperature limits of the upper air at all times of the year and the probability of rain, snow, and dust in the air.

2 The physiological and psychological reaction of passengers riding in airplanes.

3 The structural limitations of the airplane as to weight, space, and location.

4 The safety requirements that must be met in aeronautical design.

5 The sources of heat and air conditions available which can be put to use in heating and ventilating of airplane cabins.

6 The limitations and advantages of the various systems for heat transfer or generation and the applicability of each to any particular airplane layout.

It becomes necessary to make a clear statement of the conditions to be met; to discuss the mental attitude and physical requirement of the airplane passenger; to specify weights and establish locations for heater and ventilator systems; to state safety requirements; to point out available heat sources and locations from which fresh air may be obtained; and to compare the various systems which can be used in heating and ventilating an airplane.

Physical Conditions

In the United States, summer-air temperatures of over 100 F are seldom met; 90 F can be considered as an average high temperature for the West and Southwest during the hot seasons. Airplane cabins subjected to direct sunlight in flight will get several degrees hotter than this, unless very well ventilated. However, it is almost always possible to find lower temperatures at some high altitude, so that temperatures above 85 F are seldom encountered for more than a few minutes. The passengers' cabin can be maintained at atmospheric temperatures with suitable ventilation. When the pilot's cab or cockpit is located ahead of the passenger cabin and just behind the fire wall of a single-engine plane or a trimotored plane, it is more difficult to keep it cool. With the present use of N.A.C.A. cowls and Townend rings, with high-speed air baffles between air-cooled engine cylinders, the pilot's cab is enclosed on all sides and in front with a close-lying layer of hot air from the engine which has not been diluted by the outer air stream. The author has flown ships with insufficient ventilation in the pilot's cab when the thermometer in the cab read 112 F, with outside air at 85 F, which is an unsafe condition for any human being to endure while performing the duties of a pilot.

At the other extreme, the heating system must be designed to keep the entire passenger cabin and pilot's cockpit at 70 to 75 F with outside air temperature at —20 F. Heating systems designed for operation in Canada should be calculated for entering air at —40 F. The heater must supply heat to the cabin within five minutes after the engine is started for warming up and must be readily controllable to take care of sudden changes

---

[1] American Airplane and Engine Corporation. M. Gould Beard was born on November 13, 1896, at Foochow, China. He entered Oberlin College in 1916; enlisted in Aviation Corps, December 21, 1917; flight training received at Kelly Field, and was commissioned second lieutenant, November 15, 1918; entered the marine Diesel-engine field after the war and worked up to chief engineer's position; attended University of Michigan, 1921–1925, specializing in internal-combustion engines; employed by Ingersoll-Rand Company as experimental and test engineer, 1925–1927; entered the aviation field in 1927 as installation engineer and test pilot for the Fairchild-Caminez Engine Corporation; transferred to the airplane division as chief test pilot at the Farmingdale plant until October, 1932. Mr. Beard did all the test work on the Caminez engine; all development and experimental testing on the Pilgrim 100X, 100A, and 100B; all initial test work on the fast all-metal low-wing 10-place transport now known as the Clarke GA-43.

Contributed by the Aeronautic Division of The American Society of Mechanical Engineers and presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932.

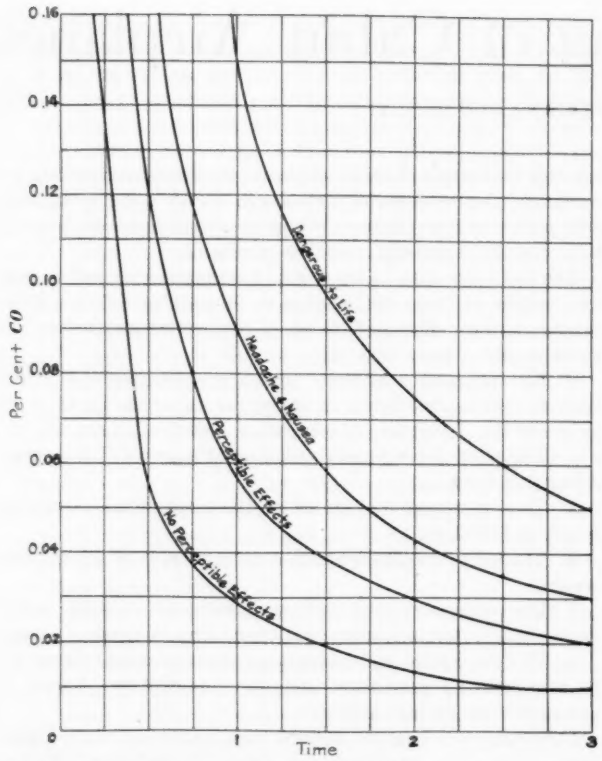

FIG. 1 EFFECTS OF CARBON MONOXIDE FOR GIVEN TIME ON HUMAN BEINGS

(Taken from Bureau of Standards Technical Paper No. 212.)

in air temperature. A modern transport plane will climb from sea level to 10,000 ft in 10 to 15 min, depending on the load. During this climb, air temperatures may change from 60 to 70 F to below 0 F. Maintaining the desired cabin temperatures with this rapid change in the air temperatures will require thermostatic control to relieve the pilot of one of the many duties that have been piled upon him in scheduled transport operation.

Rain offers the problem of water separation in some point in the ventilator ducts. Snow offers no problem, since very little flying is done in heavy snowstorms and light snow is readily melted and vaporized in the heater before reaching the heater ducts to the cabin. Dust is a problem in the Southwest part of the United States, where sandstorms are encountered in flight and where sandy fields permit the propellers to pick up dust and blow it into the ventilators. Dust separators are desirable in the ventilator ducts of planes operating through this region.

CABIN INLET AND OUTLET LOCATIONS

Effective heating and ventilating systems must admit hot and cold air from points in the cabin walls or ceiling which will give the passengers the greatest degree of comfort. Since the volume of air to be admitted is large for the volume of the enclosure, it is almost impossible to prevent drafts. Single air inlets always subject a few of the passengers to violent drafts of hot or cold air and often prevent the other passengers from receiving the benefits of heat and ventilation.

Individual inlets for hot air and cold air, correctly designed, allow each passenger to obtain temperature conditions to his own liking and eliminate strong drafts in any one part of the cabin. It has been found that cool air is most effective in keeping a passenger comfortable in hot weather if the individual ventilator is located above and in front of the seat so that it will blow into the passenger's face. The direction and quantity of the air stream being controllable, the passenger can adjust conditions to suit his needs without discomfort to the other passengers. Hot air should be admitted at a low point in the cabin through individual hot-air grids or inlets which are also controllable by the passengers.

Heater inlets or grids in the floor are undesirable because they collect dust and dirt and blow it out whenever the grid is opened. The grid in this location is subjected to continued tramping and soon gets bent and stuck in one position. Hot-air ducts are often laid on top of the floor from front to rear of the cabin between the legs of the chair. Individual shutters in the sides of these ducts are subjected to enough abuse from the feet to get jammed in service and are undesirable. A more desirable location for the heater inlet is on the side wall of the cabin close to the seat and 5 to 8 in. off the floor and designed to blow the air out and slightly down.

The location of the air outlets from the cabin requires some experimental work to determine the direction of natural air flow in the cabin and to determine the region of lowest pressure or best air-stream velocity on the outside of the fuselage. On one experimental plane several locations for outlet ducts, which presumably should have produced suction, blew air into the cabin instead. Every airplane cabin will have a definite motion of air in it. In high-wing monoplanes this is usually from the rear forward because of the openings about the wing spars and fittings which connect the cabin with the suction at the top of the wing and because the pressure on the sides of the fuselage forces air in through door and window casings, which are usually at the rear of the cabin.

If the direction of air flow is well defined, the suction vents should be located at the opposite end of the cabin from the neutral air exit. This will even up the air flow and distribution of heat in the cabin. It will be difficult to keep the other end of the cabin warm in very cold weather, if the vents are placed at the end of the natural air exit.

Recirculation of cabin air has been often proposed and practiced in a few ventilator systems. Recirculation has two advantages—namely, that the weight of the heating unit can be reduced and that rapid changes in outside air temperatures do not affect cabin temperatures as quickly. It has the very great disadvantage that odors from airsickness are recirculated through the cabin and remain in the air longer. This one disagreeable feature makes recirculating of cabin air undesirable.

LOCATION OF AIR INTAKE

The success of a good ventilating and heating system depends largely upon the location of the air-intake openings on the outside of the plane. Because of the many types of airplanes, with widely differing conditions of structure and air flow, no specific rules can be laid down for the locations of these intake openings. The following general rules may be applied to any plane:

1 Locate the intake at a point entirely free from possible contamination with exhaust gases. This rule should be self-evident; yet an inspection of heaters and ventilators now in service on many planes will prove that its importance is not appreciated.

2 Locate the intake at a point where no oil or gas fumes can enter it.

3 Locate the intake high enough to be free from dust picked up by the propeller while running on the ground for warm-up or taxying.

4 Locate the intake in the propeller slipstream if possible to get the advantage of increased air blast.

SAFETY REQUIREMENTS

Freedom from carbon monoxide and fire hazards weigh about

equally in importance. Fig. 1 gives a series of curves showing the toxic effect of carbon monoxide as determined by the Bureau of Standards. A concentration corresponding to the line of "Perceptible effects" is a danger line for the pilot. These percentages of CO are so small for the longer periods of time that every precaution should be taken to locate heater and ventilator inlets where there is no possibility of taking in exhaust gases.

The air close to the fuselage of a plane having an engine mounted in the nose of the fuselage is contaminated with fumes from the engine compartment. This is especially true where N.A.C.A. cowls and Townend rings are used, as the air from such installations flows in a stratum close to the fuselage. Because of this, air inlets should not be located close to the skin of the fuselage. One type of ventilator often used consists of a scoop on the outside of the fuselage attached to a tube passing through the fuselage wall to the inside of the cabin. The cabin end of the tube is fitted with a nozzle at an angle relative to the outside scoop, so that when the scoop is facing the airstream the nozzle blows air on the passengers. The assembly is rotatable, so that the scoop can be turned at any angle to the air stream, and when turned to the rear it produces a suction. One of these ventilators is installed for each passenger.

This type of ventilator is inferior in every respect, except weight, when compared to a ventilator fed by a duct. It is very noisy, admitting engine and propeller noises and air-rush noises, and even producing a sharp whistle if turned at an angle to the airstream. If this type of ventilator is used, it is futile to attempt to soundproof the cabin walls, as any benefit from soundproofing is canceled by the noise admitted by this type of ventilator. The cabin of a modern nine-place single-engined transport was well soundproofed during the development of the model. It was considered one of the quietest cabin planes ever developed. A customer's specifications called for the scoop-type ventilators under consideration. After these had been installed, the cabin was as noisy as any in which no soundproofing has been installed. The ventilation system was changed to a type having individual ventilators opening from ducts bringing the air in from the wing butts. With this system of ventilation the cabin was as quiet as at first, and it was found that the incoming air was 3 to 5 F cooler than that admitted by the rotating-scoop type which took air from a layer 1 in. from the surface of the fuselage.

Two very good locations are available for ventilator inlets of the duct system. High-wing monoplanes offer a very good location in the leading edge of the wing butt sufficiently far out from the fuselage to be free of contaminated air, but in the area of the propeller blast. This location has the advantage of receiving a strong blast of air at all times, even when the ship is on the ground with the engine idling. The top of the nose of the plane also offers a good location, especially if there is no engine in the nose of the fuselage. The inlet scoops may be located directly inside the ring cowl of a radial engine and the ducts carried back through the fire wall. That portion of the duct passing through the engine compartment must be insulated by asbestos, as the heat of the compartment will raise the temperature of the air several degrees if the aluminum duct is left bare.

Weight and Volume Requirements

A duct-ventilator system taking fresh air in from the leading edge of the wing at a point 7 in. out from the fuselage of a 10-place plane has been constructed for a total weight of 13.3 lb. (See Fig. 2.) This includes all parts such as the wire screen at the intake, brackets and clamps to hold the ducts, ventilator nozzles which may be turned in any direction and which are equipped with valves to regulate the amount of air blast, marker plates for each ventilator to instruct the passenger, and the ducts completely concealed between the outer and inner skin of the cabin. The weight of the ducts represents 0.29 per cent of the weight empty of this particular plane with a structure of welded-steel-tube fuselage and wooden fairing covered by fabric. A metal monocoque fuselage could incorporate these ducts as part of the structure, with the skin of the fuselage as the outer wall, thereby saving about 20 per cent of the weight of the ventilator system.

Airplane cabin volumes vary between 25 to above 60 cu ft per person for planes between 4 and 12 passengers. From tables on heating and ventilating it appears that adult persons at rest should be supplied with about 1400 cu ft of air per person per hour if the CO_2 content is to be kept below 0.08 per cent, or a total of 14,000 cu ft of air per hour for a 10-place plane.

Such a plane with a cabin volume of 440 cu ft would have about 32 complete changes of air an hour, or a complete change in 1.87 min. Two 4-in. ducts, one from the leading edge of each wing, would deliver this volume with an air velocity of only 1340 ft per min in the ducts, and there would be sufficient pressure at the end of a 20-ft duct to deliver a good airstream from the last ventilator. Changing the air in the cabin 32 times an hour without producing violent drafts requires inlets and outlets well placed along the cabin.

Hot-Air and Cold-Air Ducts

Heater and ventilator ducts properly designed can be entirely hidden between the cabin interior and outer skin of the ship. Fig. 2 shows the combination heating and ventilating system developed for the Pilgrim 100-A. The ventilator inlet openings are located on the lower side of the leading edge of each wing stub just outside the hot-air film from the engine. The ducts are $3^1/_4$ in. in diameter and are made of 0.025 in. thick aluminum. The opening is covered with No. 8 mesh wire screen. Letters A indicate the individual ventilator outlets. A_1 is a duct to a central ventilator blowing down on to the front bench and intended

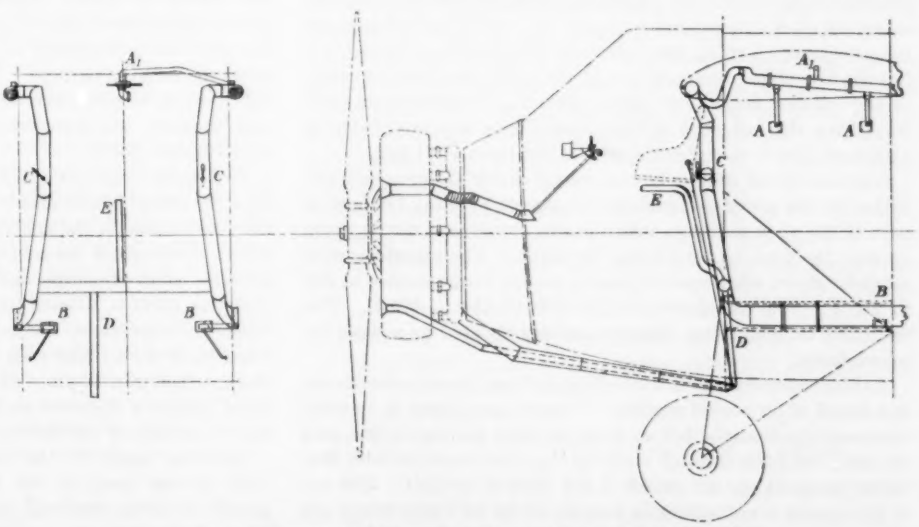

Fig. 2 Combined Heater and Ventilator Duct System

for the middle passenger. Letters *B* indicate the individual heater outlets. The last outlet blows to the rear to heat the person in the last seat.

The reverse curve in the upper ventilator ducts, as they leave the vertical ducts, is necessitated by control cables and structural members. At *C* in each vertical duct is a butterfly valve with a lever marked "Off" and "On." In cold weather these valves are shut off, cutting the cold air off from the lower ducts and allowing only hot air from the heater to enter the lower shutters. In very hot weather, the heater is shut and these valves are opened, which permits cold air to enter at top and bottom.

The duct *D* comes from the hot-air exhaust heater and enters a horizontal tube connecting the two vertical ducts. *E* is a duct leading to the pilot's cab and blows hot or cold air directly on to the pilot's feet. The location of the individual outlets, and especially that for the pilot's cab, requires a thorough knowledge through actual observation and study of the particular cabin and cockpit under consideration. The pilot's cab is subjected to very strong air currents. Any holes in the fire wall or seams and openings about the walls of the cab are undesirable because the temperature of the air leaking through cannot be controlled. Correctly located heater and ventilator outlets can make the pilot's cab very comfortable in any kind of weather.

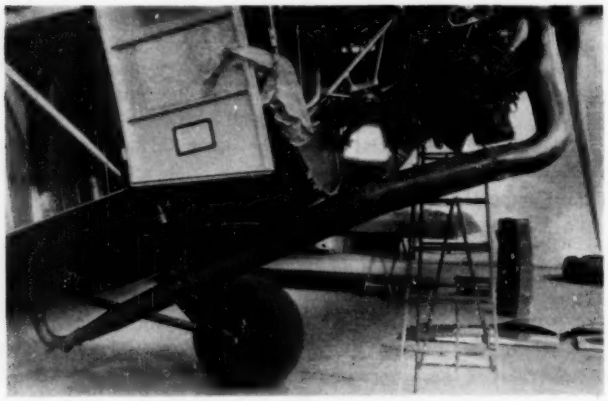

FIG. 3 HOT-AIR-EXHAUST HEATER ON PILGRIM 100-B

Heat Sources. The high temperatures of the engine exhaust permit heater units to be cut to a minimum size and weight when utilized for cabin heating. Since operating conditions vary considerably, it is impractical to figure too closely on exhaust-gas temperatures. During one test on a 575-hp radial engine in a full-throttle climb, temperatures at the junction of the two arms of the exhaust stack were above 1600 F. Temperatures halfway down the tail stack of this same engine averaged between 1100 and 1300 F at cruising speeds of 1650 and 1750 rpm.

Solution-cooled engines have a second source of heat available. Either by the use of an auxiliary radiator or by using the hottest part of the main radiators with suitable scoops and ducts, warm air may be obtained for heating the cabin. The temperature of ethylene-glycol when used for engine cooling is maintained at 240 to 250 F. The commercial liquid boils at 310 to 330 F. The operating temperatures, therefore, would be used as a basis for calculations.

A third source of heat is the cooling air from the cylinder barrels and heads of air-cooled engines. Funnels are placed at suitable locations to collect the hot air from the head and barrel fins, and the air is led back through ducts to the cabin, with suitable flap valves to direct the air outside if not wanted for heat. The use of this source is not advisable because of the oil fumes which are always collected from the engine.

HEATING SYSTEMS

It is proposed now to outline the various types of heating systems and discuss their relative merits as applied to aircraft use and to discuss a few of the important details of their design.

1 Hot-Air-Exhaust Heater. This type of heater is the oldest and most often used in the aircraft industry. Its improper construction has caused several deaths from monoxide poisoning, and many flights terminated short of their destination for the same reason. The main causes of danger from carbon monoxide poisoning are:

(*a*) Openings such as joints and splices in the exhaust pipe ahead of the air intake which permit a leakage of exhaust gases to get into the hot air going to the cabin.

(*b*) Welded seams, either annular or along the exhaust pipe, which crack open from repeated stresses set up by expansion and contraction in service, allowing exhaust gases to leak into the hot air going to the cabin.

(*c*) Poor design, which throws expansion stresses on to some part of the sheet metal, which eventually fails, allowing gases to leak into the heater.

All three of these faults may usually be found in every incorrectly designed exhaust-type heater.

The hot pipe is entirely enclosed and no inspection is possible, so that cracks developing are not caught by mechanics or by inspectors before they get big enough to become dangerous. Partial carbon-monoxide poisoning has occurred so often from hot-air-exhaust heaters that the Army will not accept this type of heater.

The hot-air type of heater, if correctly designed, can be made safe and reliable when the plane is given regular periodic inspection. At the present stage of heater development it is the cheapest to build, the lightest in weight, the simplest to operate, and the easiest to maintain. Fig. 3 shows a correctly built exhaust heater. It consists of a seamless stainless-steel tube 0.049 in. thick passing through the exhaust tail stack. There are absolutely no seams or welds in the tube inside the exhaust pipe. The tube is clamped at the entrance and exit of the exhaust pipe by bolted split collars welded to the exhaust pipe or by simple asbestos-packed expansion joints so that it is quickly removable for inspection. The air intake is located under the anti-drag ring just ahead of the engine, and flexible tubing is used between the air scoop and the heater tube. The bypass valve which controls the entrance of air into the cabin should allow a flow of air through the tube at all times, spilling it to the outside air when not wanted for heat. This keeps the heater tube from getting hot enough to deteriorate quickly. A slight increase in exhaust manifold size is necessary to accommodate this tube and not restrict the exhaust passage. This entire heater assembly, including the extra weight of the enlarged exhaust stack, heater controls, and brackets, has been built to weight 18.6 lb for installation on a 10-place plane.

Preliminary calculations for hot-air-exhaust heaters generally miss the actual heat-transfer and inlet-air temperatures by wide margins because of the uncertainty of predicting operating conditions. Location of the cold-air intake, resistance of the ducts to air flow, cabin pressures, and heat conditions in the exhaust are variables peculiar to each particular plane which must be determined by experiment. More than sufficient heat will usually be obtained if the air tube runs the entire length of the exhaust tail stack, which in a 10-place plane is about 5 ft. The tube should be of sufficient diameter to deliver about three-quarters the required amount of ventilating air.

Referring again to the combination heater and ventilator-duct system used in the Pilgrim 100-A 10-place transport plane, the cross-sectional areas of the various air ducts are as follows:

Wing-butt air intake = 8.3 sq in. each
Upper ventilation duct = 2.5 sq in. each
Heater pipe = 4.8 sq in.
Lower heater ducts = 8.0 sq in. each.

The inlets from the wing butts connect with both the upper ventilator and lower heater ducts. Butterfly valves in the connecting pipes allow cold air to be fed to the heater ducts which supply ventilation in hot weather and modulation of hot-air temperatures in winter. Undiluted hot air from this exhaust heater enters the ducts at about 140 F with outside air at +10 F. This temperature is reduced by cold air from the ventilator-duct valves. This combined heating and ventilating system can be applied to hot-liquid and vapor heaters with equal success.

The hot-air-exhaust heater is limited in application to planes having an engine in the nose of the fuselage. Planes having only outboard engines are more efficiently equipped with hot-liquid or vapor heaters.

2 Hot-Liquid Heater. The principle of operation of this type is the same as that of hot-water heating systems for buildings. Fig. 4 is a diagrammatic layout of such a system applicable to airplane use. The liquid used in this system may be glyco-ethylene (commercial Prestone), quenching oils of high boiling point, or any other liquid which has a boiling point of over 300 F, which will not freeze or congeal at —20 F, which is non-corrosive, and which will have a flash point high enough to be free from fire hazard should the system develop a leak.

It is not economical from a weight standpoint to use liquids of lower boiling point than 300 F, because the weight of the radiator goes up as the temperature difference between liquid and air is reduced. Since airplanes often stand outside, the liquid used in the heating system must flow freely enough to be easily pumped through the pipes when the engine is started in the coldest weather. Some liquids that could be used because of their physical characteristics must be eliminated because of their corrosive effect on steel, copper, bronze, aluminum, duralumin, or any other metal used in aircraft construction. The solution of the liquid in water especially must not be corrosive, since it is bound to be spilled over the structure and will absorb water from rain or the natural humidity of the atmosphere. The odors from the hot liquid must not be disagreeable or strong, since in spite of normal care they will get into the cabin from whatever small amount may be spilled in the engine compartment.

The liquid is force circulated through the system by an engine-driven centrifugal or vane pump driven either through a flexible shaft or directly from a suitable attachment on the engine, usually the gun-synchronizer drive shaft. The pump should take the cool liquid from the radiator and force it through the heater. It will handle liquid at 200 F or above, and clearances in the pump must be relieved to prevent binding at the boiling point of the liquid used.

The heater has been successfully constructed as a series of coils in the enlarged exhaust tail stack. Another type has a tube running through the manifold for a sufficient distance. A third type, shown in Fig. 4, has an independent heater through which some of the exhaust gases are bypassed. A butterfly valve manually and thermostatically controlled governs the flow of exhaust gases through the heater. The independent heater, although heavier and more expensive to build than the coils in the exhaust pipe, has the advantage that it is not continually in the heat of the exhaust and the heating surface may be made as large as desired to supply heat for any extreme condition of cold weather. If so constructed, it must be thermostatically controlled, the thermostat cutting off the exhaust gases from the heater.

No thermostats are on the market which can be applied to such use on an airplane without redesign to reduce weight and size. One type of thermostat has the sylphon bellows encased in the tube which is immersed in the liquid to be controlled. This type has given trouble from failure of soldered and compression joints and from deterioration of the bellows while operating at the high temperatures encountered. The bellows should be outside the heater and actuated by the expansion of liquid in a separate bulb or tube in the heater. The manual control to the valve cutting off the exhaust gases must be designed to permit the thermostat to function at any position of the control. The heater may be built of 0.035-in. stainless steel, with exhaust inlet and outlet ducts of 0.049-in. material. Particular attention must be paid to eliminating all possible gas pockets in the heater, as these will cause surging and hammering in the heater lines and are a cause of failure of this type of heater. The thermostat must be located at the exit point of the heater where it will be surrounded by the hottest liquid, otherwise there is possibility of the liquid reaching the boiling point, causing it to hammer in the lines.

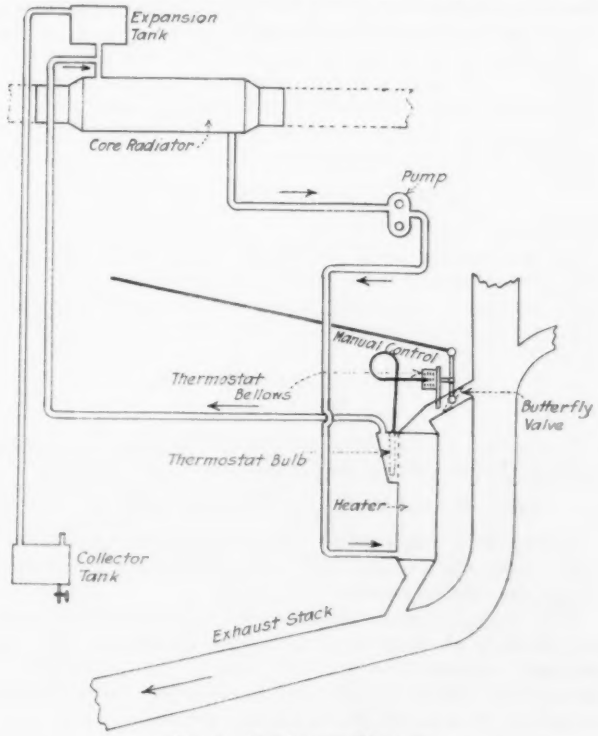

FIG. 4 HOT-LIQUID HEATER

The heating surface of coils or tubes located directly in the exhaust stack must be proportioned in relation to the radiating surface of the radiator so that the heat added to the liquid will be completely taken out on each complete cycle of the liquid and a temperature equilibrium be reached before the liquid reaches the boiling point.

Calculations for heat required must be made on the maximum operating condition of —20 F atmospheric temperature. The expression for heat required to maintain the cabin at 70 F is:

$$H = H_A + H_C - H_P$$

Continuing with the 10-place transport plane:

H = heat required to raise 14,000 cu ft of air per hour from —20 F to +70 F

$H_A = WC_P (t_2 - t_1)$.

The weight of 14,000 cu ft of air at —20 F = 1265 lb.

$H_A = 1265 \times 0.2375 (70 + 20)$
= 27,000 Btu per hr

H_C = heat lost by radiation from the cabin.

This is a very difficult quantity to calculate because there are no accurate data on heat radiation from glass, doped fabric or cabin interior surfaces, and plywood surfaces at the air velocities obtained in flight. Even data on heat radiation from surfaces such as a metal monocoque fuselage flying at speeds of 140 to 180 mph are not available.

Taking the best data available from heating and ventilating text books, the heat radiation from the fabric-covered 10-place transport was estimated to be 7100 Btu per hr.

H_P is the heat generated by the passengers in the cabin. This quantity is not large, and since the cabin temperature must be the same for one person as for ten, it will be neglected.

The total $H = 27{,}000 + 7100 = 34{,}100$ Btu per hr. The temperature of the entering air would be:

$$34{,}100 = 1265 \times 0.2375\ (t_2 + 20)$$
$$t_2 = 94\ \text{F.}$$

Using glyco-ethylene as the liquid to be circulated, the next step is to determine the size of the pump required to give the right circulation. Assume a 50-deg drop through the radiator. The specific heat of commercial Prestone is about 0.7 at 300 F. Then:

$$34{,}100 = W_z\ 0.7\ (300 - 250)$$
$$W = 975\ \text{lb per hr.}$$

The weight of the liquid at 300 deg is about 9.3 lb per gallon. The capacity of the pump would be:

$$975/9.3 \times 60 = 1.75\ \text{gal per min.}$$

A very small centrifugal or vane pump driven from the gun-synchronizer shaft, either direct or by a flexible shaft, will easily deliver the required amount.

The estimate of the heating surface in the exhaust tail stacks will be only an approximation unless experimental data are procured from which to arrive at a conclusion. A preliminary estimate can be made by taking the mean coefficient of heat transmission as 14 or 16 Btu per hr per sq ft per deg mean temp difference. Then:

$$SUd = 34{,}100$$

S = heating surface in sq ft
U = 14 Btu per hr per sq ft per deg mean temp difference
d = mean temp difference between the liquid and exhaust gas.

$$d = \frac{t_1' - t_f}{\log_e \frac{t_1'}{t_f}}$$

t'_1 and t_f = initial and final temperature difference between the liquid and gases

$$d = \frac{850 - 700}{\log_e \frac{850}{700}} = 770$$

$$S = \frac{34{,}100}{14 \times 770} = 3.2\ \text{sq ft.}$$

The liquid is circulated to the radiator from the heater. This radiator is placed as close to the heater as the layout of the plane will allow, so that unnecessary weight may be eliminated. Preferably it is placed ahead of the fire wall or at some point interposed in the air duct which is remote and shielded from passengers and pilot to eliminate the danger of scalds in the event of a wreck or failure of the radiator. Technology paper No. 211 of the Bureau of Standards gives the most complete data on radiators suitable for use with this type of heater. Especial attention should be given to radiators listed as E_6, A_7, C_{12}, and C_{14} in this report.

None of these radiators are suitable for use in the hot-liquid heater in their standard construction because they are fabricated with solder that is weak at the operating temperatures of the circulating fluid. Silver solder or a solder of equivalent strength should be used in constructing the radiator. A leak in the radiator, while not actually dangerous, may have a serious effect on the passengers because certain hot liquids when suddenly coming in contact with cold air form dense fumes which immediately fill the cabin, throwing the passengers into a frenzy.

At the highest point in the line between heater and radiators a line passes up to an expansion tank. This tank should be as high as possible above the radiator and should hold the entire liquid supply. A vent line from the top of the tank runs down to a collector tank located in the bottom of the plane to catch whatever vapor may condense in the vent line. This tank should have an accessible drain that is not difficult to get at, as this tank will be drained periodically. The liquid used in this system is usually expensive, and it pays to collect the small amount that might be wasted. The system should be filled through a funnel in the expansion tank.

Attempts have been made to eliminate the pump and operate the system on the thermo-syphon principle. These have met with failure or unsatisfactory performance. The difference in density between the hot and cold columns of liquid is too small to produce a rapid flow of liquid. The heat transfer is too slow to properly heat the cabin, and the heat is slow in starting after the engine is started. One such installation required ten minutes from the take-off of the plane before heat reached the cabin in sufficient quantities. The weight of this system was more than double that of a force-circulated system because the pipes had to be 1 in. in diameter on the hot side and $^3/_4$ in. on the cool side to prevent surging and hammering from boiling in the heater, and the vertical distance between heater and radiator had to be as great as the fuselage would permit. The force circulation system was successful with $^3/_8$-in. lines and no head between heater and radiator. The weight of the liquid in the thermo-syphon system was 14 lb as against 4.5 lb for the force-circulation system, using a separate heater unit.

Several installations have been made which substitute for the radiator, tubes carrying the hot liquid around the cabin inside air ducts in which are individual openings. This practice is not advisable, since the weight is very much greater than a unit radiator system, and it subjects the passengers to the danger of being scalded in the event of failure of a pipe or fitting either during service or in a crash.

The main advantages of the liquid heating system are that it entirely eliminates the danger of carbon-monoxide poisoning, which is a possibility in the hot-air heater. Provided that the correct installation is made, it eliminates odors such as scorching and frying oil smells, which often enter from hot-air-exhaust heaters. It is more easily adaptable to planes having outboard engines, as the hot liquid is easily circulated through insulated pipes to any desired location for the radiation. Its disadvantages are its weight and maintenance expense. It has been estimated that each pound of weight saved in airplane structures and equipment is worth $90. The weight analysis estimated from two experimental installations is as follows.

	Hot-liquid heater (independent heater), lb	Exhaust pipe coils, lb
Heater	7.0	3.0
Connecting tubes and shut-off valve	3.0	0.0
Lines	1.5	1.5
Radiators and brackets and fittings	6.0	6.0
Liquid (Prestone)	9.0	3.0
Pump and brackets	2.5	2.5
Pump drive mechanism	2.5	2.5
Thermostat and brackets	2.0	0.0
Expansion tank and brackets	2.0	2.0
Total	35.5	20.5

On the basis of $90 a pound the exhaust-pipe-coil type is worth $1350 more than the independent type. From a maintenance standpoint it is also very much more economical. In Alaska and Canada the independent-heater type might have its advantages because of its flexibility in operation.

Vapor Heaters

Several types of vapor heaters have been experimented with in aeronautical work, but have not been used to any extent in commercial planes. Few data are available from experimental work on any of the various types of vapor heaters.

Hermetically Sealed Heater System

This system consists of a boiler and radiator connected together with suitable tubing and evacuated of air. The boiler is located in the exhaust tail stack and consists of either coils of tubing or a single streamline container functioning as a flash boiler. The radiator may be any of the conventional types capable of taking pressures in excess of 400 lb per sq in. A small quantity of a liquid of low freezing point is introduced into the system before the air is evacuated. The internal volume of the system is small, and the quantity of liquid is carefully measured, since it is nearly all in the vapor state and under pressure at all times when the engine is running. Vapor from the boiler passes up to the radiator, is condensed on the walls of the radiator, and trickles back to the heater. The pressures in this system are high, usually between 300 and 600 lb per sq in.

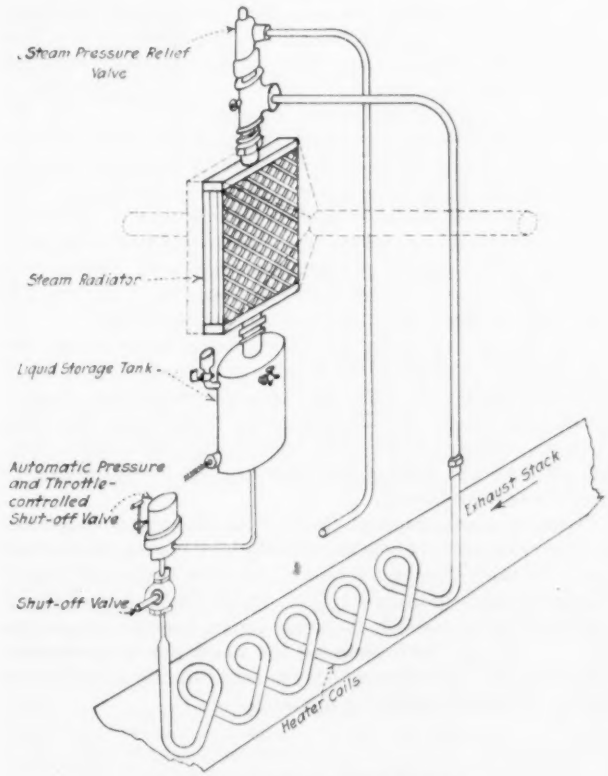

Fig. 5 Steam-Pressure Heater

The success of this system lies in keeping the radiator as close to the boiler as possible and eliminating all pockets that can catch and retain liquid. The volume of the liquid is necessarily very small, and a few small pockets in the radiator and lines will keep enough liquid out of circulation to impair or entirely spoil the functioning of the system.

No data as to weight are available on this system. It is compact, but the radiator and lines are heavy to withstand the high pressures. Attempts have been made to apply this principle to a system which piped the vapor about the cabin to individual radiators, but the system failed because all the liquid was caught in pockets in the lines and kept out of circulation. This system is best applied on planes having an engine mounted in the nose of the fuselage so that air ducts run directly from radiator to cabin. The high pressures make it undesirable because of danger from explosions in the event of crash.

Steam Pressure System

This system is the same in principle as an ordinary house-heating unit, but with added control features. Fig. 5 shows a system which has worked successfully as an experimental unit. A flash boiler consisting of coils in the exhaust stack vaporizes and superheats the heat-transfer medium, which in an experimental unit was a mixture of alcohol and water in proportions to withstand

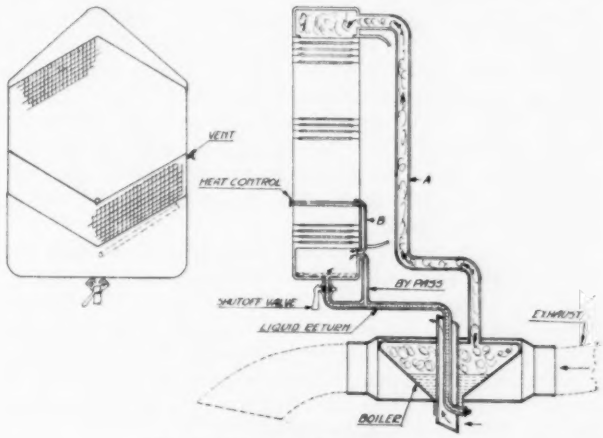

Fig. 6 Huffman Vapor Heater

zero weather without freezing. The superheated system passed to a radiator in the heater duct, from which the condensate dropped by gravity to a storage tank of 1 qt capacity. A control and regulator valve in the line between the collector tank and boiler regulates the flow of liquid. This valve is designed to automatically shut off the flow when the pressure exceeds 20 lb, and also when the engine is throttled below one-quarter speed. This prevents the pressure from rising and blowing off the safety valve, which would quickly use up the liquid in the system, and it prevents the liquid from filling the coils when there is insufficient heat in the exhaust stack to vaporize it. A second valve is closed when the ship is idle, to prevent water from accumulating in the coils if the throttle should be opened.

The boiler coils are constructed of $^3/_4$ by 0.049 stainless-steel tubing. The delivery lines are $^3/_4$ by 0.035 stainless-steel tubing. The radiator should withstand 150 lb pressure with safety, although the safety valve is set to blow off at 50 lb gage. All joints and seams must be strong at high temperatures, because the coils are designed with sufficient surface to superheat the steam to a high temperature. The collector tank is made from a $2^1/_2$ by 0.049 steel tube and for an installation in a 10-place plane, with a capacity of only 1 qt. The filler and vent cocks are in this tank.

The automatic control valve is of special design, using syphon bellows to prevent leakage. The shutdown valve is also a bellows valve so that no leakage will occur. The return lines are $^3/_8$-in. copper tubing.

A small orifice is placed in the line between the collector tank and boiler coils to limit the feed of liquid to the boiler so that the

pressure will not build up above the blow-off point of the safety valve should the automatic control valve get out of order.

By using specially designed fittings and valves, this system can be made to weigh about 12 to 18 lb for a 10-place plane. Its initial cost is greater than for the hot-air heater and about the same as the hot-liquid heater. It is easily adaptable to planes having an engine mounted in the nose of the fuselage and to multi-engined planes if the radiator can be placed above the boiler coils and a good slope maintained in the return lines from radiator to boiler. This being impossible, an engine-driven pump with a metering valve can be used to feed the liquid to the flash boiler from the collection tank. This system is capable of rapidly adjusting itself to varying conditions of air temperature, and if thermostatically controlled, with the thermostat located in the cabin, will keep the cabin at a very even heat. By increasing the heating surface of the radiator, the amount of heat delivered to the cabin may be proportionately increased without changing any other part of the system. This system also has the advantage of delivering steam to the radiator at the same temperature at all altitudes normally obtained in transport work. Some objection is raised to this system on the ground that there is danger from steam burns in event of a crash. If this system is located ahead of the fire wall, there is little danger of any injury from such cause, as the volume of the vapor is small and very little liquid is in contact with hot surfaces. The liquid in the collector tank is far enough below the boiling point so that it will not flash into steam when the pressure is relieved. The pressures are too low to cause damage from explosion.

Cabin heaters are in operation utilizing the hot liquid from solution-cooled engines. A part of the liquid from the engine is circulated through a radiator in the hot-air ducts. The air which passes through this radiator is led to the cabin or spilled outside by a bypass valve in the air ducts according to the need for heat in the cabin. The radiator is a part of the cooling system for the engine, and if made sufficiently large, it may be possible to reduce the area of the main radiator slightly.

Because of the low temperatures of the circulating liquid, the radiator tubes must be long to raise the air to a sufficiently high temperature. This system may cause complications in the engine-cooling system unless very well laid out. It seems to offer little advantage from a weight standpoint over the exhaust-heater liquid cooler or the steam coolers.

Huffman Vapor Heaters

The system consists of a boiler and radiator with the necessary steam and liquid return line connecting the two and a means of driving the heat from the radiator. The boiler is mounted in an enlarged section of the exhaust line and the radiator at some convenient point within the cabin. The radiator is divided into two sections by means of a partition, the upper section being about four times the size of the lower section. A reservoir having the approximate capacity of the boiler forms the lower part of the radiator.

The upper and the lower sections of the radiator are connected together by means of a tube extending from the lowest point of the upper section to the lowest point of the bottom section. A hand valve is installed in the line connecting the two sections. The lower section at its uppermost point is vented to the atmosphere. The steam line from the boiler enters the upper section of the radiator at its top.

The liquid return line is attached to the bottom of the radiator reservoir with a hand shut-off valve directly below the point of attachment. A bypass line from the liquid return line enters the top of the reservoir.

Referring to Fig. 5, liquid in the boiler is heated to the boiling point by the exhaust. Steam thus generated rises and fills the radiator through pipe *A*. Heat is driven from the surface of the radiator by means of a fan electrically or otherwise operated, or by means of air brought in from the outside through a suitable tube so arranged that the air will flow through it due to motion of the vehicle or airplane.

The size of the boiler with respect to the radiator and the quantity of heat supplied to the boiler are such that under normal operating conditions more steam is generated than can be condensed in the radiator. Thus it will be seen that steam will flow from the upper radiator section through the heat-control valve and pipe *B* to the bottom of the lower radiator section and rise toward the top, which is vented. If more steam than could be condensed in the lower radiator sections were permitted to pass through the heat-control valve, it would escape through the vent, with the result that the liquid would in a short time boil off.

To prevent this loss the heat-control valve is turned "in" until less steam than can be condensed in the lower radiator section is permitted to pass through it. A stop provided on the valve is then adjusted to prevent the valve from being opened beyond the point where a loss of steam through the vent would occur. After the initial adjustment of the "stop" on the valve, no further adjustments are necessary.

When the heat control valve is turned "in," restricting the flow of steam through the radiator, pressure (varying from a few ounces to 2 lb, depending upon the height of the reservoir above the boiler) is built up in the radiator, pipe *A*, and the boiler. This pressure results in the lowering of the liquid level in the boiler and a rise in the level in the return line. When the liquid in the boiler is reduced, the quantity of steam is also reduced; therefore the system automatically permits only sufficient liquid to remain in the boiler to generate the amount of steam required.

The design of the boiler and its installation in the exhaust line are such that a sump in the bottom and a small portion of the bottom surface of the boiler are below the temperature required to boil the liquid. This feature assists in stabilizing the liquid level and prevents surging and "percolating" when, due to pressure in the boiler, most of the liquid has been forced through the return into the reservoir.

When no heat is required, the liquid in the boiler is transferred to the reservoir. This is accomplished by closing the shut-off valve on the bottom of the reservoir and the heat-control valve. When the heat-control valve is closed, all liquid in the boiler is instantly forced through the liquid return line and bypass into the reservoir due to pressure on the steam side of the system. With the shut-off valve closed, the liquid cannot return to the boiler; therefore generation of steam stops.

AER-55-8

Artificial Pay Load for Coming Commercial Airships

By T. L. BLAKEMORE,[1] LAKEHURST, N. J.

The most prominent field for the lighter-than-air vessel is across long stretches of water. The "Graf Zeppelin" confirms this by selecting as its first commercial venture the route between Germany and Brazil. There is a question whether the seagoing airship will merely be a high-speed, extra-fare auxiliary to the steamship or whether by radical improvement over present limited pay-load capacity it can be developed as a direct competitor to passenger-carrying ocean vessels at somewhat near to existing rates. The author suggests a number of means for artificially increasing pay load.

IT HAS BEEN generally recognized for some time that the most promising field for the lighter-than-air vessel commercially is across long stretches of water. In fact, we find the *Graf Zeppelin* confirming this choice of field by electing a direct ocean haul from Germany to Brazil as its first commercial venture. It seems conservative, therefore, to accept the limitation that in the future the only existing form of transportation service which the coming airship will parallel is that offered by the steamship over long distances at sea. The commercial airship should today be considered definitely and solely in the steamship's field. It seems to be no question of the airship versus the airplane or the airship versus the railway.

There is a question, however, as to whether the seagoing airship will take its place in the coming transportation scheme of things merely as a high-speed, extra-fare auxiliary to the steamship schedule or whether by radical improvement over present limited pay-load capacity the lighter-than-air craft can be developed to the point where it will offer direct competition to passenger-carrying ocean vessels at somewhat near to existing rates. In other words, is there any immediate promise of so improving the percentage of pay load of the airship or (its corollary) of decreasing the operating costs to such an extent that, while retaining the great advantage of speed over the steamship, the lighter-than-air craft can be operated at a rate more in keeping with established ocean fares?

The majority school of thought to date believes that the airship will be operated for some years as an extra-fare auxiliary to surface craft, using high speed, novelty, and added comfort as justification for the higher passenger rates charged. The author concurs in the general opinion that these factors, in themselves, will attract patronage and are sufficient reason for the excess passenger rates over the steamship, initially; but if we are to judge from the history of all other forms of human transportation, there will shortly come a time when it will be necessary to earn more dividends at lesser rates to the passenger; in other words, to carry more pay load or to cut operating costs, or both. As a natural means toward this end, the major effort of airship designers has been to increase pay load "statically" by recourse to larger and larger volumes. For it is common knowledge, and easily shown in theory, that any increase in airship volume has the advantage of automatic increase in per cent of useful load, of which pay load is a proportion; and the theoretical limit of size seems to be well beyond the volume of any airship flying or projected today. Practically, however, this increment in pay load due to increased size is not being realized in full proportion to theory. Without going into the many reasons for this falling off of the "static" pay load, it is believed sufficient for the present to point out that this natural method of increasing pay load in future airships has perhaps been overstressed; and if so, it may be found not only advantageous but economically necessary to develop artificial means for increasing pay load, in order that the airship may become more quickly practicable, commercially.

The purpose of this paper, then, will be to present the cumulative advantage of minor means at hand or which can be developed for artificially increasing pay load without recourse to excessively large volumes.

Fortunately, we have already begun to realize increased pay load artificially. The swiveling propellers of the *Akron* are, in a way, the first applied effort in this direction. For it has already become operating practice to lift this ship off the ground, statically "heavy" by about 10,000 lb, using the vertical dynamic thrust of its propellers. After the ship has reached a safe altitude, this extra load is gradually transferred, as the ship gets under way, to a component of its forward motion, and is directly creditable as artificial pay load.

On reference to Tables 1 and 2, it will be noticed that the *Akron*, of 6,500,000 cu ft capacity and 60 knots cruising speed, has a useful load of about 40 per cent, or 160,000 lb. Of this useful load, it is estimated that 16,000 lb would represent the proportion of actual static pay load on a given voyage, say from Lakehurst to Friedrichshafen, Germany. This amounts to around 4 per cent of the total lift of the ship. It should be realized, further, that the swiveling propellers, as designed for this ship, are pitched for down-thrust rather than up, and have developed over 15,000 lb in the haul-down position. It is conceivable, then, that in commercial practice, in which the purpose is to get the greatest possible pay load off of the ground, these propellers could be designed for maximum up-thrust, even though it might lead into the development of adjustable-pitch propellers for this

[1] Aeronautical Engineer, U. S. Naval Air Station. Thomas L. Blakemore attended Washington University, St. Louis, Mo., receiving in 1913 the degree of Bachelor of Science in Mechanical Engineering; four years later received the M.S. degree in Aeronautical Engineering from Massachusetts Institute of Technology; specialized in lighter-than-air development engineering initially in the spring of 1917 at the Bureau of Construction and Repair of the U. S. Navy Department, on non-rigid airships, kite balloons, etc.; in 1920, joined the U. S. Army Air Corps at Fort Omaha, Neb., and organized the Lighter-Than-Air Engineering Division, which in 1921 joined the Engineering Division at McCook Field; in 1922, organized the Engineering Division representative's office at the Goodyear Tire and Rubber Company, for supervising the design and construction of the semi-rigid airship *RS-1*, the only semi-rigid airship to be developed in this country; in 1927, joined the U. S. Naval Air Station for the purpose of developing mechanical gear for rigid airships.

primary purpose. Should this be done, the addition of 15,000 lb to the pay load of the ship at the start of a flight is practicable and well within the present bounds of operation safety, due to an equal amount of reserve water on hand at this time for emergency purposes. The credit, therefore, from this first means of taking on artificial pay load would be 15,000 lb, or 3¾ per cent more pay load.

Again, should the ship be brought up to 70 knots initial speed, shortly after take-off, its dynamic lift (as an airplane) at a 6-deg angle of attack and an elevator angle of 0 deg is around 15 short tons, or 30,000 lb. The ship is already 15,000 lb heavy from the swiveling-propeller take-off, so that there is still lift and room for a matter of 15,000 lb more of pay load that could be carried if it could be gotten aboard while the ship is under way. The plan immediately suggests itself to employ a number of shuttle planes, either at Lakehurst or stationed at points along the land end of the line of flight, to bring aboard mail and express aloft—thereby increasing the artificial pay load by this amount, or as much of it as could be safely handled with our present technique of aerial transfer and airship practice. It should be realized that, as a guarantee of the safety of such an operation, there is aboard 100,000 lb of fuel, in addition to the 16,000 lb of water on hand after the dynamic take-off. The ultimate net gain, then, from this second operation could be 15,000 lb, or 3¾ per cent more pay load; and the penalty would be nothing more than a slight slowing down of the ship during its first 15 hours and the possible wastage of a proportion of reserve fuel in case of unforeseen difficulties. During these first 15 hours of flight, the water-recovery apparatus has presumably been rejecting water at the rate of 1 ton per hour, thus bringing the ship back to safe equilibrium and normal cruising flight.

As a third method of getting more pay load off the ground, for any rigid airship of given volume, the suggestion has been made to artificially superheat the helium-gas cells, thereby creating more initial static lift by reason of (*a*) a decrease in the density of the contained gas and (*b*) an increase in the normal volume. Assuming that it will continue to be the practice of airship commanders to conserve helium gas by maintaining a hangar or ground volume at take-off around 95 per cent of full cell inflation (this in order to permit operating the ship at a safe "pressure height" of around 2000 ft without valving helium), the plan would be to artificially heat the airship gas for some hours prior to take-off, so that it would leave on a voyage with an actual static increase in lift—in other words, more pay load at take-off.

After getting under way, the flow of air over the outside cover would rapidly dissipate the excess heat contained, causing a gradually increasing heaviness due to contraction of gas volume. Just how rapidly this "superheat" would dissipate or how gradually the heaviness would increase is a matter of conjecture at this time owing to lack of complete test data; but there is very little question, based on tests made by Lieut. Calvin M. Bolster on the *Los Angeles* during 1929, that sufficient cheap heat can be supplied to an airship prior to flight, in the hangar or at the mast, to give it an initial superheat over the surrounding air of 10 F. And on this basis, an additional "artificial" pay load of 9000 lb can be lifted off the ground, under normal conditions. In order to guarantee the safety of this third means of gaining pay load, it is necessary to have ready at hand an equivalent amount of disposable weight. The author suggests that it may be found to be good economic practice to have standing by 9000 lb of non-insured express matter or freight, equipped with quick releases and large parachutes, for immediate release in case of temperature inversion or other operation difficulties. Also, in order to retard a possible rapid dissipation of superheat, it may be found practicable to keep the air space hot between gas calls and outer cover (a fortunate advantage of rigid airships) by utilizing the rejected heat from the water-recovery apparatus. It should be kept in mind, in reference to the last, that immediately after take-off the engines will be at full power and the recovery of water will not be required for some hours thereafter, thereby allowing hot air from the shielded condensers to be blown directly into the insulating air space. The object in this is not to obtain further heat, but to retain what we have until the normal fuel consumption of the ship will reduce the loss of lift due to natural cooling of the gas. As a further guarantee of safety, in this respect, it is pointed out that for a great percentage of normal flights weather reports could be relied upon to give the superheated airship the advantage of the morning sun-up effect to sustain this artificial superheat. It is believed conservative, therefore, to credit the impressed superheat plan with at least 9000 lb of artificial pay load, or an increase over the straight static pay load of 56 per cent.

In the foregoing, only the direct effects of impressed superheat at take-off have been considered. In reality, if it should prove out that the application of direct heat from the condensers in flight to the insulation air space of the hull is found practical, the indirect effect of further safety to the airship against ice and wet snow formation on the top side and the control surfaces is hard to estimate. An approximation could be based on the excess amount of normal reserve fuel (or ballast) which a given commercial airship will have to carry for, say, a winter flight across the Atlantic, in anticipation of the formation of ice or sleet. Dynamically, the *Akron* has already flown 16,000 lb heavy from this cause in the early stages of a protracted cruise to the tropics. Fortunately, the ship gradually lost the load due to increasing temperatures, rather than accumulating further ice load; but had it been a commercial ship operating on definite schedule

across the Atlantic, it is probable that for that particular time it would have had to steer a course well south of freezing temperatures. And such a roundabout course, leaving favorable winds out of consideration, would have meant as much as 10 per cent more fuel to negotiate the passage. This extra fuel would have cut into the pay load by an equal amount, and from this line of reasoning, the author believes it conservative to say that any commercial airship possessing a positive means of snow and ice prevention, such as indicated, has a positive advantage in useful load of at least 5 per cent of the total fuel, or 31 per cent over the pay load of any airship not so equipped. The difference between 5 per cent and 10 per cent in fuel allows for added static weight of the necessary heating blowers, ducts, and equipment. Incidentally, the airship which can operate safely at northern temperatures has the sustained advantage of the increased lift of the colder atmosphere, and this would mean added pay load for the same fuel reserve.

For the fifth means for artificially increasing the static pay load of coming airships, it will be necessary to consider the effect of excessive parisitic drag on the present useful load and indicate possible increments by cutting down the drag. The *Akron*, for instance, has 880 sq ft of drag area, including the parasitic, and in spite of the excellence of this design and low drag area compared to other airships, the author believes that the commercial airship will find it necessary to better this drag in a number of ways. For instance, the present practice is to install sufficient water-recovery condensers in the form of surface-type aluminum panels to give 80 per cent water recovery at full power; and the drag area of this full power installation amounts to around 23 sq ft, or 2.6 per cent of the entire drag of the airship. While this full-power installation is no doubt necessary for a military airship, it should be realized that the commercial airship will operate mostly at cruising speeds on, say, four engines at two-thirds power; and on this basis, the obvious thing to do to further cut down parasitic drag on the airship is to install the eight full-power units in such a way that the four not in use are fully retracted within the hull and the four in use are slightly retracted. By so doing the water-recovery drag could be reduced to possibly 1.0 per cent of the total, and this expressed in terms of the full 100,000 lb of fuel carried on a given flight, would mean a saving of at least 1000 lb of fuel.

In a similar way, some practical means may soon be found for installing the water radiators on these eight engines as retractable units, so that when any group of power units is not in use, the parasitic drag on the ship can be automatically reduced by withdrawing those units within the hull line of the ship. This idea, of course, is not new, and in fact has already received the attention of the Bureau of Aeronautics for application to military airships. But with the coming commercial airship the importance of increased pay load may make such a step very necessary. It is estimated that an additional 1000 lb of pay load instead of fuel could be carried by the airship using retractable radiators.

One of the advantages peculiar to airships as compared to airplanes is that the full engine power installed for emergencies is rarely used. The *Akron*, for instance, operates most of the time on alternate four engines out of the eight, at two-thirds power (equivalent to 45 knots speed). From the point of view on maximum pay load of coming commercial airships, therefore, there is a possibility of cutting down the drag of the four idle engines by making all eight engines in turn retractable. At this date such a step no doubt will seem quite visionary and possibly hazardous. But when it is considered that airplanes are being "retracted" today into the hold of the *Akron* and that only a few years ago this very practical operating means of saving airship drag was just as radical, in a similar way it is believed to be a mere matter of time before commercial airships adopt this or some equivalent means for reducing the present excessive resistance and weight of power-plant installations. The concentration of power plants into four rather than eight units, as adopted for the Zeppelin *LZ-130* now nearing completion, may be considered a stop in this direction, in that the total drag area of power plants is being reduced, and, in theory at least, the pay load should be proportionately bettered.

The advent of the commodious auxiliary control station in the lower fin suggested the possibility of eliminating the present control car, thus incorporating the ship captain's bridge, navigating quarters, etc. in this aftermost station. This would automatically reduce the parasite resistance still further, say 1 per cent, thus saving another 1000 lb of fuel as well as eliminating the major control system with its cable and sheave gear now running the full length of the ship. The weight reduction thereby would be at least 1000 lb more, so that this change would, alone, increase the pay load $12^1/_2$ per cent.

It is difficult to see any further reduction in the parasitic drag of an airship of the type of the *Akron*. The ventilators and exhaust hoods are necessary and well streamlined, and fins and control surfaces are beautiful examples of fine aerodynamic form. The buffers or landing pontoons, possibly, are open to question as to whether or not these emergency ground-handling accessories are required on commercial airship routes operating between established airports equipped with mechanical handling gear. But for the purpose of this article it is assumed that any weight (or drag) saved by eliminating the buffers would be balanced by weight spent in additional local strength to meet the requirements of mechanical handling at the terminals.

From the foregoing discussion, it is believed conservative, therefore, to summarize the additional pay load accruing from possible savings in drag at a total of 4000 lb, or 25 per cent increase over the present static pay load.

Improvements in aerographic service and in terminal handling methods have also a direct bearing on the pay load of coming commercial airships. The first is that the average yearly time to cross the Atlantic can be lessened by proper weather advice, and in direct proportion to the dependability of such service, the fuel reserve for any given flight can be lessened. The second, as pointed out in another paper, "Ground Handling of Rigid Airships," by Lieut. C. M. Bolster, presented to this Society, is by lessening the elapsed time in taking off and landing. Aerograph service and mechanical-handling methods have already gone far toward guaranteeing quick and safe passages for airships of today, and for this reason are not properly to be included as further means for increasing pay load of coming commercial airships. The author's object, however, in mentioning these two factors in this connection is to point out that natural improvement in service, whether aerographic, terminal, or in flight, can be relied upon in the future to cut down the length of passage and by so doing reduce the fuel required. And this, in turn, adds to the pay load. If, for instance, instead of carrying 100,000 lb of fuel, the commercial airship can safely reduce to 90,000 lb for any given run, solely because of the definiteness of auxiliary service, then 10,000 lb of extra pay load can be carried—again an increase of over $62^1/_2$ per cent over the original.

Summarizing the cumulative advantage of the six major or minor means for artificially increasing pay load so far discussed, we find the figures as given in Table 3.

This somewhat startling total is based, of course, on the assumption that all six methods would prove fully 100 per cent practical, as estimated, and that no sacrifice in the safety of operations would be involved. It should be noted, also, that the total reduction in reserve fuel is the sum of the last three items only, i.e., 19,000 lb, or 19 per cent of the total of 100,000 lb, assumed to be necessary for a given flight of a ship of the *Akron*

TABLE 3

1	Dynamic take-off, lb	15,000
2	Shuttle planes, aerial landing, lb	15,000
3	Artificial superheat at take-off, lb	9,000
4	Ice and sleet prevention, reduction in reserve fuel, lb	5,000
5	Accumulated reduction in parasitic drag, lb	4,000
6	Lessening of average flight time, lb	10,000
		58,000
	Original "static" pay load, lb	16,000
	Combined static and artificial pay load, lb	74,000
	Increase, per cent	360

class. The other three items, totaling 39,000 lb, are purely "artificial," and are limited solely by the dynamic power of the ship immediately after take-off.

Returning to the main object of this paper, which is to point out certain artificial means by which present rates as estimated for airship travel can be reduced without resort to larger volumes, it means that, if fully applicable, there is promise of scaling down present estimates in the direct ratio of 16,000 to 74,000, or down to about one-fourth of the rate now necessary to pay dividends.

This estimate of reduction in passenger rates in coming commercial airships has been based solely on increased poundage of pay load. We should, from a commercial point of view, consider also the economic advantage of service improvement incident to certain features of the artificial pay-load plan. For instance, with positive ice and sleet prevention, the direct northern course across the Atlantic will (under favorable wind conditions) save the passenger time, and reduce proportionately the flight operation cost of the airship. Again, the added safety of this feature should attract patronage and increase the load factor. It is beyond the scope of this paper to estimate the rate advantage of such features, nor is it possible to anticipate and list all of the artificial means by which coming airships can legitimately carry more pay load. The author feels that the purpose will have been served if he succeeds in pointing out here a few of the prominent fields of airship research which may individually or collectively be the ultimate means for bringing the airship passenger rate down to that of its surface competitor, the steamship. The basic object is of course to stimulate thought along these lines.

AER-55-9

Combustion Processes in Aircraft Engines[1]

By H. K. CUMMINGS,[2] WASHINGTON, D. C.

This paper presents three general types of combustion which occur in homogeneous mixtures of explosive gases (preflame oxidation, normal burning, and the explosive wave) and reviews available experimental evidence as to the combustion processes which actually occur in spark-ignition engines. Oxidation is detected optically by changes in absorption spectra and chemically by analysis of samples removed from the combustion chamber. The progress of flame away from the spark plug has been followed by visual, photographic, and electrical means, with simultaneous measurements of pressure development. Spectra of visible radiation and measurements of infra-red radiation, obtained through windows in the cylinder head, assist in analyzing combustion phenomena. The characteristics of preignition and knock are understood, but the exact mechanism of knock remains obscure.

THE types of combustion which occur in conventional aircraft engines are those common to all internal-combustion engines with spark ignition. However, large bores, relatively high compression ratios, and the general reliance on air cooling in aircraft engines favor those undesired combustion phenomena (preignition and detonation) which may give local cylinder pressures many times the normal explosion pressure and which are accompanied by excessive heat dissipation to the cylinder walls. The requirement of low weight per horsepower and the fact that they are operated most of the time at over 70 per cent of full load make aircraft engines more likely than automobile engines to suffer mechanical damage from these phenomena.

In the paper attention will be directed mainly to combustion as studied in actual engines, but some consideration must first be given to the much greater volume of work which has been done under other conditions on gaseous mixtures such as constitute the working substance in the internal-combustion engine. Three distinct phases of the gaseous oxidation reaction (slow combustion without flame, normal burning, and the explosive wave) are possible, and all may occur in the engine. Work on the oxidation of hydrocarbons with special reference to slow combustion has been reviewed by Egloff, Schaad and Lowry (1),[3] and by Mardles (2). The usual methods are (*a*) measurement of pressure change as the gas mixture is heated slowly in a closed bulb and (*b*) analysis of gas mixtures after passage through a heated tube. Closely related to this work on oxidation rates and oxidation products, which will be considered further in a later section, is the measurement of ignition temperature which has been reviewed by Bridgeman and Marvin (3). They pointed out the wide variation in values reported, depending on the specific method and apparatus used. A "true ignition temperature," considered a property of the fuel, was defined, and a modification of the Tizard and Pye adiabatic compression method (4) was suggested for its experimental determination.

When a homogeneous mixture of explosive gases fed to a bunsen burner is ignited, the sharply defined inner cone is the zone within which the sudden transformation of the gases takes place. The study of such flames by Gouy (5) led to the important conclusion that the movement of the reaction zone with respect to the active gases is constant at constant pressure and independent of the mass movement of the gases in which it is propagated. The work of Stevens (6), using a soap bubble as a transparent spherical bomb of constant pressure with central ignition, established (*a*) that the uniform rate of propagation of the reaction zone when measured relative to the active gases is proportional to the product of their concentrations, for complex as well as for simple fuels, and (*b*) that, over a wide range of pressures, this uniform rate of propagation is independent of the pressure. These results show that in all cases of the "normal burning reaction process" the rate of transformation within the reaction zone is proportional to pressure and indicate that the ultimate processes are binary impacts as would be called for by the kinetic theory of chain reactions. In the constant-pressure bomb, the reaction zone is a spherical shell inclosing the reaction products and expanding radially at a constant rate, both in space and with respect to the active gases. In the constant-volume bomb, however, the rate of displacement of the reaction zone is not constant in space, and its rate with respect to the active gases is indeterminate, due chiefly to the mass movement of the latter. Only in case of a spherical bomb with central ignition does the reaction zone remain spherical.

In 1881, the explosive wave was discovered independently by Berthelot and Vieille (7) and by Mallard and LeChatelier (8). This mode of transformation propagates with a constant velocity of at least 1000 meters per second, the value depending on the composition of the gas mixture, and may result from normal burning in a closed container, but any means of producing in the mixture a compression wave intense enough to ignite the gases will start the explosive wave in those mixtures able to support it. The high speed of the explosive wave may be accounted for on hydrodynamic grounds according to the Chapman-Jouguet theory (9) or by means of the theory of chain reactions as proposed by Lewis (10). Velocities computed on the Chapman-Jouguet theory are in good agreement with actual velocity measurements by Dixon and others. An investigation of the limits of detonation in gaseous mixtures by Wendlandt (11) is concerned with the borderland between normal burning and the explosive wave.

The type of apparatus used by Dixon (12) to obtain photographic records of flame propagation in a glass cylinder where ignition was produced by adiabatic compression has been adapted by Duchene (13) for studying normal burning in a glass explosion chamber into which the charge is compressed by means of a piston. The charge is fired by a spark just before the end of compression, and the piston remains at top dead center. These experiments reproduce certain of the conditions which affect combustion in the engine cylinder more closely than is usual in experiments with explosions in constant-volume bombs. Four

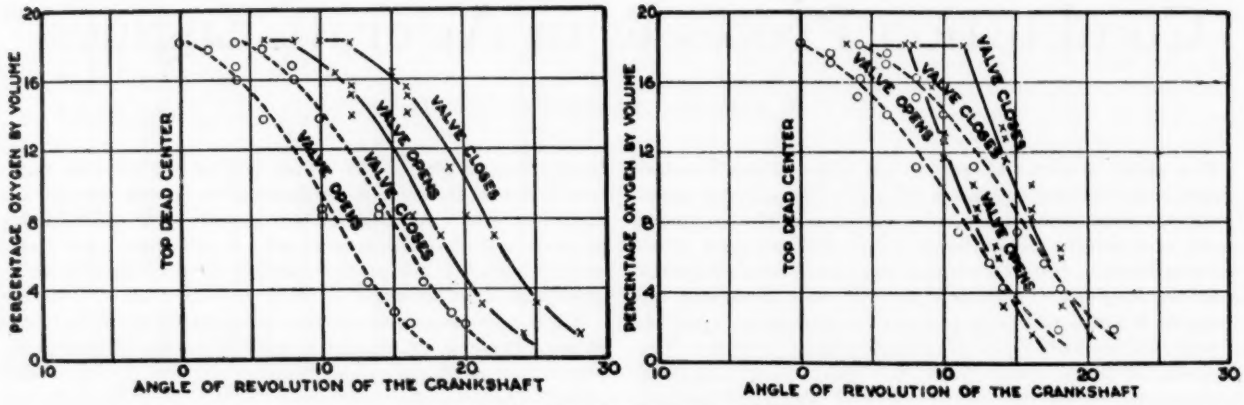

FIG. 1 OXYGEN CONCENTRATION CURVES

(At left, engine not knocking; at right, engine knocking violently. Engine speed, 1000 rpm. Spark advance, 25 deg. Mixture ratio, 80 per cent of theoretical air. Throttle, fully open. Fuel, gasoline. Compression ratio, 5 to 1. Broken line, sampling valve located 3 in., or 7.6 cm, from spark plug. Continuous line, sampling valve located 4¾ in., or 12.1 cm, from spark plug.)

fuels were used, and temperature, mixture ratio, and compression ratio were varied in the work reported. It is understood that this work, done under the direction of Jouguet, is still in progress, but no recent publication is available.

At the request of the Bureau of Aeronautics, Navy Department, the Bureau of Standards has undertaken a study of the effects of temperature, pressure, and radiation on hydrocarbon vapors, optical instead of chemical means being employed to detect molecular changes. In this work ultra-violet absorption spectra are obtained for each fuel vapor, both with and without the addition of air, at various temperatures and pressures. Spectra of aldehydes, alcohols, and other possible oxidation or decomposition products are compared with the hydrocarbon spectra in order to account for permanent changes in absorption. By inserting a pair of quartz windows in the cylinder head of a single-cylinder engine and passing a beam of light through the combustion chamber, it is possible to study changes in the absorption spectrum of the charge while the engine is being operated on any desired fuel. No test results have yet been released for publication. Measurement of pressure changes with time during the heating of various fuels with air will give data on oxidation rates.

In Callendar's second report on Dopes and Detonation (14), tests were mentioned in which a Ricardo E-35 engine was run under power and then motored over with the ignition switched off, in order to obtain from the exhaust samples of charge which had been compressed but not burned. The samples were reported to contain both aldehydes and peroxides. Subsequently, E-35 engines at Old Shoreham and at Cambridge University were equipped with water-cooled sampling valves for the purpose of obtaining gas samples at different points in the cycle, with the engine running under power. Thornycroft reported (15) that analysis of the gases withdrawn through a sampling valve, which was open for a very short period during the compression stroke, showed the presence in small quantities of alcohols and aldehydes. At Cambridge, Steele (16) found no evidence that samples taken during the intake, compression, or exhaust stroke contained peroxides, although reaction with potassium-iodide solution indicated the presence of an oxidizing agent. Work on oxidation of fuels in an engine prior to ignition was also undertaken at the California Institute of Technology in 1927, but no results appear to have been published.

The use of exhaust-gas analysis to determine completeness of combustion is a method of long standing, but the first attempt to follow the progress of combustion in an engine by chemical means appears to have been made about ten years ago. Preliminary studies of combustion in a low-compression oil engine with hot-bulb ignition were made by Brooks (17), who used a water-cooled auxiliary valve and copper cooling coil to obtain and rapidly chill gas samples at five points in the explosion stroke. A run under detonating conditions showed characteristic differences from normal-burning runs, such as the presence of hydrogen, carbon monoxide, and free carbon, and the application of this method to the study of combustion in Otto-cycle engines was proposed. A similar sampling valve was developed independently by Lovell, Coleman, and Boyd (18) and used to study the rate of burning of the charge in an air-cooled Delco engine. When the engine was operated at 1200 rpm on a maximum-power gasoline-air mixture appreciable burning appeared to start about 10 deg after ignition, one-half of the available oxygen was consumed 35 deg after ignition, and combustion was approxi-

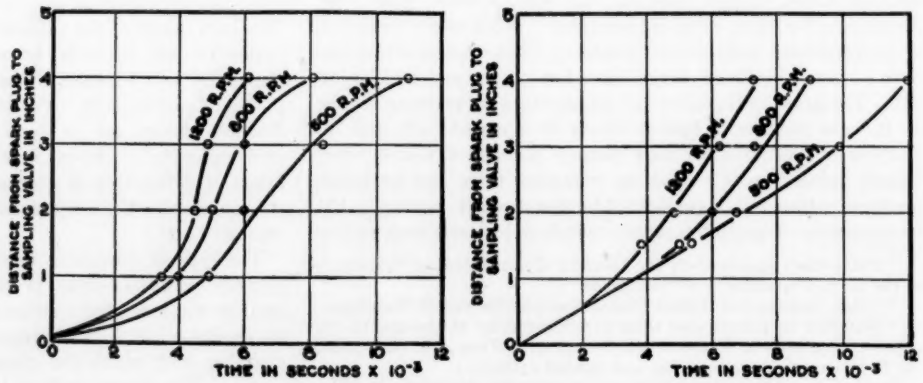

FIG. 2 EFFECT OF ENGINE SPEED ON PROGRESS OF COMBUSTION ZONE

(At left, through middle of combustion chamber; at right, along combustion chamber wall. Spark advance, 16 deg at 500 rpm, 22 deg at 800 rpm, 26 deg at 1200 rpm. Mixture ratio, 80 per cent of theoretical air. Throttle, fully open. Fuel, gasoline. Compression ratio, 5 to 1. Each experimental point, or circle, shows, for a given location of the sampling valve and a given engine speed, the time, in seconds, after ignition when the oxygen concentration began to decrease rapidly.)

mately completed at 50 deg after ignition. The location of the sampling valve with respect to the spark plug was found to have little effect on the results, but the use of a knocking fuel appeared to cause a uniform increase in the rate of burning. The conclusions drawn from these observations were subject to revision when it was found that the sampling valve opened nearly 10 deg late and that it remained open more than 20 deg instead of 2 deg. Experiments made a few years later, on a water-cooled ell-head engine equipped with a new and improved sampling valve, were reported by Withrow, Lovell, and Boyd (19). The times at which the valve opened and closed were known definitely, and samples were taken at different places, either down the middle of the combustion chamber or along one side. Values of the oxygen concentration in samples taken at two distances from the spark plug and at various points in the cycle are shown graphically in Fig. 1, which is reproduced from the original paper. The fact that the time interval, between the instant of ignition and the instant that oxygen concentration began to decrease rapidly at the sampling valve, increased as the distance between the spark plug and the valve was increased, indicates that a definite combustion zone passes through the gasoline-air mixture at a finite velocity. The steepness of the oxygen curves is affected by

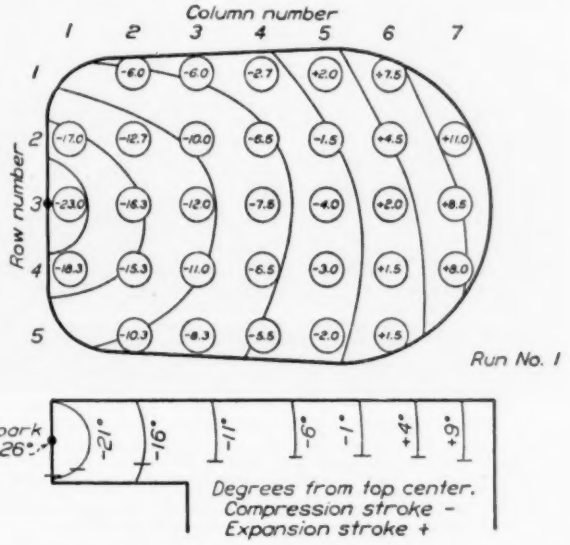

FIG. 3 TYPICAL FLAME DIAGRAM

(The circles on the plan view of the combustion chamber show the locations of the windows. The stroboscope reading within each circle indicates the position of the engine crank, in degrees from upper dead center, when the flame first becomes visible under the corresponding window. A vertical section through the middle of the combustion chamber is also drawn. In the absence of any information as to the curvature of the flame front in this view, it has been represented by circular arcs drawn about the point of ignition. Horizontal dashes show the level of the top of the piston for successive positions of the flame and indicate the extent of piston movement during a normal explosion.)

various factors, such as the duration of the valve opening and the fact that each sample averages numerous cycles, but the curves indicate that the combustion zone propagated through the mixture is comparatively narrow. These particular curves, obtained under identical conditions except that in one set tetraethyl lead was added to the gasoline to suppress knock, indicate definitely that detonation occurs in the

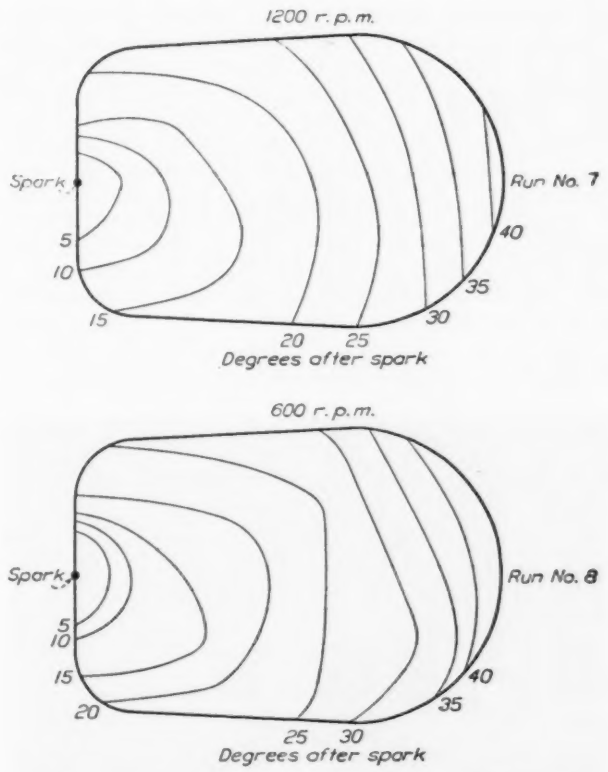

FIG. 4 EFFECT OF ENGINE SPEED ON FLAME DIAGRAMS

(The time required by the flame to cross the head is 12 milliseconds at an engine speed of 600 rpm and less than 6 at 1200 rpm. In a bomb of the same dimensions as this combustion chamber, the time required is 60 milliseconds.)

part of the charge which burns last and are not inconsistent with the view that the combustion zone travels more rapidly through the last one-fourth of the combustion space in detonating explosions than in non-detonating explosions. The curves reproduced in Fig. 2 indicate that, in normal combustion, the combustion zone travels at an average speed which varies, over the range studied, directly with engine speed. At any engine speed, combustion proceeded through the middle of the combustion chamber at an accelerated rate until it was more than one-half of the way across the chamber, and then traveled the remaining distance at a decreasing rate of speed. The combustion zone proceeding along the wall of the combustion chamber was found to travel the entire distance at an accelerating rate.

Visual or photographic observations of the appearance of flame at each of several windows in the combustion chamber of an engine have been made with the aid of a stroboscope by Ricardo

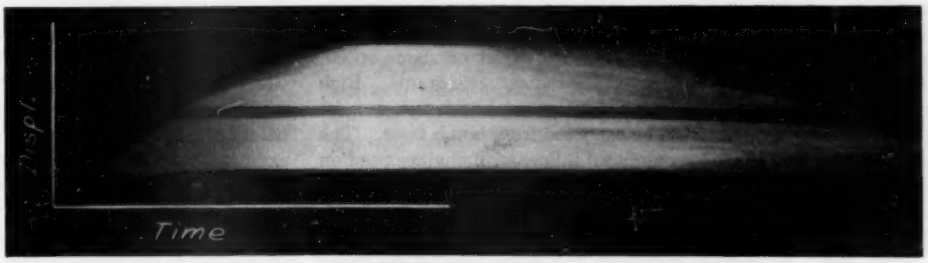

FIG. 5 PHOTOGRAPHIC RECORD OF EXPLOSION IN BOMB

(This time-displacement record of the progress of combustion down the middle of a closed bomb, similar in shape to the combustion chamber of the engine, shows the slow start of the flame, its acceleration to a maximum speed near the center of the combustion chamber, and its decreasing speed during the later portion of its travel.)

(20), Glyde (21), and Horning (22). Ricardo observed that detonation appeared only after the flame had nearly completed its travel. In work done at the Bureau of Standards for the National Advisory Committee for Aeronautics, Marvin and Best (23) provided an ell-head engine with a special water-cooled head in which were inserted 31 quartz windows symmetrically distributed over the combustion space. The work covered by the report cited was done with non-knocking gaseous fuels and with a symmetrical combustion chamber of uniform thickness, but it has been extended since to include liquid fuels, four different designs of combustion chamber, and the effect of spark position and of dual ignition. A typical flame diagram and the data used in plotting it are shown in Fig. 3. The stroboscope setting for the first appearance of flame at each window is determined and a simultaneous measurement of cylinder pressure is

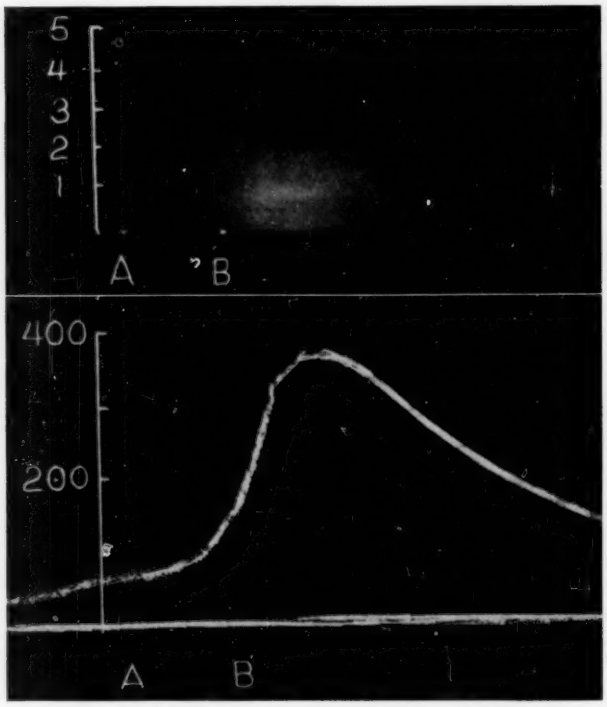

FIG. 6 RECORD OF A NORMAL EXPLOSION

(These records of flame movement and pressure development are for a single non-knocking explosion in an engine operating on benzene. The vertical scales are, respectively, distance from the spark plug in inches and pressure in pounds per square inch. The horizontal scale is degrees of crankshaft revolution, the distance *A*-*B* being 20 deg.)

made with the balanced diaphragm pressure indicator (24). Both flame and indicator diagrams thus obtained, for a given set of engine operating conditions, are reproducible, but they necessarily are averages and give no information regarding variations from cycle to cycle. Compression ratio, charge density, and spark advance were found to have little effect on flame speed, although having marked effects on the indicator diagrams. Rich or lean mixtures and increased dilution with exhaust gas decrease flame speed, as would be expected from bomb tests. The outstanding effect is the pronounced influence of engine speed on flame speed. As shown in Fig. 4, the flame crosses the head in about the same number of degrees of crank angle, or in about one-half the time, at 1200 rpm as at 600 rpm. Possibly the increase in engine speed, by greatly increasing the raggedness of the flame front, enables it to ignite a given volume of charge in a much shorter time. In a bomb of the same dimensions as the combustion chamber used, the average flame speed is less than one-tenth of that in the engine at 1200 rpm. All of the time-displacement diagrams for the engine exhibit the same characteristics as the left-hand boundary of the photographic bomb-explosion record shown in Fig. 5. The flame starts slowly, accelerates to a maximum speed near the center of the combustion chamber, and decreases in speed during the later portion of its travel.

A large number of photographs of combustion in a gasoline engine, as it appeared through a narrow quartz window that

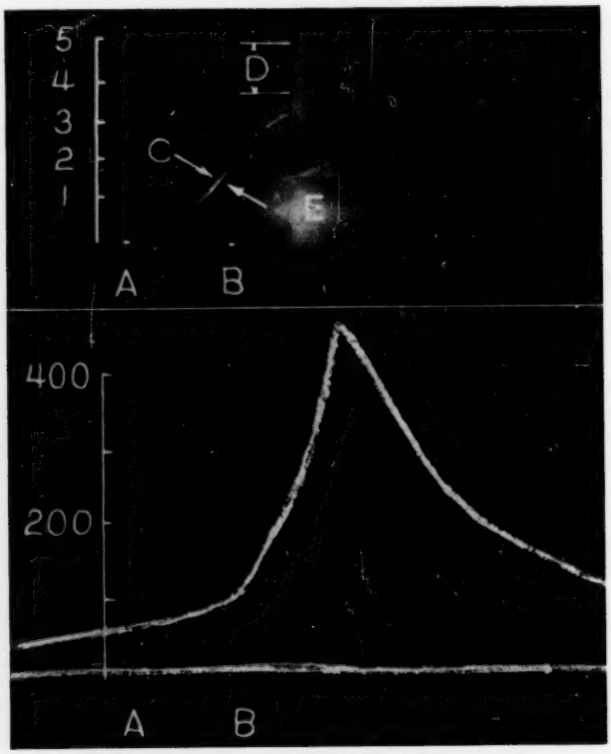

FIG. 7 RECORD OF A DETONATING EXPLOSION

(These records of flame movement and pressure development are for a single knocking explosion in an engine operating on gasoline. As in Fig. 6, the vertical scales are in inches and pounds per square inch and the horizontal scale is in crankshaft degrees. In the upper record, *A* is the ignition spark and *B* is a second spark 20 deg. later, *C* indicates the combustion zone prior to knock, *D* the detonating zone, and *E* the afterglow.)

extended over the entire length of the combustion chamber, with simultaneous records of pressure development have been obtained by Withrow and Boyd (25). These remarkably complete records of individual explosions were secured by using the electrical pressure indicator of Martin and Caris (26) in synchronism with a new combustion camera. The special water-cooled cylinder head, with its removable quartz window, carried the camera, while the pressure element was incorporated into the spark plug. The combustion chamber was a tapered wedge with the broad end over the valves and the thin narrow end at the far side of the piston. The window included a view of the spark-plug gap which was over the intake valve. Fig. 6 shows a record of a normal explosion in which a benzene-air mixture was ignited 20 deg before top dead center, and Fig. 7 shows a record of a detonating explosion with gasoline as the fuel. On the upper record in each case *A* is the spark which fired the charge and *B* is a second spark 20 deg later to establish the time scale. These two reference points are marked automatically on the pressure record also. Distances on the upper record are given in inches, and the pressure scale on the lower record is in pounds per square inch. Each flame photograph shows the projection of the combustion zone and a more or less extensive region of "afterglow," indicated,

respectively, by *C* and *E* in Fig. 7. *D* in this figure represents the detonating zone. Visual observations of explosions, by the aid of a rotating mirror, show the combustion zones more clearly because they are greenish blue, while the afterglow is a bluish white or a reddish yellow, depending upon the mixture ratio.

The records presented by Withrow and Boyd, covering the entire range from normal combustion to severe knock, indicate that a relatively narrow combustion zone starts at the spark plug and moves progressively through the charge. Oxidation of the

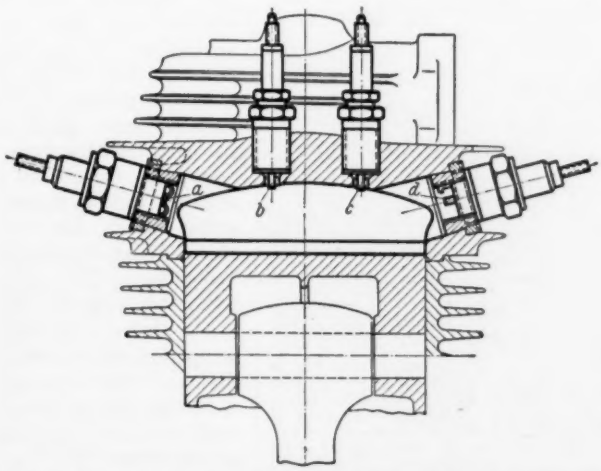

FIG. 8 COMBUSTION CHAMBER, SH-13 AIRCRAFT ENGINE CYLINDER

fuel is apparently complete within this zone, but the products of combustion to the rear of the flame front continue to emit light for some time. A knocking explosion differs from a normal explosion only in the way the last portion of the charge burns. Withrow and Boyd state this difference substantially as follows: Whereas in a non-knocking explosion the flame continues to move at a comparatively constant rate to the end of the combustion space, in a knocking explosion the latter portion of the charge inflames at a much higher rate than normal. According to their records, this rate was often so high that at the instant of knock the flame appeared simultaneously throughout that portion of the charge still remaining to be burned. The extremely high rate of inflammation in that portion of the charge which burns at the instant of knock is attributed to auto-ignition occurring within it. The authors' remaining conclusions are summarized in the next three sentences. The violence of the knock is determined by the proportion of the total charge involved in the spontaneous inflammation, or the amount remaining to be burned at the instant knock occurs. The very rapid inflammation of this last portion of charge is accompanied by a very rapid rise in pressure, and the magnitude of this pressure rise increases along with the intensity of the knock. The sole effect upon combustion of the presence of tetraethyl lead in the gasoline is to prevent the extremely rapid inflammation of the latter portion of the charge and the accompanying abrupt pressure rise.

An electrical method of measuring the rate of flame propagation in engine cylinders was developed at the Bureau of Standards in 1919, and preliminary data were published by MacKenzie and Honaman (27). A Liberty aircraft engine cylinder was provided with three spark plugs, one of which was used to fire the charge, while the arrival of the flame at each of the observing plugs was detected by ionization of the gap and recorded on an oscillograph. Turbulence effects with velocities ranging from 1 to 4 meters per second were observed, and it was found that the time intervals recorded were abnormally short when the engine was knocking violently. The somewhat erratic results obtained were due partly to inadequate control of engine-operating conditions. Recently further work on flame propagation by the ionization method has been conducted at the German Aeronautical Research Establishment (D.V.L.) by Schnauffer (28, 29). He used a Siemens and Halske Sh-13 aircraft engine cylinder, equipped with one firing and three measuring plugs, as shown in Fig. 8. The influence of mixture ratio, engine speed, turbulence, compression ratio, and fuel composition on rate of flame propagation were studied, and the results accord with those obtained by Marvin and Best. Measurements of flame propagation and pressure development under normal burning and knocking conditions obtained by Schnauffer confirm the photographic records of Withrow and Boyd. One oscillograph record, indicating that ionization of gaps *C* and *D* was nearly coincident with the development of maximum cylinder pressure, is reproduced in Fig. 9.

The spectroscopic study of visible radiation from a quartz window in the combustion chamber of an engine was begun at the Massachusetts Institute of Technology in 1926 by Clark and Thee (30) and was continued by these investigators and their co-

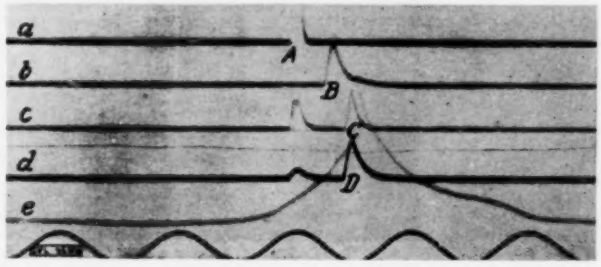

FIG. 9 OSCILLOGRAPH RECORD OF A DETONATING EXPLOSION

workers for several years. However, they were not in a position to distinguish between radiation from the flame and radiation from the products of combustion. Recently Withrow and Rassweiler (31), using with a stroboscope disk the special cylinder head developed for photographing the progress of combustion, have made separate spectroscopic studies of the flame fronts and afterglows of explosions produced with several fuels in a gasoline engine.[4] Referring to Fig. 10, spectrum 12, which represents the flame front of gasoline burning in the engine under non-knocking conditions (spark advance 10 deg) shows the CH and Swan C_2 bands characteristic of the inner cone when gasoline is burned in a blast burner. Spectrum 11, obtained from the flame front of gasoline burning under knocking conditions (spark advance 25 deg), shows the CH and C_2 bands very faintly and a heavy continuous spectrum at the red end. Spectrum 13, obtained under the same test conditions as spectrum 11 except that the knock was suppressed by adding Ethyl fluid to the gasoline, is practically identical with spectrum 12 if the lead lines and the lead-oxide bands are neglected. Spectrum 17 is the flame spectrum of lead, given for comparison with spectra 13–16. Spectra 25–28 in Fig. 11 represent the afterglows (*E* in Fig. 7) in the combustion of gasoline and benzene. It will be seen that these spectra re-

[4] In an article on the "Emission Spectra of Engine Flames," which appeared after this paper was written, Rassweiler and Withrow report the extension of their spectrographic studies into the ultraviolet. They find bands characteristic of free OH radicals present in both flame-front and afterglow spectra. See *Ind. & Eng. Chem.*, 24, 528 (1932).

semble the spectrum of the carbon-monoxide flame front much more closely than that of the gasoline flame front. Hence it appears likely that spectra 25–28 are due to CO, CO_2, or O_2. The authors state that "the afterglow spectrum is emitted by the same molecules as those which give off light during the reaction between carbon monoxide and oxygen. At present it appears probable that carbon dioxide molecules are the emitters." The luminescence of the products of combustion in a gas engine on successive compressions noted by David and Davies (32) may be significant in connection with the increase in intensity of the afterglow as cylinder pressure approaches a maximum.

A study of infra-red radiation from the engine cylinder during combustion was undertaken at the Bureau of Standards last year by Steele (33). The apparatus used by Marvin and Best was modified so that the total radiation transmitted by a fluorite window in the cylinder head could be passed through the stroboscope and focused on a sensitive vacuum thermocouple which was connected with a suitable galvanometer. The variation in total radiation (up to 11μ) through the explosion period was determined first, and then the energy in certain regions was investigated with the aid of suitable filters.

Preignition, defined as ignition from any source prior to the passage of the ignition spark, has been discussed very fully by

Spectrum 18 Gasoline flame front in detonation zone, engine knocking
Spectrum 19 Carbon-monoxide flame front in detonation zone, engine not knocking

Sparrow (34). With some fuels, especially hydrogen, preignition may be due to spontaneous ignition, but it is usually caused by the presence of hot spots in the cylinder, such as an improperly cooled exhaust valve or an overheated spark-plug electrode. Slight preignition may cause only a small reduction in engine power such as would result from an excessively advanced spark. However, mild preignition is likely to grow worse rapidly with progressive loss in power. Fig. 12 shows an indicator card taken in the altitude laboratory at the Bureau of Standards with an

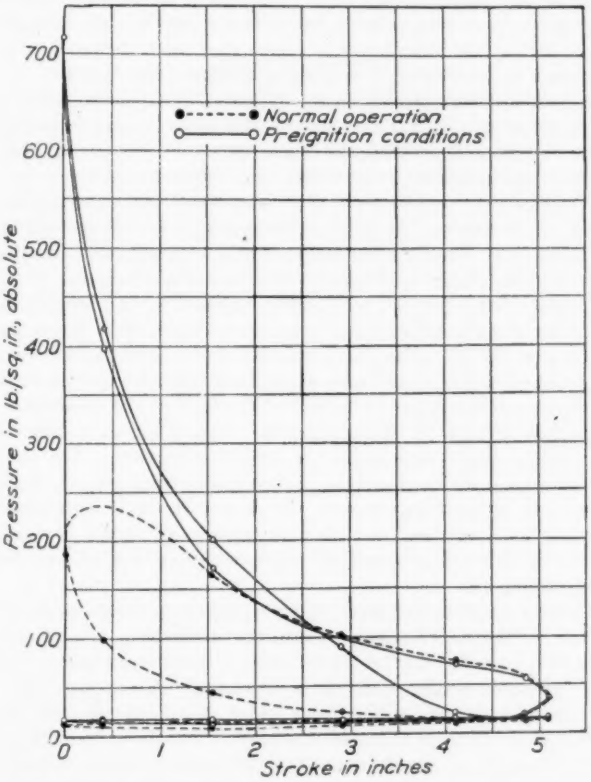

FIG. 12 EFFECT OF PREIGNITION ON INDICATOR CARD

Tests were made on individual cylinders of a multi-cylinder engine in the altitude laboratory at the Bureau of Standards. Engine speed, 1600 rpm. Compression ratio, 8.3 to 1. Barometer, 57.8 cm. Hg (corresponding to an altitude of 7000 ft). The power developed in the preigniting cylinder was negative.]

engine preigniting. The power developed in the preigniting cylinder was negative, and a portion of the power developed by the other cylinders was employed in overcoming the resistance which it offered. Severe detonation may result in preignition, but these are separate and distinct combustion phenomena. Preignition occurs prior to the passage of the spark, and detonation seldom earlier than 30 deg after the spark.

In regard to detonation in aircraft engines, the report made to the Society of Automotive Engineers five years ago by a Research Sub-Committee on the Causes and Effects of Detonation (given in the appendix to this paper) still remains substantially true today. The present review shows that our knowledge regarding combustion processes in engines has been made more definite and that promising new lines of attack on the problem have been developed, but it still appears that we do not know exactly what detonation is nor precisely how anti-knock dopes act. It has not even been established beyond controversy that the Berthelot detonation wave ever is set up in the engine cylinder.

Appendix

RESEARCH SUB-COMMITTEE REPORT ON THE CAUSES AND EFFECTS OF DETONATION

Fundamentally, detonation is a type of combustion which is abnormally rapid as compared with what may be called normal or non-detonating combustion. The behavior seems somewhat analogous to the difference between the slow burning and detonation of many common explosives. Just what mechanism is responsible for the speeding up of the reaction or some part thereof has not, in our opinion, been at all definitely established, although many ingenious theories have been set forth. It is known, however, that detonation is increased by increasing the temperature or the pressure of the charge during the time of the explosion, which may be brought about in many different ways. The presence of localized hot spots or an increase in the length of flame travel also tend to increase detonation. Detonation varies greatly with mixture ratio, generally passing through the maximum between the point of maximum power and that of maximum economy.

Probably the greatest single factor which influences detonation is the chemical composition of the fuel, but even here there are apparently few generalizations which can safely be made. Apparently those paraffin hydrocarbons which occur in many straight-run gasolines tend to knock badly, while certain other paraffin hydrocarbons are good antiknock fuels. As a class, the naphthene, aromatic, and olefin hydrocarbons which occur in many straight-run or cracked gasolines tend to knock distinctly less than the normal paraffin hydrocarbons.

A great many elements and compounds have the quality of affecting detonation profoundly. While no hard and fast statements can be made, it appears in general that the anti-knock property is fundamentally a property of the individual element, although it is modified to a certain extent by the form of the compound in which the element occurs. Thus many, though not all, compounds of nitrogen have a moderate anti-knock effect, and practically all volatile compounds of iodine, selenium, tellurium, nickel, cobalt, tin, and lead have marked anti-knock effects, some of them being effective even when present in extremely small quantities.

The effects of manifestations of detonation are, first, a disagreeable noise, varying from a slight "ping" to a very loud clatter, a loss of power if knocking is at all severe, and a tendency to overheat the engine and the cooling water. If marked detonation continues, this overheating frequently results in preignition, which is, however, an entirely separate phenomenon. In extreme cases, mechanical effects such as breaking of spark-plug porcelains, the actual rupture of piston heads, and damage to bearings or other structural parts of the engine may result.

Probably the most important effect of detonation is an indirect one, in that it limits the compression pressure which it is practicable to embody in an engine to give satisfactory performance with ordinary commercial fuels, and this, in turn, seriously limits the fuel economy which could be obtained if this limitation could be removed.

One of the most serious problems in connection with detonation is that of accurately comparing the detonation characteristics of different fuels. This is complicated by the fact that so many factors in engine design and operation have their several effects on detonation; but many laboratories are now working on this problem, and while we do not believe that any entirely satisfactory standard method has yet been developed, this should be worked out to a satisfactory point within the next year.

Future work directed toward the solution of this problem should largely proceed along four lines:

(1) The development of a standard and reproducible method of testing and rating anti-knock fuels
(2) Modification of engine design to make it possible to get higher compression pressures with a given fuel without detonation
(3) Modification of the fuel in the direction of making it stand higher compression pressures in a given engine without detonation
(4) Fundamental research to determine the mechanism of detonation and its prevention.

Discussion

EDWARD ADAMS RICHARDSON.[5] In a paper presented before the National Oil and Gas Power Meeting of June 8, 1932 ("Heating Fuels for Injection Engines"), the writer discussed basic theories of combustion. Reference should be made to this paper by those interested in combustion processes.

In discussing detonation waves, it is most important to note their high velocities, from over 3000 fps to as high as 9000 fps. The writer believes that Withrow, Boyd, and others have been misled into believing that spontaneous self-ignition occurs ahead of the combustion wave when detonation sets in, owing to failure to realize how high these velocities may be. In the Withrow-Boyd photographs of flame progress, for instance, the apparently vertical combustion line at detonation would make an angle of 0.001 to 0.003 radian with the vertical if we deal with a wave phenomena. It would require careful measurement to detect such a small angle. Furthermore, these same photographs uniformly showed a fillet between the normal combustion region and the "vertical" line. This fillet points very plainly toward a very high rate of flame-front acceleration, not to self-ignition of the mass. Furthermore, a study of the flame-front reaction as a chemical process affected by temperature, density, and wave motions in the gases shows that high rates of flame acceleration are possible. This being true, it must be realized that a flame front is a form of discontinuity in a gaseous mixture which tends to increase. It is highly improbable that even a homogeneous mixture at nearly uniform temperature as high as the ignition temperature could ignite uniformly and instantaneously throughout the mass. Any slight temperature difference tends to increase due to chemical action rates which differ, and such a tendency leads naturally to the development of a flame front. The only stable phenomena in a homogeneous or heterogeneous mixture is the tendency to develop a flame front based on the element of volume most favorably situated. Several flame fronts may start from several elements, but the element most favorably situated grows faster than the others until it dominates the scene. Other reasons will be found in the paper referred to.

The increase in the rate of combustion with engine speed deserves comment. It must be obvious that turbulence will be substantially directly proportional to the engine speed. Hence, for a given engine configuration, the space displacement of an element of the gas will be roughly constant for a given crank position irrespective of speed. As normal combustion flames are very slow affairs, while the circulation of the contents of a combustion chamber is much more rapid, it should not be particularly surprising if the flame is distributed throughout the combustion chamber largely by the circulation. Fig. 4 shows a lack of symmetry easily explainable by normal circulation. We need more data on air movement in engines during combustion. Such data are of basic importance. If a slow flame is distributed largely by circulation, and the circulation is a function of crank position rather than speed, the observed effect is accounted for approximately.

With respect to the effect of dopes, reference should again be made to the paper noted. There the mechanism of chemical reaction from the kinetic theory point of view is discussed, and the probable action of dopes is developed. A vaporized substance of high self-ignition point which can dissociate with the absorption of energy at a proper temperature is shown to have the ability, even in small quantities, of almost instantaneously absorbing energy which otherwise would be utilized in the work of accelerating the flame velocity to that corresponding to detonation. A very slight delay in energy liberation is sufficient to permit the gas to burn normally, whereas otherwise it would detonate. This suggestion deserves further consideration, for it is based squarely on the most basic principles of physics and chemistry and is in line with the mathematical requirements of the kinetic theory. The effect is similar to that which occurs at the critical point on the heating of steel. At this point the temperature rise is halted while energy is absorbed for molecular changes.

With regard to the suggestion that we do not know whether Berthelot detonation waves are ever set up, the writer is convinced that the Boyd pictures require it. Also, the pressure effects noted may be higher than any theoretical mean pressure obtainable. This is only possible when a flame front is involved having high velocity which is brought to a halt at the walls, and calculation shows that the flame velocity must be of the order of the detonation-wave velocity. The kinetic theory practically demands such an effect. It requires work and time to accelerate a flame front.

The writer showed, in the paper referred to, that any fuel could be burned without detonation provided it were introduced into the cylinder by injection while at a temperature above the self-ignition temperature corresponding to the conditions existing in the combustion chamber. Hence he recommended such heating,

[5] Bethlehem, Pa. Jun. A.S.M.E.

particularly for injection engines, as an alternative preferable to fuel choice, modification, or the use of dopes.

In the same paper it is shown that this degree of heating and mode of injection would eliminate dependence on spark plugs or the temperature of the compressed air for ignition and so would secure that wide range of choice of compression ratios considered desirable by the designer and operator of engines.

Obviously, the writer considers the Research Sub-Committee Report on Causes and Effects of Detonation very much out of date in many respects. A reexamination of available data appears to be in order, and a new report is desired.

Author's Closure

The lack of symmetry in Fig. 4 which Mr. Richardson mentions merely indicates a normal circulation or swirl of the charge conditioned by the geometry of the combustion chamber, but the primary effect of turbulence on flame speed may be a local mixing which materially increases the effective depth of the reaction zone at the higher engine speed.

Mr. Richardson is quite justified in pointing out that such records as Fig. 7 and Fig. 9 do not require the assumption of spontaneous inflammation of the charge remaining at the instant of knock. If a detonation wave were set up, this would give similar records, but we cannot agree that the records which were obtained by Withrow and Boyd necessarily involve the Berthelot wave.

In addition to the references contained in the paper, it may be of interest to note that the National Advisory Committee for Aeronautics has recently issued as Technical Memorandum No. 694 a translation of a further report by Duchene under the title, Combustion of Gaseous Mixtures. American Chemical Society Monograph No. 61 ("The Catalytic Oxidation of Organic Compounds in the Vapor Phase," by Marek and Hahn) contains a chapter on The Cause and Suppression of Knocking in Internal-Combustion Engines which considers several proposed mechanisms of hydro-carbon oxidation and discusses various theories which have been advanced to account for detonation and for the action of knock inducers and knock suppressors.

AER-55-10

Developments in Aluminum Alloys in Relation to Economies in Aircraft Construction

By C. F. NAGEL, Jr.,[1] and G. O. HOGLUND,[2] PITTSBURGH, PA.

This paper reviews the mechanical properties and corrosion resistance of available aluminum-alloy structural materials, and as to the fabricating situation, discusses the status of technical information, equipment, and practices (forming, jointing, and corrosion prevention). A summary coordinates these matters to show what has been accomplished and the general direction of present developments, with the thought that the present lull in production provides an opportunity to plan for the future and conduct the indicated experimental work. The discussion is limited to the structural parts of aircraft, such as fuselage and wing and control surfaces, omitting power plant, landing gear, and accessories.

PRIOR to 1923 there was available only one strong aluminum alloy, commonly known as duralumin (17ST). The quality of this material has gradually improved. The present specifications give a minimum yield point of 30,000 lb per sq in. for the common gages of sheet, but the 1920 specifications guaranteed only 25,000 lb. The tensile strength of all 17ST sheet produced during 1923 averaged 56,600 lb per sq in., but for 1931 the figure was 60,000 lb. By improvement in internal soundness and elimination of surface imperfections, workability has been bettered, and hence uniformity in fabrication.

Then came Alclad 17ST sheet, introduced in 1927. This provided a material of greatly enhanced corrosion resistance, at a sacrifice of about 10 per cent in strength. In 1928 17SRT sheet was made available. This possesses a guaranteed minimum yield point 40 per cent greater than that of 17ST. The structure of the U.S.S. *Akron* was fabricated from this material.

Now a new alloy, 24S, in development for the past two years, will be placed on the market. This is also of the duralumin type, but has much higher strengths than 17ST. It will be available in four grades, 24ST, 24SRT, Alclad 24ST, and Alclad 24SRT. There is also now available a new aluminum-alloy tube (17SRT) having a guaranteed minimum yield point of 52,000 lb per sq in. Table 1 gives the typical or average mechanical properties of 24S in comparison with 17S.

Corrosion Resistance

So gradually has the change come about, it probably is not realized that the corrosion resistance of 17ST has been improved greatly during the past few years, particularly that type described as "intercrystalline embrittlement." Only rarely do we now find, when the product heat treated by the manufacturer[3] is subjected to severe corroding influences, that the resulting attack is of this nature. The principal reason for this lies in improved heat-treating equipment and technique and a more complete knowledge of the subject. The same trend has been true of the product heat treated by the various fabricators,[3] though naturally this has trailed behind to some extent.

With the production of Alclad 17ST (1927) an improvement of an entirely new magnitude was effected. Fig. 1 shows the appearance of 17ST and Alclad 17ST sheet samples that have been constantly in salt spray for $3^1/_2$ years for one group and 5 years for another set. The superiority of the Alclad 17ST is evident.

Fig. 1 shows four samples. In all four cases the test samples were exposed in the bare state, without protecting coating of any kind. Beginning at the left side these are described as follows:

1 Alclad 17ST channel made from 20-gage sheet. This sample was exposed to 20 per cent salt spray for 5 years. Metal is stained, but still entirely sound.

2 This channel was made from 20-gage 17ST sheet and shows the effect of corrosion after the same exposure as sample 1.

3 This is a riveted joint made from two pieces of Alclad 17ST sheet and a 17ST rivet $^3/_8$ in. in diameter. This sample has been exposed to 20 per cent salt spray for about $3^1/_2$ years. The absence of corrosion attack on the surface and the cut edges of the sheet, as well as on the 17ST rivet head, should be noted.

4 This joint is similar to that of sample 3, except that it was made from $^1/_{\text{c}}$-in. 17ST sheet. The exposure was the same as that for sample 3. The severe corrosion attack on the surface and edges of the sheet, as well as on the rivet head, should be noted.

Just as 17ST equals 17SRT and Alclad 17ST equals Alclad 17SRT in corrosion resistance, so 24ST equals 24SRT and Alclad 24ST equals Alclad 24SRT. It is necessary to indicate the relationship of the 24S group (bare and Alclad) to the 17S group. To be technically correct, it should be said that each grade in the 24S group is a trifle inferior in corrosion resistance to its counterpart grade in the 17S group. However, test data indicate that

TABLE 1 AVERAGE MECHANICAL PROPERTIES OF 0.064-IN. SHEET

	Yield point, lb per sq in.	Ult. ten. str., lb per sq in.	Elongation, % in 2 in.
17ST	36,000	60,000	20
Alclad 17ST	33,000	54,000	18
17SRT	45,000	61,000	14
24ST	43,000	65,000	20
24SRT	53,000	68,000	14
Alclad 24ST	39,000	60,000	17
Alclad 24SRT	48,000	62,000	13

[3] By "manufacturer" is meant the materials (sheet, tube, etc.) producer, while "fabricator" refers to the aircraft plant.

---

[1] Technical Director, United States Aluminum Company. C. F. Nagel, Jr., was graduated from Cornell University in 1915 with the degrees of A.B. and B.Chem. He has been with the Aluminum Company of America since that date, except for two years of service with the United States military forces. His activities in the Aluminum company embraced development, manufacture, and exploitation of aluminum and aluminum-alloy products, with especial attention to use of these products in the aircraft industry.

[2] Associate Engineer, Aircraft Development Aluminum Company. G. O. Hoglund, after graduating from the University of Michigan in 1925, took a position in the Bureau of Aeronautics, Navy Department, working on the design and development of propellers for naval aircraft. In 1928, he was transferred to the engineering department at the Naval Air Station, Lakehurst. This led to an appointment as assistant professor of aeronautical engineering at the University of Minnesota in 1928–1929. Since that time he has been with the Aluminum Company of America, working first on the application of the aluminum alloys in the aircraft field and since January, 1932, in charge of the welding development division.

Contributed by the Aeronautic Division of The American Society of Mechanical Engineers and presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

this difference is so small as not to warrant any difference in fabricating procedure, the difference being especially small when comparing the Alclad grades. With 24S or Alclad 24S the heat-treating temperature is somewhat lower, namely 920 F, than in the 17S group.

Forms, Dimensions, and Uniformity

Prior to 1923 duralumin (17ST) was available in all forms such as sheet, tube, extruded shapes, and rivets, but the available

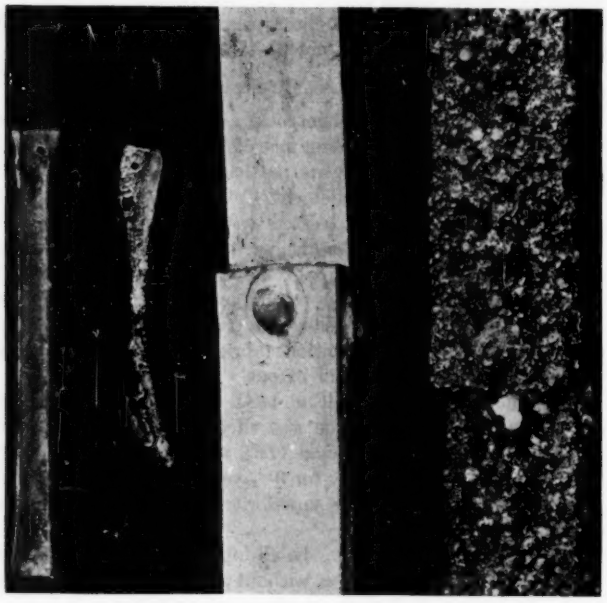

Fig. 1 Sample Sheets in Corrosion Test

sizes were limited. These dimensions have since been extended, and sheet is now available much wider and longer and in lighter gages, permitting reduction in joints and weight and improvement in appearance, especially as improved flatness has been accomplished. There is a greatly increased range of streamline tubing and other shapes, and data regarding their characteristics have been developed. In extruded shapes much thinner sections are now possible, permitting of more efficient metal distribution.

Technical Knowledge in Fabricating

Prior to 1923 the aircraft industry naturally was unfamiliar with the aluminum alloys, and in fact the available knowledge was quite limited. With few exceptions aircraft plants possessed little or no metal-fabricating equipment. During the following period an enormous amount of experimental work and practical experience has been accumulated and disseminated. The various government bureaus, the many units in the aircraft industry, the raw-product manufacturers, and scientists all over the world have concentrated upon solving the problems involved.

The past ten years has seen most aircraft plants equipped with aluminum-fabricating equipment. A new class of experienced workmen has been created, versed in the technique of manipulating the light alloys. Where ten years ago the mere task of handling aluminum alloys was in itself a formidable problem, these changes, wrought by increased facilities and experience, have been so complete that today it is generally the easiest metal to employ.

Forming

In the earlier stages, the aircraft industry was largely forced to base design on those available materials which needed no further fabrication in their plants except assembly. Hence, sheet forming was carried out only to a minor extent, most of such materials being purchased in the preformed condition.

Gradually, as newer designs called for increased amounts of the light alloys, and as production warranted, the fabricator installed his own forming equipment. Next, based on the new facilities accumulated meanwhile, designs were altered to permit more efficient use of metal, the parts being formed in the aircraft plant.

While details differ from plant to plant, the sequence of fabricating operations on sheet now generally consists of heat treating, flattening, shearing, and shaping.

As duralumin is more workable promptly after quenching, the four operations are so coordinated that a piece of sheet will go through them in not over one hour. Certain intricate parts may require shaping while in the annealed state and heat treating thereafter, and also some fabricators make various details from material as received from the manufacturers in the heat-treated state.

It also has been the general practice to heat treat the rivets just prior to use; though where strengths and freedom from danger of corrosion permit, a modified or dilute form of duralumin rivet is employed which may be driven in the heat-treated and fully aged condition.

The practice of eliminating heat treatment in the fabricator's plant and forming heat-treated sheet as received from the manufacturer has been gaining adherents, and rightly so. The reason this has not come into more widespread use is a combination of lack of appreciation of the degree of forming that can be so accomplished and the occasional necessity of allowing for a little larger radius in the design, with its attendant tool change. An illustration of what may be accomplished is the forming in the girders used in the construction of the U.S.S. *Akron*. The material is 17SRT sheet, which possesses a workability not quite so high as that of 17ST. Fabrication consisted simply of shearing the sheet to required width and length, and then putting it through the forming operations. This material was not heat treated in the fabricator's plant. Compared to the previously mentioned procedure, this reduces fabricating costs and insures maximum corrosion resistance.

Jointing

The standard assembly procedure to date has been by means of rivets and bolts. Considerable progress, however, has been made in the direction of improving heat-treating technique, so that corrosion resistance has been improved, and in developing more efficient riveting technique and equipment, which have lowered costs. A unique advance along this line is the patented automatic riveting machine developed by the Aircraft Development Corporation and employed in the assembly of the 0.0095-in.-thick Alclad 17ST skin of the Metalclad *ZMC-2*. This apparatus took three strands of 0.035-in.-diameter A-17ST wire and sheared off the rivet lengths, punched the necessary holes through two thicknesses of sheet by means of these tiny wire lengths, inserted the wires, and then headed them, all in continuous operation. The spacing also was automatic. This equipment was capable of driving 140 rivets per minute, or about 40,000 per 8-hour shift, and required two operators. Jointing is one of the expensive items of fabrication, and much promise can be held out for reduction in costs by improving upon design and equipment so as to facilitate this process.

Recently, electric spot welding has definitely come into the picture. Considerable experimental work has already been done. At least two planes have been built—one by Nicholas-Beazley Airplane and Motor Company several years ago, and this past

year a plane by the Fokker Aircraft Corporation. Both these planes substituted spot welding to a great extent for riveting. Several aircraft companies, as well as other agencies such as the Aluminum Company of America, are now actively experimenting in developing design and technique. The art has been advanced to a status warranting practical application in the industry. The logical sequence of application would be, first, to secondary joints and then, later, as experience may justify, to more important items. Application of spot welding should greatly reduce fabricating costs.

Merely to indicate the efficiency obtainable from a spot-welded joint, figures are given in Table 2 comparing the tensile strength of spot welds and rivets in Alclad 17ST sheet.

TABLE 2 TENSILE STRENGTH OF SPOT WELDS IN ALCLAD 17ST[a]

Gage	Spots or rivets per in.	Tensile strength, lb[b]	Rivet strength, lb[c]
0.064	1	675	368[d]
0.064	2	1335	736
0.064	3	1940	1079
0.051	1	490	368
0.051	2	914	736
0.051	3	1360	1077
0.032	1	320	300
0.032	2	690	600
0.032	3	880	900
0.020	1	177	140[e]
0.020	2	356	280
0.020	3	528	420
0.016	1	147	112
0.016	2	258	224
0.016	3	406	336

[a] These values are not to be used in design. They only represent actual values obtained and have been included to show that a spot-welded joint in tension possesses about the same strength as a riveted one. [b] Average of four specimens. [c] Calculated. [d] These nine tests are with 1/8-in.-diameter rivets. [e] These six tests are with 3/32-in. rivets.

One may naturally question the effect of spot welding upon corrosion resistance. Spot-welded 16-gage Alclad 17ST sheet placed in a 20 per cent salt spray continuously for one year showed a loss in tensile strength of only 0.86 per cent. While the pure aluminum layer on Alclad 17ST is somewhat pierced during spot welding, the potential difference between the exposed 17S core and pure aluminum protects the spot. This phenomenon naturally indicates the desirability of an Alclad material when spot welding.

Corrosion Prevention

Prior to 1923 this subject was hardly recognized as a problem. In fact, during the early years the principal task confronting fabricators was to use metal at all. While the materials manufacturer was inviting attention to the need of protection, actual troubles had to be encountered before this subject received much consideration; there were enough problems on hand without thinking of protection against corrosion. It is not surprising, therefore, that some corrosion troubles were encountered. However, in keeping with the progressive attitude of the industry, the subject was actively attacked, and in due course of time methods were developed that have proved successful. The peak of corrosion troubles has been definitely passed. This is especially evident upon visiting the larger repair stations and comparing the volume of reconditioning work necessary today with that of previous years.

Seaplanes operating in the tropics represent the most severe type of service to which aircraft are subjected. Constructed largely from normal duralumin, the standard practice today for this service is to anodically treat and shop-prime all details prior to assembly, followed by a second coat of paint after assembly.

To this must be added suitable heat-treating equipment and supervision to insure proper operations in order to obtain maximum corrosion resistance. This system is giving the desired protection. It is recognized, however, that this degree of protection is not necessary for all types of service nor for all parts of planes.

The next developments will be in the direction of reducing the expense of protection. It is not necessary to build landplanes with that same degree of protection required by seaplanes operating in the tropics. Even in seaplanes the superstructure is not subjected to as severe conditions as the boat hulls or pontoons. Experimentation will gradually indicate safe but less costly procedure. Undoubtedly bare Alclad, without any paint except that desired for decorative reasons, will prove entirely satisfactory for most landplanes, and probably also for superstructures in seaplanes. Two coats of aluminum paint applied to both surfaces of a sheet 0.064 in. in thickness will increase the weight by about 4.3 per cent. Also the operation of treating details prior to assembly is costly. However, bearing in mind former materials available and maintenance costs when adequate protection was not provided, these practices have been justified. With the Alclad materials, however, as for example Alclad 24ST and Alclad 24SRT, it will be possible to build lighter and less costly structures.

This should not be interpreted as suggesting any broad-scale let-down in corrosion-prevention practices. The present practices for boat hulls and pontoons should be retained in their entirety. There is warrant, however, to investigate unprotected Alclad materials in landplane structures and superstructures in seaplanes. It is not advisable to use normal duralumin in an unprotected state.

Summary

The past decade has been concerned with introducing aluminum into aircraft. The coming decade will be concerned with applying it more efficiently and at lower costs. It is believed that the direction these efforts will take will be the employment of higher-strength materials possessing greater corrosion resistance with refinement of fabricating technique to reduce cost. The immediate indications are that this will be accomplished by the wider use of Alclad in the form of Alclad 24SRT and Alclad 24ST. Heat treatment in the fabricator's plant will be largely eliminated. Proper use of bare Alclad will greatly reduce expense of protection. Along with this will come an increased application of spot welding, further contributing to reduction in costs. By virtue of the higher strengths of the materials, there will be lighter structures, increasing the pay load.

An illustration follows of approximately what might be expected in a hypothetical plane when fabricated from either 17ST or Alclad 24SRT. With 17ST material, minimum yield point of 30,000 lb per sq in.: Gross weight, 13500 lb. Weight, empty (everything except fuel, oil, crew, and pay load), 7600 lb. Useful load (crew, passengers, oil, fuel, and cargo), 5900 lb. Pay load, 3643 lb. With Alclad 24SRT material, minimum yield point of 46,000 lb per sq in.: Increase in yield point over 17ST, 53 per cent. Decrease in structural weight, 906 lb (0.53 × 3420 lb × 1/2 = 906 lb). Increase in pay load, 906 lb. Pay load, 4549 lb. Percentage of increase in pay load, 24.8.

Calculations have been based on guaranteed minimum yield point. It is realized that there are structural parts in which form failure may occur before the full yield strength of the material will develop, and that the application of a material with a higher yield point in members subjected to compressive loading would not, in general, enable a reduction in weight in a direct ratio to the increase in mechanical properties. Tensile members, however, are not subjected to this limitation. In a composite structure the assumption is made that one-half of the decrease in structural weight that is obtained if a material of higher yield strength is applied can actually be realized in an airplane.

Discussion

R. S. Barnaby.[4] One of the most interesting developments in naval aircraft structures, from the material engineer's point of view, has been that connected with the use of the strong aluminum alloys. It has been an uphill road, at best. Prior to some time around 1920 or 1921 the use of aluminum was avoided because of its susceptibility to corrosion when exposed to sea service. When the American equivalent of duralumin, the German alloy made famous by its use in the Zeppelin airships, was put on the market, it was hailed as the "corrosion-resistant" strong aluminum alloy, and the Navy forthwith incorporated a lot of gussets of this material in some wooden floats for seaplanes. No finish of any kind was used. Results were speedy, conclusive, and disappointing.

Shortly after this sad experience the phenomenon now known as "intercrystalline corrosion" was recognized, and it became apparent that while this high-strength alloy might be more corrosion resistant than some of the other aluminum products, it was not practicable to use it without protection. This brought up the problem of finish—a difficult one because it is notably hard to get paints to stick to aluminum.

One by one these problems have been attacked and solved. Proper heat treatment has been found to practically eliminate intercrystalline attack. The anodic oxide film has not only increased the corrosion resistance measurably, but has improved paint adherence so that it is now possible to get paint coatings to stick satisfactorily. The introduction of Alclad has further strengthened the defenses against corrosion, so that now aluminum alloy is a standard structural material for naval aircraft.

A point, however, that cannot be too strongly emphasized is that extreme care in design, construction, and maintenance is the price which must be paid to obtain satisfactory results. No paint coats are perfect. Most of them are not entirely impervious to water, especially if the water can stand on the coating long enough. Consequently, designs must be such that there are no places where water can be trapped and stand in contact with the material for long periods of time. Undrained ledges, pockets, corners, etc., must be avoided. Seams and lap joints must be completely filled with some protective compound. The use of leather, fabric, or wood in contact with aluminum should be avoided. Where such a combination is necessary, the leather, fabric, or wood used must be impregnated with some water-excluding material so that it will not become water soaked and foster corrosion of the metal.

Probably the most important and at the same time most difficult thing to eliminate is in connection with the use of dissimilar metals in contact. Where such joints occur in the presence of moisture, corrosion is greatly accelerated due to the electrolytic reaction. While copper, brasses, and bronzes are the worse offenders, stainless steel is almost equally bad, and recent serious corrosion in Navy flying boats has occurred where cadmium-plated chrome-molybdenum steel and aluminum alloy have been used in contact with one another.

These various difficulties are mentioned, not in a discouraging vein, but to indicate the practical precautions which years of service have shown to be necessary if the advantages of the aluminum alloys are to be enjoyed in seaplane and seaboard aircraft construction.

The Navy has not found that one coat of primer and one coat of paint are sufficient. At least two coats of paint over the primer are necessary to secure adequate protection. While it appears possible that bare Alclad may be used for many parts of land planes, it should be borne in mind that the aluminum shell does corrode, and that while its corrosion has little effect on the physical properties of the core metal, its appearance, when used in a place where it cannot be kept wiped off and polished, is likely to be disconcerting.

The writer would like to refer to Table 1 and call attention to the fact that the properties listed are the average mechanical properties, and are therefore not figures which the designer may use in the design of aircraft. He must use lower figures—those which the Aluminum Company will guarantee. These will be found to be some 8 per cent lower in the case of the ultimate strengths, 10 to 15 per cent lower in the case of the yield points, and 10 to 15 per cent lower for the elongations. The design or guarantee figures should be added to Table 1 to make it complete for the designer's use.

[4] Lieutenant-Commander (CC), U. S. Navy; Bureau of Aeronautics, Navy Department, Washington, D. C.

Authors' Closure

By C. F. Nagel, Jr. Commander Barnaby states, "When the American equivalent of duralumin, the German alloy made famous by its use in the Zeppelin airships, was put on the market, it was hailed as the 'corrosion-resistant' strong aluminum alloy, and the Navy forthwith incorporated a lot of gussets of this material in some wooden floats for seaplanes. No finish of any kind was used. Results were speedy, conclusive, and disappointing."

I have heard this statement made previously and in some cases, I know, with the belief that the American manufacturer desired to create the impression that duralumin was resistant to corrosion to the extent that it could be used successfully in the bare unprotected state. It so happens that I have been connected with the development and production of duralumin, or 17S, as put out by the Aluminum company, since 1915, which marks the date when this was first done in this country, and hence I am in a position to know the attitude the Aluminum company has taken. Of course, we know far more about this material today than we did in that early period. However, we have at no time advocated the use of this material bare and unprotected. I agree with Commander Barnaby, on the other hand, that in many quarters the impression did exist that duralumin was so resistant to corrosion that it could be successfully used bare and unprotected under a great variety of service conditions. In my opinion, this unwarranted impression arose from rather too optimistic statements in publications, principally those from abroad.

With reference to the statement that "it is notably hard to get paints to stick to aluminum," in some measure this is true, but it might be interpreted wrongly. Normally, aluminum and aluminum-alloy sheets are produced with a much smoother or glossier surface than some other common metals, as for example steel. The adherence of paint to a surface is enhanced by a slight roughness due to a mechanical bond and is conversely made more difficult with increasing smoothness. To this extent, I subscribe to Commander Barnaby's statement. On the other hand, one might interpret this statement as implying that the characteristics of aluminum and aluminum alloys are such as to make it more difficult for paint to adhere to it than to steel. I am quite positive that the opposite is true. The ability of paint to adhere to a metal surface is also influenced by the inherent corrosion resistance of the underlying metal. All corrosion is attended with the formation of corrosion products, and I believe that in most cases these corrosion products, in addition to oxide, consist of gas. The formation of these products, therefore, tends to destroy the bond and to strip off the paint. All the aluminum alloys employed in aircraft possess an inherently greater corrosion resistance than the normal variety of steels, excluding the stainless steels, and I am sure Commander Barnaby will subscribe to the statement that, if the glossy surface will be removed from aluminum, the paint will adhere more readily and retain its integrity better on aluminum and aluminum alloys than on steel.

AER-55-11

Relation of Quality to Economics of Manufacture of Aviation Gasoline

By G. G. OBERFELL,[1] BARTLESVILLE, OKLA.

Quality of aviation gasoline is the problem of the fuel manufacturer and the designer of aircraft engines. Present aviation gasoline is the result of demands for an increase of power output per unit of weight and displacement of aircraft engines. The improved engines represent designs intended to take full advantage of the best grades of gasoline available in sufficient quantities. Any future improvement in gasoline quality should bring about commensurate improvements in gasoline engines. The quality of aviation gasoline is thus setting the pace for improvement in aircraft engines of the spark-ignition type in use at present.

THE quality of aviation gasoline is a mutual problem of the fuel manufacturer and the designer of aircraft engines. The aviation gasoline of today represents the results of improvements in fuel-manufacturing processes as effected by the insistent demand for an increase of power output per unit of weight and displacement of aircraft engines. The improved engines represent designs which are intended to take full advantage of the best grades of gasoline available in sufficient quantities. It is therefore to be expected that any future improvements in the quality of aviation gasoline, if the fuel is available in sufficient quantities, will bring about commensurate improvements of aircraft engines. To this extent, then, the quality of aviation gasoline is setting the pace for future improvements in aircraft engines of the spark-ignition type in present use.

The properties of gasoline essential to good operation of aircraft engines may be listed as follows: 1 A.S.T.M. distillation range, volatility. 2 Reid vapor pressure, vapor lock. 3 Octane number, anti-knock characteristics. 4 Gum content. There are other properties which, while probably not less essential, are common to practically all gasolines, such as absence of entrained water, low sulphur content, freedom from acids, alkalis and non-volatile residues, color, odor, etc. This paper is confined to the four properties first mentioned, since the differences in quality of aviation gasolines are due primarily to differences in those four major properties.

In general the properties of fuel necessary for satisfactory performance of automobile engines are the same as those required for aviation gasoline. It is mainly a question of the magnitude or the degree to which emphasis for the particular property is given. For the purpose of explaining and emphasizing the important characteristics of aviation gasoline, the properties and specifications of motor fuels as well as of aviation gasolines are included in this discussion. The term "motor fuel" refers to gasolines intended for automobile engines. In reviewing properties and testing methods, the author has purposely omitted those tests which have been found by experience to be less significant of the characteristics of the fuel which they were intended to valuate.

A.S.T.M. Distillation Range, Volatility

The A.S.T.M. distillation test (D 86–30) is useful only because it has been correlated with engine performance. The same statement holds true for any satisfactory testing method, because the value of the testing method is limited by the degree to which it has been correlated with actual practice. While the conditions under which the gasoline is distilled in the A.S.T.M. distillation test are vastly different from the conditions under which the gasoline is distilled or vaporized in the induction system of an internal-combustion engine, relations have been established between test results and performance of engines in actual service. The A.S.T.M. distillation test therefore affords a satisfactory measure of the volatility characteristics of gasolines.

It has been found that the 10 per cent, 50 per cent, and 90 per cent evaporated temperatures of the A.S.T.M. distillation test will give the required information regarding the volatility of gasoline. These points are therefore the ones to be considered for specification purposes. A low 10 per cent temperature denotes good starting and contributes to the accelerating characteristics of motor fuels. It is the volatility of that portion of the gasoline up to the 10 per cent point that assures quick starting rather than the 10 per cent temperature alone. In the case of an exceptional fuel having a high vapor pressure, but otherwise little front-end volatility, the vapor-pressure test discussed farther on is a better criterion of the starting qualities than is the 10 per cent point. For this reason, the vapor-pressure test and the 10 per cent temperature are both useful from the viewpoint of ease of starting. The 50 per cent evaporated temperature is a criterion of the warming-up and accelerating characteristics of gasolines. Since these factors depend upon the proportion of fuel-air mixture and its distribution to the engine cylinders, it is more a question of the volatility or actual boiling-point range of a gasoline up to the 50 per cent point than the 50 per cent temperature alone. Therefore, a consideration of vapor pressure and of the 10 per cent and the 50 per cent temperatures is useful in this connection. The 90 per cent temperature has been correlated with the temperature

[1] Director, Research Department, Phillips Petroleum Company. G. G. Oberfell was born in Butler County, Ohio. He received his education in the public schools; 1907–1910, Miami University, Oxford, Ohio, A.B. degree, chemical course; 1908, Chicago University, chemical course; 1910–1912, Miami University; 1914–1915, University of Pittsburgh, physical and organic chemistry. In 1904–1907, he was teacher, Butler County rural schools; 1910–1912, instructor in chemistry, Miami University; 1912–1916, junior chemist, Bureau of Mines, on natural gas by-products; 1916–1917, chemist, natural gasoline industry; 1917–1919, captain, Chemical Warfare Service, toxic gases; 1920–1923, research engineer, natural gasoline industry; 1923–1925, consulting engineer, design of natural gasoline plants; 1925–1932, director, Research Department, Phillips Petroleum Company. Since 1915 he has written for trade journals and technical magazines. The book, "Natural Gasoline," is by G. G. Oberfell and R. C. Alden.

Contributed by the Aeronautic Division of The American Society of Mechanical Engineers and presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

at which condensation takes place from a mixture of gasoline, vapor, and air. This temperature, which is the dew point of the mixture, is of course a measure of the tendency toward dilution of crankcase oil due to the presence of high boiling constituents of the gasoline. Due to the relatively high overall volatility of aviation gasoline and to the high operating temperatures of air-cooled aviation engines, crankcase dilution is not as important to the aviation industry as it is to the automobile industry.

The relations which have been established by many investigators prove definitely that the 90 per cent evaporated temperature is a much better criterion of oil-dilution tendencies than is the A.S.T.M. end point that was formerly used. Specifications which limit the percentage of residue left in the flask

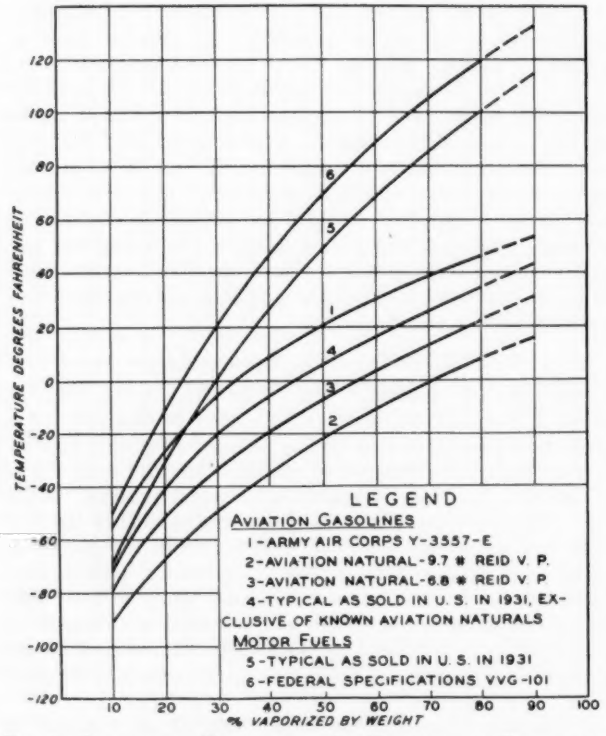

FIG. 1 CALCULATED EQUILIBRIUM AIR-DISTILLATION CURVES FOR AVIATION GASOLINES AND MOTOR FUELS

at the end of the A.S.T.M. distillation test prevent the presence of appreciable quantities of non-volatile residues. However, the distillation processes used by the motor-fuel manufacturers preclude the presence of any non-volatile residue. For this reason no difficulty is experienced in manufacturing gasolines to pass this specification. It is only by accidental contamination with other products that the presence of a non-volatile residue would be encountered.

The A.S.T.M. distillation test is a batch process; as the distillation proceeds, the undistilled portions become progressively less volatile. In the induction system of the engine the gasoline is partially vaporized in an air stream. In order to simulate engine-operating conditions, various investigators have conducted laboratory tests in which there were determined the percentages of gasoline evaporated at different temperatures in a stream of air in which the air-vapor mixture was in equilibrium with the unvaporized portions. Due to the relations which have been established between the equilibrium air distillation and the A.S.T.M. distillation test, it is possible to calculate for various air-fuel ratios the approximate equilibrium air distillation or volatility characteristics of gasoline from the A.S.T.M. distillation test. Calculations of this nature for a 12-to-1 air-fuel mixture are shown for various types of gasolines in Fig. 1. The data show that there is a pronounced difference between the relative volatility characteristics of the various gasolines. Curve 1 is an aviation gasoline complying with specification Y-3557E of the U. S. Army Air Corps, curve 2 represents a natural gasoline product having a Reid vapor pressure of 9.7 lb, while curve 3 is the same natural gasoline product reduced to a 6.8 lb Reid vapor pressure by distilling off part of the pentanes, the components of which are almost entirely responsible for imparting the front-end volatility to aviation natural gasoline. A comparison of curves 2 and 3 shows that in going from 9.7 lb to 6.8 lb there is a noticeable reduction in the overall volatility of the gasoline, which lowers the quality in this respect due to the more rigid 7-lb vapor-pressure specification. Reputable pilots with years of experience claim that there is a very noticeable difference between these two fuels when flying a plane with the surrounding atmospheric temperature below —20 F. Curve 4 represents a typical aviation gasoline as computed from the A.S.T.M. distillation tests of 329 samples obtained as the result of our survey of aviation gasolines marketed in the United States by the major companies during the past year. Curve 5 represents the typical motor fuel sold in the United States during 1931. The gasoline for which curve 6 was plotted coincides with U. S. motor gasoline specifications VV-G-101, which superseded 622A. An inspection of the curves emphasizes the much higher overall volatility characteristics of aviation gasoline as compared with motor fuels.

In the manufacture of gasoline the volatility of the product is controlled by segregation of products, by blending, and by distillation processes. If the gasoline is manufactured from crude oil, the volatility problem is primarily one of eliminating the high-boiling-point constituents or converting those components into low-boiling compounds in order to bring the volatility of the resulting product up to specifications. For the

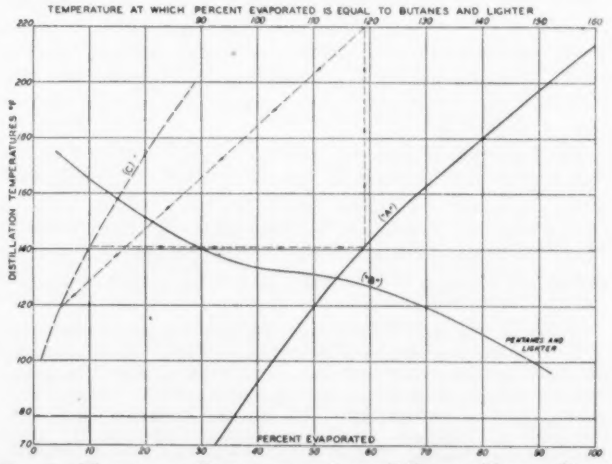

FIG. 2 METHOD FOR DETERMINING A AND B FACTOR VALUES FROM A.S.T.M. DISTILLATION CURVE

gasoline extracted from natural gas or from refinery vapors, the problem is just the opposite in that the low-boiling-point constituents are the ones removed in order to bring the vapor pressure of the gasoline down to the required specifications. In both of these cases a decrease in yield takes place in which the rejected products are wasted or are diverted to uses for which there exists a lower market value. Segregation of products always entails extra equipment and higher operating costs. Demands for higher quality for any commodity should always take into consideration all of these economic factors.

Reid Vapor Pressure, Vapor Lock

The vapor pressure of a liquid is a measure of its tendency to boil. A vapor-pressure test is in effect merely a more accurate and more satisfactory means of determining the initial boiling point of the gasoline than can be obtained by the A.S.T.M. distillation test. Vapor pressure is therefore dependent upon the true initial boiling point and is distinguished from volatility in that the latter is dependent upon the entire distillation range, although for all practical purposes volatility can be defined by the 10, 50, and 90 per cent evaporated temperatures.

Many testing methods have been proposed for measuring the vapor pressure of gasoline, and test results of the various methods have been compared with vapor-lock conditions that would be encountered in the operation of airplanes and automobiles. So far the Reid vapor-pressure method (D 323–31T) has given a better indication of vapor-lock conditions than any of the other methods which have been proposed.

The possibilities of establishing a relation between the A.S.T.M. distillation test and the Reid vapor-pressure test has been investigated by several laboratories. There is shown in Fig. 2 a relation which has been found as a result of work by our research department. This correlation was made possible by having in addition to the Reid vapor-pressure and A.S.T.M. distillation test results, a composition analysis covering the percentages of butane and pentane fractions for 270 samples of motor and aviation gasolines marketed throughout the

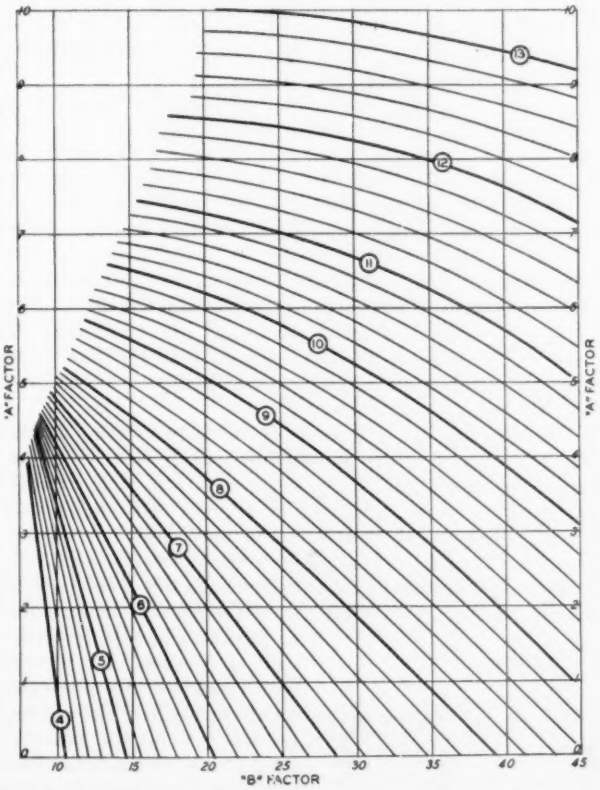

Fig. 3 Reid Vapor Pressure as Indicated by A and B Factor Relationship

United States. A relationship was established between the A.S.T.M. 10 per cent evaporated temperature and the temperature at which was distilled off that volume which was equal to the percentages of butanes and lighter found by actual composition analysis. A similar relation was found for the pentanes and lighter.

An illustration will serve to show how Fig. 2 is used. The heavy dashed curve C is plotted from the A.S.T.M. distillation record of the gasoline for which it is desired to estimate the Reid vapor pressure. The 10 per cent evaporated temperature of this particular fuel as read from the curve is 141 F. A line is drawn horizontally from this 10 per cent evaporated point to the curve A, and at the point of intersection with the curve A another line is drawn vertically to the upper axis which shows a temperature of 119 F as being the temperature in the A.S.T.M. distillation test at which is distilled off a percentage which should be equal to that of the butanes and lighter as found by composition analysis. The volume evaporated at 119 F in the A.S.T.M. test was 4.8 per cent as read from curve C.

The volume evaporated during the A.S.T.M. distillation test which was equal to the percentage of pentanes and lighter is obtained by noting the amount evaporated at the point of intersection of the curve C with the curve B. This point of intersection represents 14.9 per cent evaporated as read from the lower horizontal axis. This figure of 14.9 is a measure of the percentage of pentanes and lighter in the gasoline. To obtain the Reid vapor pressure of the sample refer to Fig. 3. The group of parallel curves represents Reid vapor pressure values. The A factor used as the ordinate denotes the percentage of butanes and lighter. The B factor used as the abscissa is the percentage of pentane and lighter. To estimate the Reid vapor pressure of the sample cited, find the intersection of the ordinate 4.8 with the abscissa 14.9. This point of intersection lies on the curve representing 8.2 lb Reid vapor pressure. The composition analysis and the Reid vapor pressure of the gasoline used in the example were as follows:

	Observed	Estimated
Propane and lighter, per cent	0.5	..
Butane fraction, per cent	4.7	..
Butanes and lighter, per cent	5.2	4.8
Pentane fraction, per cent	10.6	10.1
Pentanes and lighter, per cent	15.8	14.9
Hexane and heavier, per cent	84.2	85.1
Reid vapor pressure, lb	8.6	8.2

There is presented in Table 1 a list of samples selected for the

purpose of showing the wide range of products for which the described graphical method has been found applicable.

Experience with the graphical method of estimating Reid vapor pressures shows that the predicted results are in most cases within the limit of accuracy of the testing method, which is about 0.5 lb. The method is not proposed as a means of eliminating the Reid vapor pressure test, but it does provide an independent check which has been found to give reasonably accurate estimations. It is therefore useful in those cases in which only the results of the A.S.T.M. distillation test are available.

In actual practice vapor locking is occasioned by the rise in temperature of the gasoline in the fuel-feed system. This rise in temperature is caused by heat originating from the engine. If the temperature rise is high enough, the vapor pressure of the gasoline may increase enough to cause boiling and thereby produce vapor locking. One of the difficulties encountered in obtaining a direct measurement of the vapor-lock temperatures from the vapor pressure of the gasoline is explained by the fact that the vapor pressure of the gasoline is lowered by any evaporation loss that takes place from the time that the vapor-pressure test is made until the gasoline is used. These losses occur in transit, unloading, storage, and transfer of gasoline to the airplane. The magnitude of change in vapor pressure of gasoline due to evaporation loss differs for gasolines of widely different A.S.T.M. distillation characteristics. Thus two gasolines having the same original vapor pressure and undergoing the same percentage of evaporation loss might have decidedly different vapor pressures after this loss had been encountered. The gasoline with the flattest A.S.T.M. distillation curve would change less in vapor pressure for any given evaporation loss, and consequently would be susceptible to vapor lock at a lower temperature.

In addition to this ever-changing vapor-pressure condition of all gasolines prior to usage, another complication of determining the vapor-locking temperature from the vapor-pressure measurement is encountered due to the fact that the fuel-feed systems will accommodate a certain amount of vapors due to incipient boiling of gasoline which may take place before vapor lock occurs. Consequently, it is not the original vapor pressure of the gasoline but the vapor pressure of the gasoline after a certain amount of evaporation or boiling has taken place that determines the vapor-locking temperature of that gasoline. Moreover, the amount of evaporation that can be accommodated in the fuel-feed systems without vapor locking varies with the different fuel systems and for the same system under different operating conditions. Despite all of these variables, the Reid vapor pressure has proved to be a fairly good criterion of the vapor-locking characteristics of the gasoline.

Much has been said regarding the vapor pressure of the more volatile components of gasoline. Some of the more important properties of these highly volatile fractions are shown in Table 2. It is believed that the practical deleterious effects of the presence of propane in gasoline has been overemphasized. In any event, erroneous impressions have frequently been gained from the various published statements in this connection. For gasoline of the same original vapor pressure, propane is beneficial rather than detrimental when looked at from the viewpoint of vapor lock alone. For reasons given, it is evident that for gasolines of the same original vapor pressure the gasoline with propane would lose its vapor pressure more rapidly due to the same amount of evaporation loss than would the gasoline without propane. This means that if two gasolines leave the refinery with the same vapor pressure, one with propane and one without, and both gasolines are subjected to exactly the same conditions up to the time that vapor lock occurs, the one with propane will have the higher vapor-lock temperature. It also means that if two gasolines have the same vapor pressure when they enter the fuel-feed system, the one with propane will have the higher vapor-lock temperature in actual service if all conditions of service are exactly the same in both cases.

The elimination of propane is purely an economic problem. It concerns the fuel manufacturer primarily. The aviation and automotive industries need not give this problem any serious consideration. The progressive fuel manufacturers will of necessity solve this economic problem because elimination of propane means an increase in yield of gasoline from a given quantity of raw material. As a matter of fact, most gasolines contain only small quantities of propane. Of 24 aviation gasolines analyzed during the past year none contained more than a trace of propane.

In order to obtain some idea regarding the vapor-locking tendencies of gasoline of the same Reid vapor pressure, but having different volatility characteristics as evidenced by the A.S.T.M. distillation test, our laboratory conducted tests with a Waukesha knock-test engine to determine vapor-lock temperatures under carefully controlled conditions in such a laboratory unit. The relationship which we found cannot be considered more than an indication of trends. But certain tendencies were definitely established as far as vapor-lock temperatures under these particular conditions are concerned. For gasolines having the same Reid vapor pressure, but with widely varying distillation characteristics, the vapor-lock temperatures can vary to a measurable degree.

The vapor pressure of gasoline is controlled in plant practice by segregation of stocks, by blending, and by distillation processes. Frequently the vapor pressure is too high, and the more volatile components, such as propane and butane, must be removed without the loss of less volatile constituents. Otherwise, the reduction in vapor pressure will be accomplished at the sacrifice of plant yield and of front-end volatility of the resulting product. It is a real problem for the motor-fuel manufacturer to produce a fuel that combines ease of starting and freedom from vapor lock due to the limitations of many of the fuel-feed systems. Aviation gasoline should have the maximum volatility judiciously correlated with the required vapor-pressure specification.

It is important that any vapor-pressure specification for gasoline should take into consideration the point at which the sample for the vapor-pressure test is secured. A large number

TABLE 2 PROPERTIES OF VOLATILE FRACTIONS OF GASOLINE

of tests have shown that normal evaporation losses incurred in transportation, unloading, storage, and filling the airplane tank cause a drop in Reid vapor pressure of about 1.0 lb between the tank car at point of shipment and the airplane gasoline tank. This loss in vapor pressure varies, as explained, depending upon the vapor pressure of the gasoline, upon its A.S.T.M. distillation characteristics, and upon the conditions of storing and handling the product. The high octane number of the light hydrocarbons coupled with their increasing availability should demonstrate that anything the aviation industry does which will permit of higher vapor pressures will improve the quality of the gasoline as evidenced by ease of starting, higher overall volatility, and better anti-knock characteristics. Improved fuel systems and rational vapor-pressure specifications are the only answers to the problem.

Octane Number, Antiknock Characteristics

It is with considerable trepidation that the author treads upon the ground belonging to octane numbers and anti-knock characteristics of motor fuels. Much work has been done by eminent authorities upon this subject. About one year ago one of them stated: "While anything like a complete knowledge of the relative behavior of different fuels in multi-cylinder aircraft engines and fuel-test engines is probably several years off, a test which provides partial control of anti-knock value is preferable to no test at all."

Most of the efforts thus far developed for determination of anti-knock characteristics have been devoted to motor fuels. The nearest approach to standards for aviation gasolines are the methods employed by the military services, particularly the ones in use by the Army Air Corps. Even in the case of motor fuels much doubt still exists as to the significance of the test results determined by methods now prevalent.

The Cooperative Fuel Research Steering Committee is to be highly commended for its work in developing the test procedure and apparatus for determining octane numbers of motor fuels. It is believed that the impelling motive to establish test conditions that will give duplicable results by different testing laboratories has to a certain extent overshadowed the necessity for having the test results afford a measure of the anti-knock characteristics of the gasoline under actual service conditions. When it appeared that the matter of knock testing of motor fuels was pretty well solved, further discrepancies appeared which have delayed the final standardization of the knock-testing method. Recognizing these deficiencies of the present testing methods, the U. S. Army Air Corps, the Cooperative Fuel Research Steering Committee, and the Ethyl Gasoline Corporation have adopted or have considered the adoption of test conditions that will insure more definite relations between test results and actual service conditions of aircraft engines and automotive engines. The general trend is toward an increase in jacket temperature and speed of the test engine.

It is well recognized that the magnitude of changes in anti-knock characteristics due to changes in engine-operating conditions depends upon the composition of the gasoline. Since no two gasolines are exactly alike in composition due to the large number and the complex nature of the compounds present in gasoline, it is imperative that any fuel used as a standard for knock reference should be capable of exact duplication. Normal heptane and iso-octane provide the desired requisites for such a standard. Normal heptane is a notorious knocker. Iso-octane has excellent anti-knock characteristics, and at the same time all of its other properties are similar to normal heptane. Since each of these compounds can be prepared in a high state of purity and for the reason that each substance is of definite chemical composition, they provide the basic requirements for the standards of knock reference. In addition, the wide range in anti-knock characteristic of heptane and octane makes it possible to determine the anti-knock characteristic of a sample of gasoline by matching it with a known mixture of the two pure compounds.

The octane number of a gasoline is defined as follows: "The octane number of any gasoline is the percentage of octane by volume in the mixture of octane and heptane that just matches the gasoline in anti-knock quality, as determined in the apparatus described and by the procedure specified." For example, if a gasoline is matched by a mixture of 65 parts of octane and 35 parts of heptane, its octane number would be 65.

Octane numbers above 100 are expressed numerically as 100 plus the percentage by volume of benzene in a mixture of benzene and octane. By definition, heptane would have an octane number of zero, iso-octane would have an octane number of 100, and benzene would have an octane number of 200.

From the title of this section it might appear that octane number and anti-knock value are synonymous. Such is not the case. The octane number of a motor fuel is a figure determined by a prescribed testing method and may not be an accurate indication of the anti-knock value of the gasoline. For example, investigations have been reported indicating that straight-run gasoline with an octane number of 64 evidences about the same tendencies to knock in automobiles as an average cracked gasoline with an octane number of about 69. In cases of gasoline made by very intensive cracking, this difference in octane numbers for equivalent knocking tendencies between straight-run and cracked gasoline may amount to 10 octane numbers or even more. Changes in the testing method in which a higher engine-jacket temperature and higher speed are employed may prove to give octane numbers having a more definite relation to anti-knock values encountered in actual service.

Two testing methods for determining the octane numbers of gasolines are in general use. One of these which was developed by the Cooperative Fuel Research Steering Committee thus far is used almost entirely in testing motor fuels. The more important conditions under which this test is conducted are as follows:

1 Engine, C.F.R. unit, manufactured by the Waukesha Motor Company, Waukesha, Wis.
2 Engine speed, 600 rpm
3 Engine-jacket temperature, 212 F
4 Spark advance, for maximum power, automatically controlled (basic setting 15 to 22.5 deg, depending upon compression ratio)
5 Carburetor adjustment, for maximum knock
6 Knock indicator, bouncing pin.

Aviation gasolines are tested by many laboratories with the series 30 engine of the Ethyl Gasoline Corporation. The essential requirements for tests of aviation gasoline for the U. S. Army Air Corps (Y-3557E) are as follows:

1 Engine, Ethyl Gasoline Corporation series 30 knock-test engine
2 Engine speed, 900 rpm
3 Engine jacket temperature, 375 F
4 Spark advance, 15 deg
5 Carburetor adjustment, for maximum knock
6 Knock indicator, temperature plug.

The paraffin hydrocarbons have greater anti-knock stability; that is, they retain their anti-knock characteristics over a wider range of engine-test conditions than do the unsaturated and

aromatic hydrocarbons. This is particularly true in the case of increased engine-jacket temperatures. The paraffin hydrocarbons are in general also more responsive to increase in octane number resulting from the addition of the first few cubic centimeters of tetraethyl lead. Straight-run refinery gasoline and gasoline from natural gas are composed primarily of the paraffin hydrocarbons. Generally speaking, it also appears that the more volatile paraffin hydrocarbons possess the two very desirable characteristics of anti-knock stability and lead responsiveness to a greater extent than do the less volatile paraffins.

It is undoubtedly true that progress in standardization and correlation of knock-testing methods with actual service conditions has been delayed, due in part to the costs of the primary standards, normal heptane and iso-octane, which sell for $25 per gallon. This price situation has necessitated the use of secondary standards. Due to the inherent anti-knock characteristics of the more volatile normal paraffins, the suggestion is made to use the strictly normal paraffin compounds of propane, normal butane, and normal pentane as primary standards. The gasoline industry can offer propane, normal butane, and normal pentane, having a purity of 99 per cent or higher, at a price which ought not to exceed more than about 5 to 10 per cent of the price of the present primary standards.

Many possible combinations of these normal paraffins could be worked out. It would be possible to eliminate both heptane and iso-octane and cover an anti-knock value range greater than that covered by all grades of commercial gasolines. If desired, normal heptane could be retained and thereby cover an even wider range of anti-knock difference. The retention of heptane would provide further possible combinations for devising a satisfactory scale of units for measuring anti-knock characteristics. The numerical ratings could be known as the "butane numbers" or "pentane numbers," whichever proved to be more generally acceptable. Since pentane would be a good base gasoline for comparison of anti-knock values of premium gasolines, the term "pentane number" might be more attractive.

It is realized that difficulties would be encountered in proportioning the fuel-air mixtures in some cases. In addition to the carburetor in present usage, it may be necessary to develop a "high pressure carburetor" or an auxiliary device by which the easily vaporized mixtures could be handled in the vapor state. If the fuel temperatures were maintained at temperatures below —20 F prior to carburetion, it would probably be possible to use a low-pressure type of carburetor in tests of all grades of commercial gasolines. If all products were handled and used under pressure at 60 F, no volumetric corrections would be needed.

Another interesting possibility in connection with the use of paraffin compounds in knock testing is the uniform increase in octane number of the heavier fractions of natural gasoline when lead is added. Due to the narrow boiling-point range of natural gasoline of low vapor pressure, it is possible to economically prepare from it suitable secondary reference standards possessing high knock stability and a lead responsiveness approaching that depicted by a straight-line relationship.

The anti-knock characteristics of gasoline are maintained and controlled in refinery practice by segregation of stocks from which the gasoline can be blended to the required octane number, by varying the volatility of the gasoline, by more extensive use of cracking processes, by blending with natural gasoline products, and by judicious use of lead. As stated, the tendency is toward higher engine-jacket temperature and higher speed during the testing of gasoline for anti-knock characteristics, and since cracked gasoline on account of the presence of unsaturated and aromatic compounds rapidly loses its octane number rating as the engine speed and jacket temperature are increased, it means that cracked gasolines do not have as high anti-knock values as the octane ratings have implied. Cracking processes will therefore have to be revaluated in so far as the economics of producing anti-knock gasoline is concerned.

The anti-knock characteristics of aviation natural gasoline are controlled chiefly by varying the volatility and vapor pressure of the product, to a less extent by segregation of stocks, and by the use of lead. Since aviation natural is composed almost entirely of paraffin hydrocarbons, its high knock stability and responsiveness to lead are in its favor, and as has been previously stated, the more volatile fractions of the natural gasoline show the best behavior in this respect From the standpoint of availability of aviation gasoline of minimum vapor pressure combined with maximum volatility it is imperative that butane be excluded from the aviation gasolines for the same reason that propane should be eliminated from motor fuels. There are enough pentanes available from the natural gasoline industry to supply at economic price levels the wants of the aviation industry for many years. The aviation industry in considering high-quality gasoline is therefore justified in demanding a product free from butane. In manufacturing aviation natural gasoline to meet present vapor-pressure specifications, it is necessary to remove all of the butane and part of the pentane. This procedure of eliminating part of the pentane which has high volatility and valuable anti-knock characteristics results in a fuel of an inferior quality than would otherwise be obtained. There seems to be no reason why all airplane-fuel systems in the future could not be adapted to satisfactorily handle aviation gasolines with a Reid vapor pressure of at least 10.5 lb. Such being the case, aviation natural gasoline would have a pentane content upward of 35 per cent. If a fuel system could be made to satisfactorily handle a gasoline with a Reid vapor pressure of 17 lb, it would be possible to have the fuel composed entirely of pentanes. Such a product would have the maximum possible overall volatility regardless of the source of the petroleum product.

Any limitation on volatility or vapor pressure not founded upon justifiable operating conditions encountered in actual service results in needless sacrifice of the more important qualities of the gasoline. To prevent the inclusion of pentanes in aviation gasoline or of butanes in motor gasoline by unduly rigid vapor-pressure specifications means not only a sacrifice of the valuable properties of the gasoline, but also necessitates an utter waste of natural resources accompanied by additional expenses for lead or a reduction in anti-knock value for the same amount of lead. If the additional volatility and vapor pressure can be safely used, more, better, and lower priced aviation gasoline will be available from the petroleum industry.

Gum Content

If gasoline is allowed to remain in storage for a long period of time, a resin-like deposit may result. Cracked gasolines and especially those from vapor-phase cracking processes are the ones most likely to evidence this phenomenon. If this gummy or resinous material is present in gasoline, it may deposit in the gasoline tank or fuel lines. It is more likely to make its appearance in the fuel-induction system, the intake valves, and the engine, where evaporation of the gasoline causes the gum to be deposited as a carbonaceous residue. Any method for the determination of the gum content of gasoline must take into consideration the fact that the amount of gum present in the gasoline increases with the period of time in which the gasoline is kept in storage. The rate of gum formation is slow at first, and after a certain period of time, depending upon the gasoline and conditions of storage, this rate increases very rapidly. The period of slow rate up to the time that the rapid rate of gum formation begins is frequently referred to as the "induction period."

For the reasons indicated, it has been necessary for the industry to consider two methods for determining the gum content of gasoline. If the gasoline is to be used very soon after the sample has been tested, the test should reveal the amount of gum present in the gasoline when the sample was taken. This determination is generally made by evaporating a measured quantity of gasoline and then determining the amount of residue left upon evaporation.

To determine the gum content of gasoline that may form due to long periods of storage, modification of an accelerated aging test has been used by different laboratories. U. S. Army specification Y-3557E requires that a 200-cc sample of the gasoline shall be subjected to an accelerated aging test at 212 F with oxygen at 100 lb pressure for four hours and that on evaporation of 100 cc of a mixture of the oxidized sample and gum solvent the amount of residue shall not exceed 10 mg.

It is probable that the foregoing test may be unduly severe in that it may exclude cracked gasoline that would give satisfactory performance with respect to gum behavior. It may also be equally true that any gasoline which passes the test will not give any gum-formation difficulties. Much remains to be learned regarding the amount and kind of gum that might be tolerated in gasoline without encountering noteworthy difficulties with engine operation. The low limit of 10 mg may be unduly severe, but it is the opinion of several investigators that an increase in this limit would not be justified until more definite information is obtained regarding the problem.

From a practical viewpoint, the problem of controlling the gum content of gasoline is one that mainly concerns the manufacturer of cracked gasolines. Manufacturing difficulties in this respect are solved by various refining methods, by segregation of stocks, and by the use of gum inhibitors. Natural gasolines are not subject to gum formation, but it occasionally happens that very small quantities of oil are carried over with the gasoline during its distillation from the absorption oil. This trace of oil shows up as gum in the method for determining the gum content. This problem is solved by using more efficient dephlegmators during the distillation process or by redistilling the gasoline.

Gasoline Specifications

A tremendous amount of valuable research work has been carried out by the various industrial organizations and Federal bureaus on the properties of gasoline. The data which were obtained have been used in formulating specifications for aviation gasolines and motor fuels.

The most widely known gasoline specifications are those of the Federal Specifications Board. Not infrequently these specifications are designed to meet special requirements of certain Government agencies and to that extent may be unduly restrictive in certain respects. Unfortunately the prestige carried by the technical bureaus of the Government has the undesirable effect in some instances of generally promulgating the Federal specifications. This is especially true in connection with the gasoline specifications adopted from time to time by the various states.

Many of the states require that the state specifications should be the same as those of the Federal Government and that the state specifications should automatically change with any revisions made in the Federal specifications.

There is presented in Table 3 a summarized review of recent Federal specifications for aviation gasoline. For the purpose of comparing with recent U. S. motor gasoline, specifications for the latter are also included. There has been a gradual tendency to increase the quality of all gasolines as evidenced by the provisions affecting the four major properties. The overall volatility of all gasolines has been increased as shown by the 10, 50, and 90 per cent evaporated temperatures. The specifications relating to vapor pressure have become more rigid, but such restrictions are in effect a backward step as far as quality is concerned. They may be justified from the viewpoint of the nature of the equipment in which the gasoline is being used, but this does not deny the fact that the quality of the gasoline is being sacrificed. The obvious remedy is better equipment as soon as replacements are in order.

Aviation Gasolines Marketed in the United States

For the past four years our company has been conducting a survey of aviation gasolines sold throughout the United States. The samples represent the products of the major refining companies and were in most instances obtained from the various airports in which the gasolines were sold. Extreme care was taken to see that the samples were truly representative of the products being sold. Upon arriving at the laboratory, the following tests upon most of the samples were made: A.S.T.M. distillation (method D 86–30), A.S.T.M. Reid vapor-pressure (method D 323–31T), composition analysis, and anti-knock determinations.

The results of the tests of the aviation gasoline survey are

too voluminous to include results of all tests separately. They are presented in summarized form in Table 4.

Since our survey indicated that the aviation gasolines being sold in the United States were undergoing gradual changes in quality, we have tabulated separately characteristics of the aviation gasoline sold last year in order to facilitate comparison with those sold prior to 1931. The following trends are evidenced: Vapor pressures were slightly lower, octane numbers slightly higher, and volatility slightly higher for the 1931 aviation gasolines.

It is interesting in this connection to observe the trend of changes in U. S. motor gasoline, the data for which are available in various Bureau of Mines reports. The pertinent data pertaining to the volatility and vapor pressure of U. S. motor gasoline are shown in Fig. 4. The increase in vapor pressure and volatility of motor fuels during the past five years has been due to cracking processes and vapor-recovery systems at refineries, since the percentage of natural gasoline available has not increased since 1927. Moreover, the vapor pressure and volatility of the natural gasoline have been gradually lowered of recent years. Last year there was a material decrease in natural gasoline used by the refiners. This was due to some extent to the increased amounts of natural gasoline that is going directly to the consuming market, a situation which has been brought about by an increased knowledge of the value of the product and the low level of the prices for natural gasoline as compared with motor fuel.

Summary

The four major properties essential to good operation of aircraft engines and in which gasolines may differ greatly are volatility, vapor pressure, gum content, and anti-knock characteristics. Other properties not necessarily less essential but possessed generally by practically all gasolines pertain to absence of entrained water, low sulphur content, freedom from acids and alkalis and non-volatile residues, color, odor, etc.

The testing methods for determining volatility and vapor pressure of gasoline are well standardized, and relation of test results to service conditions are fairly satisfactory. The possibility of securing a fuel with better volatility characteristics which would at the same time improve the anti-knock quality of the gasoline is in the hands of the designers of aircraft and automotive engines. The restriction in volatility characteristics is due to the limitations of some of the fuel-feed systems of the equipment in which the fuel is used.

Much work has been done on determining the gum content of gasoline and an early solution to problems affecting duplicability of test results looks promising. However, much remains to be learned regarding the nature and deleterious effect of gums in gasolines. In the meantime the present low gum contents required by gasoline specifications will safeguard the industry.

A knock-testing method giving results susceptible of reasonably close duplication has been developed by the Cooperative Fuel Research Steering Committee. Trouble has been encountered by several investigators in that the test results are not always truly indicative of service conditions. The tendency is toward testing fuels at higher jacket temperatures and higher speeds, which procedure gives promise of affording a better measure of the real anti-knock value of the fuel.

The properties of aviation gasoline sold in the United States last year showed the following ranges:

Reid vapor pressure, lb	4.0 to 11.9
10 per cent evaporated temperature, °F	110 to 178
50 per cent evaporated temperature, °F	140 to 254
90 per cent evaporated temperature, °F	195 to 360
Octane No. (at 212°F and 600 rpm Waukesha engine)	50.0 to 89.0
Propane and lighter, per cent	Trace
Butanes, per cent	Trace to 4.8
Pentanes, per cent	8.6 to 38.9

By excluding some of the gasolines which may have possessed abnormal characteristics, it is estimated that the properties of

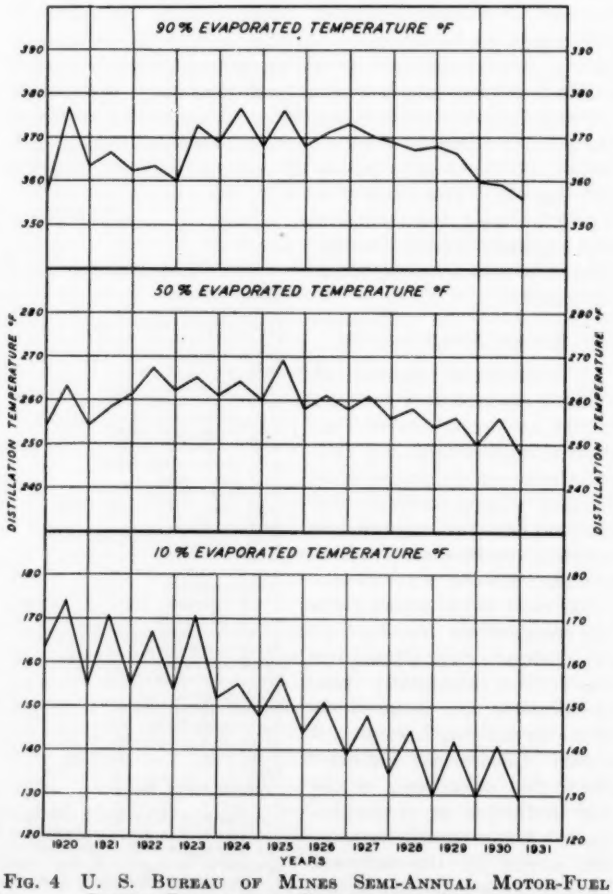

FIG. 4 U. S. BUREAU OF MINES SEMI-ANNUAL MOTOR-FUEL SURVEY DISTILLATION TEMPERATURE AVERAGES

(For 10, 50, and 90 per cent evaporated, January, 1920, to January, 1931, inclusive.)

motor gasoline sold in the United States last year varied through the following ranges:

Reid vapor pressure, lb	3.9 to 12.4
10 per cent evaporated temperature, °F	109 to 179
50 per cent evaporated temperature, °F	208 to 295
90 per cent evaporated temperature, °F	290 to 397
Octane No. (at 212 F and 600 rpm Waukesha engine)	44.5 to 83.0

	Range	Average
Propane and lighter, per cent	Trace to 2.0	0.2
Butanes, per cent	2.0 to 9.0	4.9
Pentanes, per cent	6.0 to 25.0	9.8

The quality of aviation gasoline is a mutual problem of the petroleum and aviation industries. The quality of the best aviation gasolines available in sufficient quantities has been used by the aviation industry as a basis for improvements pertaining to power output per unit of weight and displacement of aircraft engines. It is to be expected that this situation will continue. The aviation industry can render itself a valuable service in connection with the quality of aviation gasoline if future airplanes are designed to handle aviation gasolines with higher vapor pressures.

Any limitation on volatility or vapor pressure not founded upon justifiable operating conditions encountered in actual service results in needless sacrifice of the more important qualities of the gasoline. To prevent the inclusion of pentanes in aviation gasoline and of butanes in motor gasoline by unduly rigid vapor-pressure specifications means not only a sacrifice of the valuable properties of the gasoline, but also necessitates an utter waste of natural resources accompanied by additional expenses for lead or a loss in anti-knock value for the same amount of lead. If the additional volatility and vapor pressure can be safely used, more, better, and lower-priced aviation gasoline will be available from the petroleum industry.

Bibliography

The author has drawn freely from the various publications pertaining to the subject. Specific citations have been omitted throughout the report for the reason that the voluminous amount of published data would have rendered it well-nigh impossible to have given credit to all of the investigators. Stainless Steel in Aircraft Construction

By E. J. W. RAGSDALE,[1] PHILADELPHIA, PA.

Stainless steel will assume its position in the aircraft industry when and where the urge is strong enough to study its possibilities, to acquire its technique, and to overcome the discouragement of first efforts. The first use of stainless steel in aircraft was in England. Tons of it were used in the construction of the "R-101." In this country a trend toward stainless steel is noted, particularly for air-transport units.

PART I—STAINLESS STEEL

AVIATION, emerging from its formative stages, now faces problems of production. Its methods and materials have to be reevaluated in the light of fabrication and maintenance. Much has already been done, and more will be. The desire for improvement is sufficiently keen to preface its accomplishment. A general lack of prejudice or convention on the part of aeronautic engineers seems to assure it.

Methods are inherently bound to materials, and must be considered as a part of them. Aviation has had three materials, and it still has them. Nor is the choice an easy one, for spruce, duralumin, and high-tensile steel all equate in the formulas for structural value. The ratios of weight, strength, and modulus of elasticity leave little margin for preference. Decision must rest on a different consideration, and that consideration is the fabrication of a serviceable article.

Strangely enough, it was serviceability that first prompted the use of stainless steel for aircraft—and that at a time when structural permanence was the least of aviation's worries. A recurring interest in the material comes simultaneously with a growing appreciation of its need. Study of its possibilities then reveals unsuspected structural qualities—qualities which would be self-sufficient even without the non-corrosive feature.

The term "stainless steel" is in a way unfortunate, for its behavior is no more like that of steel than is bronze like that of copper, and its proportion of alloyed material is certainly as great.

Again "stainless" covers a wide range of composition and property; but, fortunately for the purpose of this paper, the issue can be confined to that most common alloy known as 18-8. The others seem not so likely to find wide application in structures. The 18-8 has, roughly, 18 per cent chromium, 8 per cent nickel, and a little less than 0.18 per cent carbon. It is further known by a score of trade names, such as Allegheny Metal, Nirosta, KA2, Resistal, and Enduro.

Its chief claim to structural use lies in the capacity for retaining toughness after having been cold worked to high tensile values. Tensiles of over 400,000 lb per sq in. have been known. The material, however, is not tractable above half that figure, and will give difficulty in fabrication.

In stress-strain relation, the curve of cold-worked 18-8 approximates that of cold-drawn wire. Yield point and elastic limit are poorly defined. The modulus is about 29,000,000.

Here, then, is a material which is possessed of properties superior to those of chrome-molybdenum steel and one which can be fabricated without heat treatment. In addition, it is non-corrosive and non-magnetic.

That this material requires a special technique in handling and that it may lose some or all of its virtues under abusage is true, but what material does not? Even ordinary steel requires some understanding of its behavior. Tool steel requires a definite and specific knowledge. So one can hardly resent the fact that the use of stainless involves close study of the instructions regarding it. This is particularly true in view of the widespread misconception of its nature. A few fundamentals will explain many an apparent vagary.

In the first place, 18-8 is not inherently stainless, thanks to its composition. It is stainless only when in a certain physical state; this state is known as austenite. Austenite is that condition wherein the carbides remain in solid solution with the iron. It obtains in plain carbon steels between the temperatures of solidification and dull-red heat. It could be preserved down to normal temperatures were an immediate and severe quenching possible, but as a matter of practice the carbides are precipitated out at the critical temperature around 1200 F. They become grain boundaries, and since the steel is now no longer homogeneous, but is a mixture of materials possessed of different electrolytic potential, a marked change of character results.

Austenite is non-magnetic, malleable, and susceptible to extreme cold working. There is a strong semblance, in fact, to gold, lead, or copper; its preservation seems desirable, and in 18-8 such has been accomplished. Chromium and nickel hold the carbides in solution during a reasonably short quench. In slow cooling or reheating the influence is not sufficient, and carbides of iron and chromium will precipitate. They cannot be reabsorbed without reheating to some 2000 F. The temperature range of precipitation is from 1200 to 1600 F. In all heat operations on 18-8, consideration must therefore be given to the time element, the critical range, and the corrective temperature. No complete change from or to austenite can be effected without regard to time.

The outward effect of excluded carbides is that the material becomes magnetic and is less resistant to corrosion. It is also less resistant to fatigue—a condition which is more alarming than the mere appearance of rust. Many a welded seam has eventually shown cracks at some distance from the weld, and the cause is unmistakable, though corrosion may or may not have been evident.

It stands to reason that a material having a homogeneous structure will not display the same characteristics as one composed of crystals of that material with interlarded boundaries and nuggets of carbides.

---

[1] Resident Engineer, Edward G. Budd Mfg. Co. Col. E. J. W. Ragsdale received his technical education at Charlottenburg, Germany, and at the Massachusetts Institute of Technology. Upon graduating from the latter in 1910, he was commissioned in the Coast Artillery of the Army and later detailed to the Ordnance Department. During the war he organized and remained chief of the Trench Warfare Division. In this capacity he originated what later became the Chemical Warfare Service and was also identified with aircraft armament. After the war he resigned his commission and has been with the Budd company for the last 11 years in the capacity of a free-lance engineer. The use of stainless steel in structures for aircraft, as well as railroad service, is his latest contribution.

Contributed by the Aeronautic Division of The American Society of Mechanical Engineers and presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

As indicated, 18-8 can be given this condition by heating to from 1200 to 1600 F and cooling. If then it is boiled in Strauss's solution (10% $CaSO_4$, 10% H_2SO_4 + H_2O), the carbides will be dissolved out, leaving a loose mesh of metal which breaks readily in the fingers and has no metallic sound, but is again magnetic. The experiment has practical value only in determining deleterious effects due to welding or other heat operations.

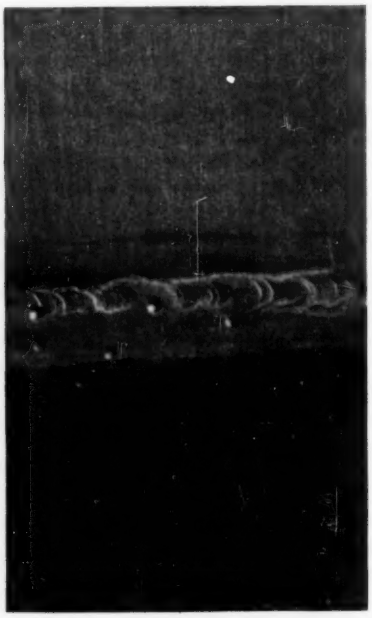

FIG. 1 GAS WELD BOILED IN STRAUSS'S SOLUTION AND SLIGHTLY BENT

(Two cracks immediately developed parallel to the weld, showing a severe and highly localized precipitation of carbides.)

It would therefore seem that 18-8 cannot be welded by any conventional method (gas, arc, or electric resistance) without producing localized precipitation of carbides. Such is true; but just how serious this is depends on a number of factors—some controllable, others not so.

Certain it is that the condition can be entirely remedied by heating the piece to some 2000 F and then air quenching. The carbides will be reabsorbed, and a homogeneous stainless structure restored.

Unfortunately, the reheating of a fabricated part is not always feasible. More unfortunate still is the fact that all beneficial effect of cold work is lost. However, 18-8 has a wide application of uses outside of structures, and welding by gas or arc has been successfully done. Some particularly good work is done with the atomic hydrogen method. A skilled welder can control his heat so that the precipitation of carbides is minimized. However, the technique required for gas or arc welding of stainless differs considerably from that which suffices for plain carbon steel.

Better results have been had with electric spot welding. The conditions favor it. In the first place, the surfaces are clean and free of oxides; secondly, the material resistance is from 8 to 14 times that of carbon steel. Both conditions make for lower current value, so that commercial welders must be regulated down below normal in order to avoid burning. The welded spot has heretofore usually been surrounded by an annular ring of precipitated carbides, but these cannot be positively detected without the aid of a microscope after sectionalizing and etching with hydrofluoric acid. This ring has been termed the "corona." Its extent is known to be a function of time and current; its existence cannot be recognized by the eye. In fact, it is axiomatic that no one can tell a good or a bad weld by inspection. Surface condition means absolutely nothing, for fusion rarely extends to the outside of the sheets. The visible marking, more often than not, is due to arcing at the electrodes or secondary heat influence. However, all argument and evidence to the contrary, welds continue to be judged at face value.

Appreciation of these conditions has led the Edward G. Budd Manufacturing Company, of Philadelphia, to develop a spot-welding machine the outstanding features of which are absolute uniformity of current supply, use of high currents in a very brief time element, and a recorder which supplies visible and audible record of performance. Results seem to justify differentiation, and the term "shot weld" has been coined.

With use of the shot welder, corona-free welds can be consistently made, which automatically opens up a large structural field to stainless steel. Without such, there is inevitably that uncertainty which has always been associated with uncontrolled welding.

The first use of shot-welded stainless steel was in connection with aircraft, which at the same time was conceived as its severest test. Development, extending over years, has been gradual and cautious. Not until last year did an entire airplane result, though many sub-assemblies had previously been fabricated. This plane, an amphibian patterned after Savoia-Marchetti design, has demonstrated its worth in test. The type seemed to offer

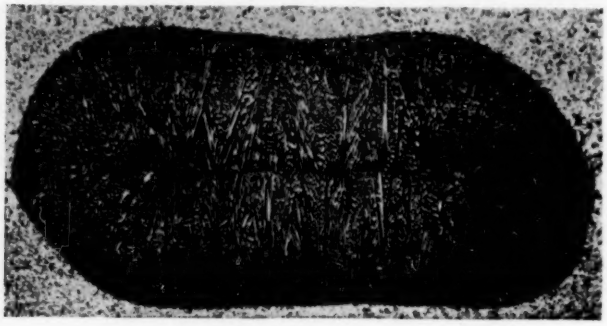

FIG. 2 OVERETCHED SECTION OF A SHOT WELD IN TWO SHEETS OF 0.030 IN. THICKNESS

(No visual inspection from the outside could tell the extent or condition of the fused material. Carbide precipitation, if any, would be found at least a weld diameter to either side of the limit of fusion and would require higher magnification.)

to stainless its ultimate utility, both as to structural value and as to corrosion resistance. Success of the venture, coming simultaneously with an increased general interest in stainless steels, presages wide application and makes justifiable a description of the structural methods employed.

PART II—THE USE OF 18-8 IN AIRCRAFT STRUCTURES

DESIGN

The design philosophy developed primarily in England for thin, heat-treated steel structures offers guidance, but cannot be too closely followed. In the first place, if high-tensile stainless be used, "springback" makes difficult the forming of sinuous curves and convolutions, such as characterize most British practice. Stainless is best formed by braking operations. Sections are apt to consist of a series of flats, sharp angles, V-beads, and flanges. Thinness being requisite, closed sections predominate in all compression members. Crinkle tests must be frequently made to determine minimum P/A, and values under 100,000 lb

per sq in. are not found to be economical. The problem of attachment to other members or fittings influences the eventual shape.

Steel structures should show an equal, if not superior, weight-strength relation to spruce or duralumin. Skilful design can do it, but the tricks learned from one material are not translatable to the other two.

Here, as elsewhere, deflection usually governs the structural design. While the modulus of stainless is some 29,000,000, this value falls off under high stress. Furthermore, if the section is built up of "flats" not properly proportioned to thickness, a waviness results and deflection becomes greater than that proportioned to the load. The capacity of 18-8 to recover itself after deformation, or even apparent failure, is phenomenal.

The 18-8 Alloy

As 18-8 differs from other alloys of the non-corrosive group, so does it differ in itself under varying conditions of cold work. When quenched from 2000 F, it assumes its most ductile and soft state. The tensile is from 85,000 to 90,000 lb per sq in., and the elongation is some 65 per cent in 2 in., but the yield point is only 38,000.

What is most important from a welding point of view is that the electric resistance is only eight times that of carbon steel and it is susceptible to corona formation. Its use in highly stressed structures is therefore limited to fittings.

On the other hand, when cold drawn or rolled to a tensile of 200,000 lb per sq in., the yield point approaches the ultimate, elongation drops to some 8 per cent, but the electric resistance becomes about 12 times that of low-carbon steel. It responds slightly to the magnet. It will not tear along the grain as will spring steel, and it displays a toughness seldom associated with material of this tensile. The resistance to corrosion, though still very high, has been lessened, while resistance to fatigue has been materially increased. Physical properties across the direction of rolling are slightly higher than those established in the direction.

This material is available in wire or strip form—the latter from 0.005 to 0.125 in. ($^1/_8$ in.) in thickness and seldom over 12 in. in width.

Then, when cold working progresses beyond 200,000 lb per sq in., utility becomes limited. The material responds even more to the magnet, and corrosion resistance falls off markedly.

Chief interest lies in avoidance of excessive working by fabrication, such as might produce these effects. Angles too sharply bent are the commonest offender. They should be examined for incipient cracks or coarse granulation of outer edges. A good test is to reflatten a bent-up section to see whether a crack develops.

Specifications

The stocks commonly carried in stainless steels are not of a gage or quality suited to aircraft use. They are confined to sheets from 0.025 to $^1/_8$ in. in gage and of soft anneal. Several mills, however, are prepared to execute orders for strip to meet apparently simple but very exacting specifications. One specification is:

Gages, 0.005, 0.010, 0.0125, 0.016 in.
Tolerances, plus or minus 0.0005 in. in gage, plus or minus 0.010 in. in width
Widths, up to 14 in.
Tensile strength, 180,000 to 200,000
Elongation in 2 in., 8 to 6 per cent
The material shall bend dead flat upon itself in a vise, both across or along the grain, without developing an open crack.

Another specification is:

Gages, 0.024, 0.030, 0.035, 0.040 in.
Tolerances, plus or minus 0.001 in. in gage, plus or minus 0.020 in. in width
Widths, up to 9 in.
Tensile strength, 180,000 to 160,000 (diminishing with thickness)
Elongation in 2 in., 8 to 12 per cent
The material shall bend at right angles in a brake with an inside radius equal to that of its thickness and shall show no incipient cracks. This is to be done along and across the grain. It shall then be flattened out without developing an open crack.

Fig. 3 Spar Fitting, Showing Compression Strut
(With attachment points for wing strut and flying wire.)

The mill practice to meet these specifications is not an easy one. Operators, too, have found that 18-8 does not follow steel conventions. The secret of success may lie in roll temperatures, for 18-8 does some funny things when worked between —100 and +100 F.

Wherever soft material is required for sheets or strip, it is found expedient to have it come with annealed and pickled finish. This contrasts with polished high-tensile stock, and confusion is not apt to result.

Forming and Machining

High-tensile stock is not readily formed in hand or power brakes. It slides too readily in the grips. Short lengths, however, can be done, but attention must be paid to springback. This is easily predetermined by braking sample strips beyond the required angle and observing the degree of return.

Fundamentally, stainless construction depends upon rolled sections, and the closest attention must be given to this department. Drawbench work has not proved satisfactory; the dies give trouble with hard material and the lubricant causes trouble in subsequent assembly by shot welding. Driven rolls have been but sparingly used. The best success has been had by pulling the strip through a series of forming rolls. Four pairs are sufficient to form any usual section. Speed and tension vary with the complexity of the formation.

Cutting of strip is done by shear, but knife edges must be maintained sharp and in close contact. The strip will show a tendency to crowd over as the shearing blade is depressed if a guide rail is not used. Sections are cut on a high-speed bandsaw having fine or blunted teeth.

Punching can be done, but is hard on dies. Drilling is more difficult, since the material hardens so quickly under the point. Great pressure, slow speed, and a sharp drill are required. The hole is apt to be ragged.

Several of the mills offer a variety of stainless steels which lend themselves better to machine operations; none are really good, being only preferable to 18-8.

Any forging or forming under heat destroys all value incident to cold work. The piece should be rectified by heating to

2000 F and air quenching. It will have 90,000 lb tensile—a fact which is apt to be misleading if one does not reflect that the elastic limit is only 38,000 lb.

Joining

The problem of joining materials, though as old as craftsmanship, has never been completely solved. It still commands our best effort.

Low-tensile stainless, especially where heat effects can be disregarded or rectified, may be joined by fusion (gas or arc) welding, electric spot or flash welding, and brazing. Shot welding or soldering do not require corrective treatment.

The high-tensile material finds a cheap and satisfactory solution in shot welding; a ready but less satisfactory one in soldering.

Riveting is not considered for normal structural work. The holes are difficult to make, stainless rivets harden too fast, and hot riveting is not yet indicated.

Folded seams, where usable, are satisfactory, and if spotted by welds every inch or so, resist considerable pull without opening up. For instance, a 1-in. test strip folded in the center opened at 370 lb, while the same seam held 1200 lb after having had one shot weld put through it.

In fusion welding by gas, arc, or atomic hydrogen, satisfactory results are to be had, once a technique is acquired. No attempt will be made here, however, to duplicate the instructions which are available from any of the sources of material supply. The warning against corona effect is repeated, and rectifying treatment is urged. In case a doubt exists, simply boil a specimen weld in Strauss's solution and bend. If no crack develops, all is well and good.

Soldering is a simple, easy, and fairly effective method of joining. No particular technique is involved. The surfaces should be cleaned and washed with a 10 per cent solution of phosphoric acid. No flux is needed. The soldered joint must then be washed free of any remaining acid.

Shot Welding

In shot or spot welding, the diameter of the fused slug should have some reasonable relation to the thickness of the sheets to be joined. No closed section can economically suffer large welding flanges, for it is here that compression failure initiates. Shot welding encourages use of a narrow flange—much narrower than would obtain in a riveted connection—and in consequence good practice dictates that a spot no greater in diameter than three times the double thickness of material should be used. The flange, in turn, should be at least three spot diameters in width.

It will be appreciated that a large corona effect would reach the edge of the flange, where, as experience shows, all fatigue failures to start. A corona-free spot is essential, and such is obtained by

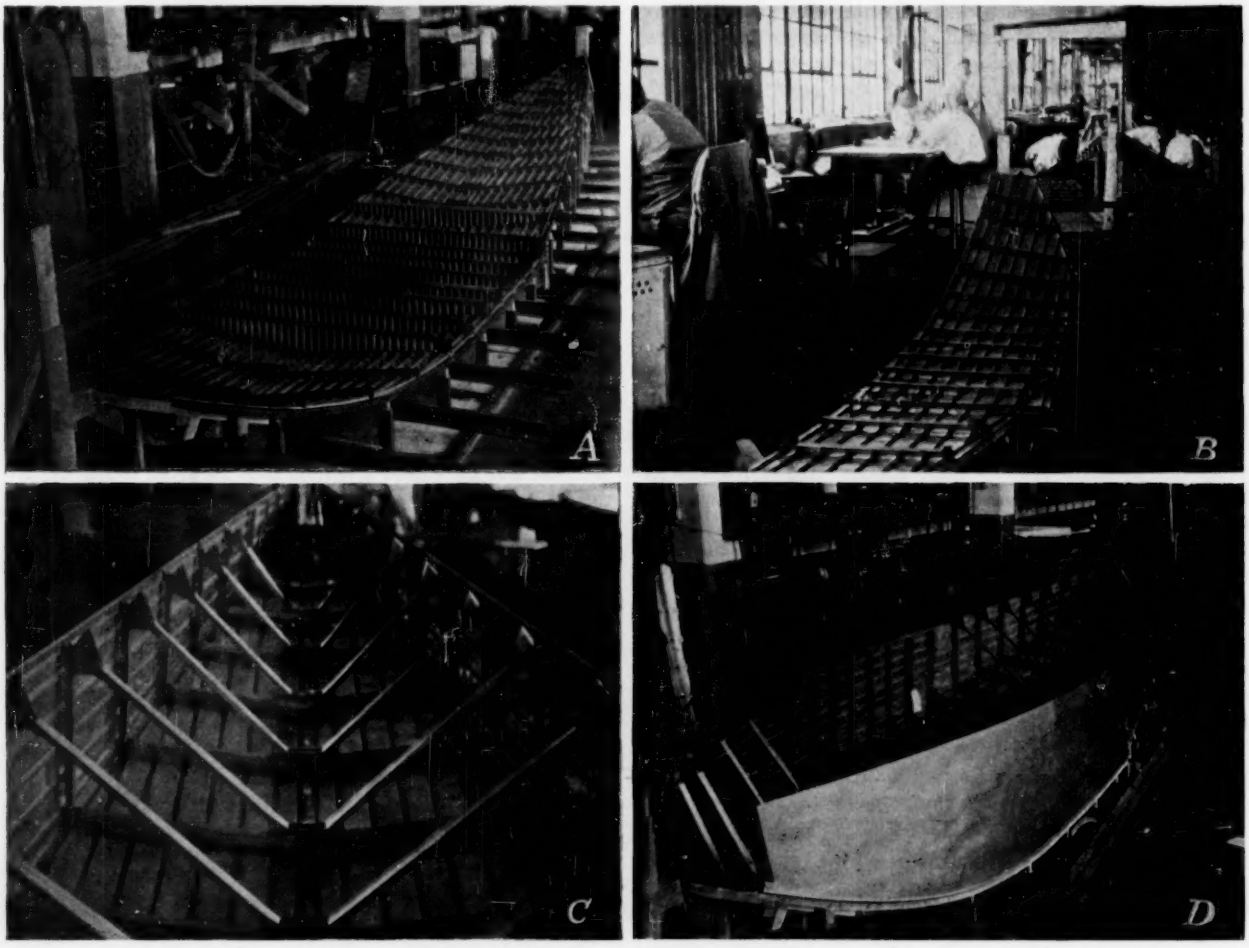

Fig. 4 Hull Assembly of an Amphibian

(*A* is the bottom, completely framed and sheathed as it lies in assembly jig. *B* is one side ready for assembly. *C* is a rear view of assembled sides and bottom before deck beams have been attached. *D* is a view of hull just after removal of side jigs.)

short time of current dwell. There is really no need for large areas of fusion, since good welds will show twice the shear of a rivet of like diameter and can be spaced 50 per cent closer together.

Shear is not the only test for welds; they must be tough—tough enough to permit rotation through at least 60 deg. Again, current and time relation will determine the character of the fused slug.

Probably the one outstanding essential of a shot welder designed for aircraft or other structural use is portability. It is rarely practical to progress the work past the apparatus. In the

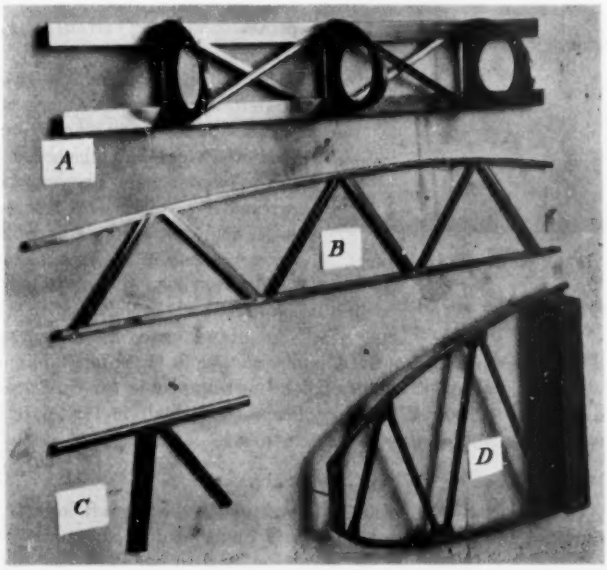

FIG. 5 FOUR FORMS OF CONSTRUCTION

(*A*, section of aileron spar before nose is covered with 0.010 in. of stainless steel. *B*, simple rib-type construction, with channel caps and Z-strip truss members. *C*, another rib-type construction, showing a compression and a tension shear member attached to cap strip. All are channel sections; the cap being of heavier gage and slightly wider. *D*, a rib nose using double gusset construction.)

Budd machine, long lines of cables are attached to hand or air tongs, and these are dragged into almost inaccessible places. The machine can be rolled about the floor or lifted by cranes to any desired position, but the current loss in cables and tongs is substantial and must be compensated for.

Since the current and dwell are established by the machine, the operator has no choice in these matters. The inspector usually makes the settings for test welds, and then adjusts the recorder to the new value. Any variance of conditions which may make for over or insufficient current-time relation causes a bell to ring continuously until the machine is reset. Every weld made or failed is recorded on a tape, the length of line being a function of the I^2Rt, where I represents amperes, R the resistance, and t the time of dwell. This is the total heating value of the electric energy supplied. It is interesting to note that the heat which actually goes into a single shot weld in two pieces of 0.012-in. material is but 0.035 Btu.

This also explains how assemblies can be made without that distortion so troublesome in gas welding.

While normal practice is to use two electrodes (one directly opposite the other, and both of similar shape), unusual conditions often dictate welding by indirection. One electrode may consist of a pad clamped to a sheet, while the other is conventionally pointed and held against the member to be welded to that sheet. Again, both electrodes may be pointed and held against the member, some distance apart, while a copper plate rests beneath the sheet. Here, two welds are made simultaneously, the current passing from one point through the member and sheet into the copper plate, then along the copper plate until it comes opposite to the other point where it exists through sheet and member. This is made possible by virtue of the superior conductivity of the plate over that of the combined sheet and member of steel.

Both methods find application in shot welding a corrugated member to a flat sheet such as is used in flooring or partitions. The sheet rests on a large copper plate, and the only care is that electrodes are held far enough apart to insure sufficient resistance in the steel pieces.

Any of the many forms of indirect welding are apt to be more uncertain than in conventional practice. Both care and control must be exercised through the operation. Even then, good design will obviate the condition where the structure is important.

Welding through several thicknesses is possible, and is frequently done, nor do the pieces have to be of equal gage.

ASSEMBLIES

The accompanying photographs must tell their own story of structural methods. This paper could not possibly picture the result of years of thought in devising ways and means, nor

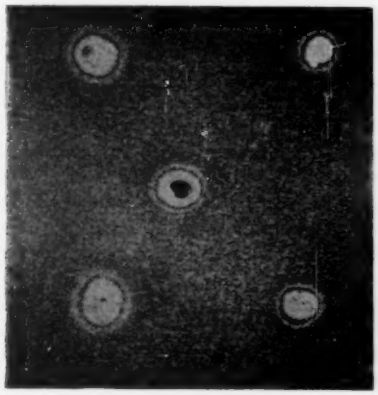

FIG. 6 FIVE SPOT WELDS VARYING IN TIME OF CURRENT

(The time varies from 1/4 to 1/2 sec. Polishing and etching developed the corona ring.)

should it attempt to guide others whose ingenuity will devise new ones. Suffice it to say that the amphibian shown incorporates type structures for every department of aircraft design.

Much novelty is to be found in the hull, where a thin material usually stands at greatest disadvantage. Here the thickest skin sheet is 0.016 in.; the thinnest 0.010 in. In order to prevent billowing or dents, the entire skin is carried by longitudinally running channels, and these attach to the frames and bulks. No cross-member touches the shell. As a consequence, all distortion results in longitudinal waves between fore-and-aft members, and these disappear upon release of pressure. The washboard effect between ribs, which is so characteristic of thinly sheathed hulls, has been successfully avoided. Again, since the shell is "hung," so to speak, it flexes under pressure and is strangely quiet.

Another feature peculiar to this design is that the bottom and sides were completely fabricated before assembly, and then swung into position, without removal from their respective jigs. Side jigs were made to dowel and bolt to the bottom jig. Assembly consisted of flanging over a lap joint at the chine and securing the side and bottom frame pieces by knee gussets. Deck frames were then thrown across and the deck sheathing attached. By

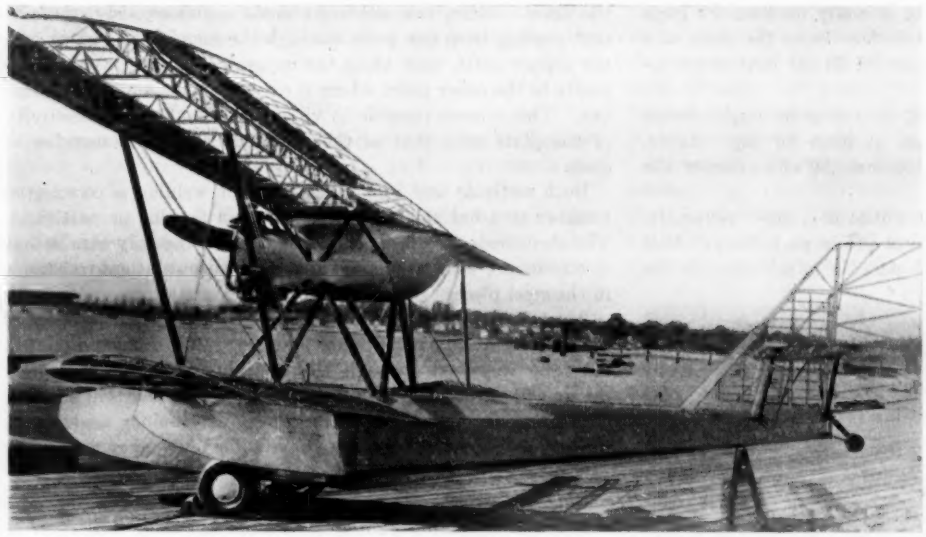

FIG. 7 THIS AMPHIBIAN IS THE FIRST COMPLETE STRUCTURE TO BE MADE OF STAINLESS STEEL AND ASSEMBLED BY SHOT WELDING
(The resulting weight, strength, performance, and quietness showed improvement over the equivalent aircraft made of wood.)

this method a minimum of inside work resulted. Work in the open is always done more expeditiously.

In this and other experimental work, it has been found that expense runs no higher than in the more common forms of aircraft structure. After all, the cost of such work can be attributed more to indecision than to any other one item.

Shot welding, however, makes the use of stainless attractive in experimental work. It is so easily and quickly done, it involves no elaborate jigs, and local reinforcing becomes simple.

For small structures, the only jig required consists of a number of wooden blocks nailed over the blueprint. For more elaborate ones, a wooden frame is erected, and significant points are notched out. The component strips which go to make up a closed section are, in themselves, flexible and can be naturally bent to even sharp curvature. They are then welded together and attain the rigidity peculiar to a closed member.

While it is futile to discuss weights of exact structures made up in different materials, since each has its own design tendency and limitation, it can be safely said that no complete design need suffer in weight or strength owing to its fabrication in stainless steel. In fact, the amphibian in question was lighter and stronger than its equivalent in wood. Had the craft been larger, an even wider discrepancy would have obtained.

COST

However tender the subject, cost cannot be ignored. The 18-8 costs in fair poundage from 40 to 60 cents a pound, depending upon gage, width, and specification. It comes in coils. Scrap lossage is very little where design cooperates. A low figure is 5 per cent; 20 per cent is high.

Draw rolling of sections is cheap—much cheaper than braking.

Shot welding is perhaps the quickest and cheapest form of attachment. One operator can average 10 welds a minute on complicated work and 40 on fairly straight seams. Machine welding has no apparent limit. Using only one pair of points, 100 welds per minute have been consistently done.

Stainless steel, however, is not a cheap way out; it is a good way. Where maintenance can be considered, it more than justifies itself. The 18-8 is a material of permanence. Shot welding is a method of rigid attachment which will not work loose with time.

Up to now, the chiefest factor of cost is engineering. Such is always the case in a pioneer development.

CORROSION

Talk of corrosion comes last, where it rightfully belongs. The 18-8 does not naturally corrode, nor does it materially age harden or show signs of instability. Certain chemicals will attack it slightly; certain abuses will render it corrodible.

When shot welded, it will show in the salt spray a pigmentation due to the rusting of iron particles which have flashed out of the fused zone. This can be arrested by washing in diluted nitric acid, but need really cause no apprehension. Certain shot welds have been in a salt immersion test for 14 months with no sign of weakened effectiveness. The pigmentation, however, is disquieting to those not familiar with the process or condition, and is responsible for continual discussion of corrodibility—a discussion which is fortunately academic rather than of serious moment.

CONCLUSIONS

Stainless steel will assume its position in the aircraft industry only when and where the urge is great enough to study its possibilities, to acquire its technique, and to overcome the discouragement of first efforts. Such an urge has not been uncommon in aviation. In fact, its brief history has been a continual search for better materials. The Wright brothers, having demonstrated a theory with a device of wooden sticks and iron telephone wires, next perfected their technique by the use of spruce and piano wire. Then with fabricated wooden sections, aircraft structures rested for a while; the material certainly was as reliable as the calculations by which it was stressed. When science stepped in to guide ingenuity and courage, the search for materials was resumed. Steel tubing offered that ideal which the formulas required, but the joining of such was a problem for the mechanic rather than the professor. Gas or arc welding, somehow, did not seem consistent with the ideal. Heat warped the structure, and the weld depended on the skill of the operator. Production dare not depend upon personal skill. Then, too, corrosion raised a question.

In the meantime, lighter-than-air machines had developed duralumin to commanding position. It answered the urge for all-metal planes, monocoque construction, and hulls. The relatively thick plates made skeleton structures simple. Heat treatment had the earmarks of magic, for the metal could be worked soft and would harden after assembly. But, again, corrosion raises its head, and this time with the added discordant note of fatigue failure.

England turned to heat-treated steel and fabricated structural members. Then, of late, one hears again of stainless; and let it be remembered that the first use of this material in aircraft was over there. They used it; they spot welded it; they built tons of it into that ill-fated *R-101*. But for some reason the development was never carried to its logical conclusion. Only now does one hear of resumed interest and a desire to learn the technique which may have been lacking before. Certainly, the urge is there.

In this country we note a trend, and it is not toward the air flivver with all that that implies, but toward transport units. With it comes added interest of governmental agencies, and that interest will spell "quality." It will inquire into conditions which may obtain in structures, not today, but five years or more from today, and that means "permanence." Then, cost of initial production can be balanced against service and maintenance, and that spells the end of long-enduring stick-and-wire construction. Then, the urge toward proper materials will not have to be stimulated.

Whether or not that urge will be toward stainless remains for time to tell. But the author of this paper, enjoying the prejudice which has been his through years of experimentation, believes it will.

AER-55-13

Recent Developments in Grading Fuels for Aeronautical Use

By W. W. WHITE,[1] NEW YORK, N. Y.

The subject of fuel grading is somewhat unknown to engine constructors, airplane operators, and others. In dealing with the grading of aviation gasoline, the author, instead of drawing on the great mass of experimental and published data on the subject, with the complexities of each of the component parts, and preparing an exhaustive discussion of one of the components, has chosen to present a general discussion of the factors involved. To this the author has added his opinion of the probable trend in the near future. Some of the points raised are to a degree controversial. The paper also includes a review of recent flight tests with various fuels.

IT HAS BEEN generally accepted by engineers, as a result of thousands of tests conducted in this country and abroad, that the tendency of a fuel to detonate in an engine is by far the outstanding characteristic of importance. Probably the next most important item is the shape of the volatility curve. Aviation gasoline must contain sufficient proportions of low-boiling (highly volatile) constituents to permit the easy starting of a cold engine. These constituents must not be present in excessive quantities, as this encourages any tendency to premature vaporization in carburetors or fuel lines, with resulting vapor lock. Likewise the presence of an undue proportion of high-boiling constituents is undesirable, as this may cause irregular distribution and excessive heat in those cylinders which fail to receive their proper proportion of fuel.

The gasoline should have a reasonably high volatility in order to insure good flexibility or response to throttle variations when the engine is below usual operating temperatures. Volatility is usually determined by means of a distillation test made under carefully specified conditions. The interpretation of results is best illustrated by the example of the United States Army's specifications for aviation gasoline, fighting grade. These specify maximum temperature limits for the 10 per cent point in the distillation range, the 50 per cent point, the 90 per cent evaporated point, and the maximum allowable distillation loss, specified as 2 per cent. The maximum limit for the 10 per cent point insures that the gasoline is sufficiently volatile at low temperatures to assure easy starting. Since "gas lock" may be encountered if the fuel is too volatile, the volatility at low temperatures is further controlled by specifying a maximum allowable vapor pressure. The limits on 90 per cent point insure against tendency toward poor distribution and excessive oil dilution. The limit on the 50 per cent point, in conjunction with the other limits, insures the desired average volatility. It will be noticed that no mention is made in the foregoing of either the initial distillation temperature or the end point. Conclusive tests, covering both the aeronautical and the automotive fields, have pointed to the conclusion that neither has any significance when related to engine performance. (See "The Meaning of the Gasoline Distillation Curve," by Graham Edgar, J. B. Hill, and T. A. Boyd, A.P.I. paper presented at Chicago, Ill., Nov. 12, 1930.) The end point does serve, however, as an excellent indicator of possible contamination, especially when viewed in conjunction with the distillation loss.

A short discussion of the other items governing present-day specifications for aviation gasolines or appearing in analyses of these fuels may be in order as matters of general knowledge, tabulated for ready reference:

Color. A comparative test performed usually with the Saybolt chromometer. A figure of +25 indicates that the product is water white and colorless. Successively lower numbers indicate increasing color content.

Doctor. Should be "negative" or "sweet."

Odor. Self-explanatory; a fuel may be characterized as having a coal-tar, aromatic, cracked, naphthenic, or paraffinic odor, etc.

Sulphur. Expressed in percentage of sulphur content by weight. It should under no circumstances exceed a value of 0.1 per cent.

Acid Heat. Of primary significance as an indicator of the manufacturing method employed. A very low number indicates a straight-run product, a high number that it is a product of cracking.

Acidity. Self-explanatory. The fuel should show a neutral reaction.

Corrosion. Determined by evaporating 100 cu cm of fuel in a polished copper dish, after which no gray or black corrosion of the copper should result.

Gum. Usually determined in a copper dish, as in determining corrosion. Weight of residue should not exceed 3 mg.

Accelerated Oxidation. Determined by subjecting gasoline to accelerated aging at 212 F in presence of oxygen at 100 lb pressure for 4 hr. Subsequent evaporization of 100 ml of oxidized sample should yield residue not to exceed 10 mg—an indi-

[1] Aviation Department, Standard Oil Company of New Jersey. W. W. White was born April 7, 1900, at Bozeman, Mont. He attended University of Montana, 1918; was admitted as cadet, U. S. Military Academy, West Point, July 1, 1919; was graduated June 12, 1923, and commissioned second lieutenant in the U. S. Air Corps; Air Corps Primary and Advanced Flying Schools, 1924; on duty as flying instructor, Air Corps Primary Flying School, Brooks Field, Texas, 1924–1926; assigned to McCook Field, Dayton, Ohio, June, 1926, as student, Air Corps Engineering School; was graduated, June, 1927; assigned to Flight Section, Matériel Division, Wright Field, as test pilot; on duty U.S.M.A. as instructor in physics, mechanics, and aerodynamics, 1927–1928; assigned to Massachusetts Institute of Technology for post-graduate work in aeronautical engineering, 1928; received degree of Master of Science in Aeronautical Engineering, June, 1929; assigned to duty at Wright Field as project officer in charge of pursuit, observation, and attack airplanes, June, 1929; served until February 5, 1930, when he went with Standard Oil Company of New Jersey as research engineer and chief test pilot; present commission as Captain, Air Corps Reserve; coholder with Captain Clements MacMullen, U. S. Air Corps, of present record New York to Buenos Aires, Argentina, and Buenos Aires to Rio de Janeiro.

Presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

cator of the stability of the gasoline in storage and in service.

Breakdown Period. Used as substitute for, or supplementary to, accelerated oxidation test. Technique is similar in general to the latter, except that test is continued until gasoline becomes unstable. A period of 3 hr without breakdown is equivalent to at least one year's storage. This test is thought by many to be more severe than the accelerated oxidation test.

Reid Vapor Pressure. Determined by heating a small bomb containing the sample to 100 F. It is generally conceded that the pressure rise should not exceed about 7.5 lb to insure safety from vapor lock in all installations. This stipulation reacts to limit the 10 per cent point in the distillation range, as the highly volatile fractions are those which raise the vapor pressure.

Freezing Point. Self-explanatory. To insure against clogging of jets and icing in manifolds, this figure should be below —76 F. Gasolines containing 20 per cent or more of benzol seldom meet this requirement.

Gravity. Expressed either in A.P.I. units or as specific gravity. It is as valueless in the determination of desirable qualities or the constituents of gasoline as using the total weight of a pile of dirt as a measure of the proportion of sand, gravel, or stones that the pile contains. The Government does not in a single instance consider this item in its specifications.

Octane Number. The great variations in anti-detonating characteristics which have been noted in gasolines which are perfectly satisfactory for aeronautical use in all other respects have been responsible for a vast amount of research and test work. Oil companies, engine builders, governmental agencies, and technical societies have labored, both individually and co-operatively, to arrive at a basis for measurement of this all-important factor which can be applied directly as a criterion of the adaptability of the fuel to engines in actual operation. A direct result of these intensive investigations has been the adoption of the present American method for determining and expressing anti-knock properties. This practice, which is receiving international recognition, and which it is hoped will shortly be adopted as a universal anti-knock yardstick, is to compare the fuel in question with a basic chemically pure fuel. This basic standard is a mixture of iso-octane (2-2-4 tri-methyl pentane) and normal heptane, two hydrocarbons which can be obtained in a chemically pure state. Iso-octane has exceptionally good anti-detonating properties, well above all classes of current clear gasolines. Normal heptane possesses pro-knock characteristics to an equally marked degree. By mixing these two substances in proper proportion, a fuel of any desired knock characteristics may be obtained, against which a given sample of gasoline may be compared. The anti-knock quality of the fuel may then be expressed in terms of "octane numbers," the number designating the percentage of iso-octane in the octane-heptane mixture which corresponds in knocking characteristics to the fuel sample under test. Since the octane is the knock suppressor in the mixture, it follows that the higher the octane number of a gasoline, the better its anti-knock qualities.

After having established the basic comparison fuel, it has remained to define and perfect the test conditions under which the fuels are to be compared. These conditions, if the ideal is to be realized, must predict accurately the performance of the fuel in a full-scale engine, under the most strenuous conditions of operation. At the same time it is necessary that they be readily and inexpensively realized by "run of the mine" laboratory personnel, and that the results of tests be reproducible by widely separated agencies.

The vast amount of cooperative experimentation which has been expended upon the problem has produced results which are extremely encouraging. Proceeding from the groundwork established through developing the technique of rating automotive fuels, it is now usual for several separate laboratories to agree on the octane rating of a particular aeronautical fuel to within one octane number, under the current commercial method in vogue. Briefly, this method employs an Ethyl Gasoline Corporation series 30 single-cylinder test engine, operated at a jacket temperature of 300 F and at 600 rpm, with 15 deg spark advance. Substitution of the Cooperative Fuel Research Committee's variable compression engine, operated under similar conditions, gives results of comparable accuracy. The detailed conduct of these tests has been widely discussed before the Society and elsewhere, and may be referred to by those interested.

The correlation of data obtained on the anti-detonating characteristics of fuels in the laboratory, with actual full-scale performance in aeronautical engines, still remains a problem of the first magnitude. It is relatively simple to determine, for a gasoline from a selected crude and produced under a particular set of manufacturing specifications, the octane number required by any engine or series of engines for satisfactory operation. An excellent example of this type of correlative work is the fuel recommendation chart prepared by engineers of the Stanavo Specification Board, Inc.

The situation is enormously complicated, however, when we consider that gasolines from various crude sources, or of varying methods of refining and manufacture, or variously blended with lead tetra-ethyl, benzol, or other anti-detonant, refuse to cooperate with the investigator. He finds that a series of gasolines of diversified antecedents which have identical octane numbers when tested, say, at 300 F jacket temperature, 600 rpm, and 15 deg spark advance, fail by a large margin of being identical in octane rating if the test conditions are changed to 375 F jacket temperature and 900 rpm. Moreover, he discovers that these gasolines, which have so neatly catalogued themselves in the same anti-knock bracket in the laboratory under the 300 F, 600 rpm conditions, fail just as dismally to perform comparably in a full-scale test in an engine which is supposedly critical at that octane number. Horsepower, cylinder temperatures, smoothness, and fuel economy vary in a manner which is inexplicable, until the investigator notes that those fuels whose octane numbers have been reduced the least by the more severe 375 F, 900 rpm method of test, are the products which are in the same degree satisfactory to the engine.

A sequence of events such as the foregoing was noted by technical experts at the Matériel Division, Army Air Corps, and sufficient corroborative data were amassed to warrant the establishment of an amendment to its specification Y-3557-D. This amendment requires the determination of octane numbers in the series 30 Ethyl Gasoline Corporation engine, at 900 rpm, 375 F jacket temperature, and 15 deg spark advance. Mr. S. D. Heron has described the preliminary investigations which led to the adoption of this amendment in a paper delivered before the S.A.E. Aeronautic Session, Chicago, August 26 to 28, 1930, entitled, "Fuel Requirements of the Gasoline Aircraft Engine."

The Naval Bureau of Aeronautics has likewise signified its acceptance of the fact that these more stringent test conditions are better representative of full-scale engine requirements by insisting on similar speed and jacket temperature conditions. Its schedule 7567, domestic aviation gasoline, includes these stipulations in its specifications.

The Detonation Sub-Committee of the Cooperative Fuel Research Steering Committee has realized the importance of this problem, with particular reference to automotive engines. This committee is sponsoring investigations which are similar in purpose to the cooperative test at the General Motors proving ground, carried out by the General Motors Corporation, the

[a] F. G. signifies that the fuel meets all of the provisions of U. S. Army specification Y-3557-E, aviation gasoline, fighting grade, with the exception of octane number. D. A. G. signifies that the fuel fails in one or more items to meet F. G. specifications, but that it meet domestic aviation gasoline specifications in every particular. It should be borne in mind that any fuel meeting the fighting grade specifications will of course meet D. A. G. specifications.

[b] Standard reference fuel B-2 is an especially prepared secondary testing fuel, checked against pure octane and heptane. Secondary standard fuels are used in routine test work to avoid the expense of rating against the chemically pure octane and heptane.

Standard Oil Development Company, and the Ethyl Gasoline Corporation, arranged for the purpose of verifying preliminary conclusions based upon the work of the Ethyl Laboratory in this connection. Their results show that the present automotive test conditions, which are even less stringent than the commercial aeronautical conditions (600 rpm, 212 F jacket temperature), fail just as completely to predict gasoline performance in the automobile engine. (Ethyl Gasoline Corporation Report, "Correlation of Knock Testing Engine Ratings With Knocking in Automobile Engines," February 5, 1932.)

Table 1, which is taken from investigations carried out by the Standard Oil Development Company, shows the effect upon octane ratings of various types of aviation gasolines, of varying the knock test procedure from the commercial standard of 300 F, 600 rpm, to the new military standard of 375 F, 900 rpm.

Full-scale flight tests have been carried out by the author on gasolines B to J, inclusive, in one of the test airplanes of the Standard Oil Company of New Jersey. The engine had been rated by the manufacturer as requiring a fuel of 73 octane number, at 300 F and 600 rpm, and it was found to be extremely critical. Fuels C, D, E, F, and H were found to operate with normal cylinder-head and base temperatures and approximately equal maximum rpm and fuel economy, under full-throttle level-flight conditions. Fuel G did not give audible detonation on the ground, but full-throttle, level-flight conditions at ground could be maintained for less than two minutes before cylinder temperatures reached dangerously high figures, with an accompanying loss in rpm of about 200, necessitating immediate partial closing of the throttle. Fuel J gave audible detonation on the ground, and such violent detonation at full throttle in level flight that continuation of the test was deemed inadvisable. Fuel B showed no detonation on the ground. Flight tests showed gradually increasing head temperatures during four full-throttle runs at the ground over a two-mile speed course.

Flight-test data are always subject to criticism because of the inability of the pilot exactly to duplicate all flight conditions, to say nothing of being able to control temperatures, humidity, and other atmospheric variations. It appears to the author that this very lack of uniformity in flight test work, augmented as it undeniably is in routine military and commercial flight operations, provides the most excellent case in favor of choosing a test basis for gasolines which is, as closely as possible, comparable to the most severe engine requirements in service.

Further investigation of the correlation of laboratory test data to engine requirements is at present under way. Through the cooperation of the Wright Aeronautical Corporation, all of the fuels tabulated are at present undergoing full-scale dynamometer tests, under the supervision of Mr. R. F. Gagg. The engine selected for examination of fuels A to J, inclusive, has been found to be very critical of octane-number variations from 73, while that assigned to the test of fuels K to S, inclusive, is equally critical at 80 octane number. In these tests, of course, it is possible to control practically all variations for which corrections cannot be made. Results to date indicate further substantiation of the growing mass of data in favor of changing commercial test conditions to correspond to those required by the governmental agencies for military use. These dynamometer tests will be supplemented by flight tests in one of the Stanavo "Eagle" Lockheed Vega airplanes, powered with a Pratt & Whitney Wasp "C" engine with 10-to-1 supercharger gearing. This engine is supposedly subject to detonation using gasolines rating below 80 octane at 300 F and 600 rpm.

If the results of these investigations and of those now in process by other agencies are in further substantiation of the conclusions which have grown from the previous work, it would seem that the next and a very long step forward would be the adoption, as standard commercial test basis, of rating aviation fuels on octane number at 375 F, 900 rpm, and 15 deg spark advance, in accordance with current Army practice. Further, it would seem logical and practical to grade these fuels in brackets of ten octane numbers, i.e., 50, 60, 70, 80, and 90, assigning each gasoline to the next lower bracket in every case. Under these conditions a fuel which tested in the laboratory at 67 would fall in the 60-octane-number classification, one which tested 84 in the 80-octane bracket, etc. The adoption of such classification would insure that the purchaser of fuel would receive a product which was at least as good as and very probably better than that for which his engine had been proved to be critical by the builder, if he demanded his supplies in accordance with the manufacturer's recommendations. The present commercial method of rating is apt to give fictitiously high values, so far as full-scale engine operation is concerned, which would certainly be materially reduced under the proposed conditions to octane values more nearly representative of engine requirements.

Erratum

On page 38 of AERONAUTICAL ENGINEERING for January-March, 1933, in paper AER-55-5 ("Air Compression With Temperatures Above Adiabatic With Special Reference to Airplane Superchargers," by Sanford A. Moss) in the last line of column (2), "T" should be "T_2."

AER-55-14

National Air-Tour Formulas and Other Methods of Handicapping

By P. ALTMAN,[1] DETROIT, MICH.

Methods of scoring and handicap used in aircraft competition events are given. The first part contains a historical review, and the second contains criticism of handicap formulas, these having a bearing on aircraft design and the improvement of airplanes. In many cases airplanes are especially designed for air races, and if the design is good, it increases progress. The paper takes up the important formulas for handicapping and considers them from a race and design point of view. Useful curves are plotted.

NO TWO contestants in an air race will agree that the handicap is entirely fair. It really is difficult to devise a handicap to suit all competitors, with widely varying equipment and piloting skill, especially in such events as tours, derbies, and free-for-all races. In the National Air Tour for the Edsel B. Ford reliability trophy, the airplanes entered ranged from a single-place airplane with a two-cylinder engine of 20 to 30 hp to a sixteen-passenger airplane with about 1200 hp, and this year a forty-passenger airplane of about 2500 hp might have been entered.

These conditions in an event open to all aircraft require a method of handicapping suitable to the smallest "flivver" airplane and to the biggest air liner, with the necessary factors of simplicity and ease of application.

It is true that handicaps are not always equally just to all entrants, and the fact that events where obviously there was partiality were completed without official protest shows the contestants' high standard of sportsmanship. Without this, all the slide rules and regulations developed by the handicapper or referee would not make for a successful event.

The answer as to why there is a handicap is a simple one, and much has been written on its origin, development, and failings (1).[2] Its origin probably dates back to the earliest organized competition between fellow men and is because in the development of man his stature, ability, and character have had as many forms as the equipment with which he has become accustomed to work. As a result no two groups of men in developing a machine will produce exactly the same structure or performance characteristics. But in their own minds they believe that their equipment is the best for the purpose. This was true in the earlier machines of transportation, and the condition is even more pronounced in the airplane. One designer may believe that low landing speed is essential, another that high speed should be the criterion, and still another that the major requirements are convenience of schedule, comfort of travel, and low cost, regardless of the factors of pay load and speed range.

To judge the varying equipment collectively in any contest presents a problem to the handicapper, whose instructions are to apply the handicap so as to place all contestants on an equal basis. The handicap may take the form of:

(*a*) Personal judgment by a group of authorities, a method practiced with fair success in England (1).

(*b*) A mathematical formula, employed at one time or another in most countries.

(*c*) A point system developed from the characteristics of a hypothetical airplane having ideal performance for a particular case, such as the point system used for the Guggenheim Safe Airplane Competition (2) and many contests in Germany (3).

In archery tournaments (4), one of the oldest of sports, the contestants are handicapped on their record of previous contests and also upon the improvement shown between contests. Automobile (5) races in America are seldom handicapped. Contests are usually divided into classes, with the division based on piston displacement. There are automobile contests, such as the cross-country tours so popular ten or twelve years ago, that are conducted on a handicap basis, the method depending largely upon the objective to be achieved. The figure of merit of each car is obtained by a formula based on the weight of the car in tons multiplied by the miles covered and divided by the gasoline consumed. This can be reduced to a formula familiar to some aircraft efficiency contests:

$$\cdot \frac{W \times S}{C \times \text{bhp} \times t} = \frac{WV}{P \times C} = FM$$

where

FM = figure of merit
W = weight of car in tons
S = distance in miles
C = specific fuel consumption
P = bhp = brake horsepower of motor
t = time in hours
$V = S/t$ = speed in mph.

[1] Director, Aeronautics Department, University of Detroit. Peter Altman had primary and high-school training, Montreal, Que., Canada, and college training, University of Detroit, receiving the degree of Bachelor of Aeronautical Engineering, 1925, University of Detroit. He was co-builder of the Power Racer, winner of the 1925 Light Airplane Events at the International Air Races, and first place for Aero Digest Trophy, Dayton Daily News Trophy, and Scientific American Trophy. He is author of manuals in aerodynamics, airplane design, and propeller design in use at University of Detroit. He has served as sub-chairman, Technical Committee, National Air Races, 1931 and 1932; sub-chairman, Technical and Contest Committee, National Glider Association, 1929–1931; member, Committee on Gliding and Soaring Flight, National Aeronautic Association, 1933; chairman, Rules Committee, National Air Tour, 1929–1932: chairman of Aeronautics and chairman, Detroit Section, Society of Automotive Engineers, 1930–1931. Mr. Altman was with the Royal Canadian Air Force Reserve, 1920–1923; laboratory assistant, Electric Welding Company, Montreal, 1919–1921; laboratory assistant, Aeronautical and Mechanical Laboratories, University of Detroit, 1921–1925; instructor in aeronautics, University of Detroit, 1925–1928; consulting engineer, Verville Aircraft Corporation, 1929–1931; engineering representative, Barber & Baldwin, Inc., 1929 to date.

Presented at the Cleveland Air Races meeting, Cleveland, Ohio, in cooperation with the Cleveland Local Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS and the Cleveland Engineering Society, September 1, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Numbers in parentheses apply to references at the end of the paper.

In speed events entered by cars of varying size and power, qualifying time is usually the basis of the handicap, and the slowest car is started first. For example, if ten cars are entered in an event on a 1-mile track and the fastest qualifies at 37 sec for one lap and the slowest at 42 sec, the time differential is 5 sec, and for ten cars, we can assume, if the differential between cars is equal, that on a handicap of $^1/_2$ sec per car per lap, all cars would finish at the same time. If the time differential varies, the handicap has to be varied accordingly between cars. Also, consideration is given to the fact that it is difficult for a car to maintain its qualifying speed on a race of considerable length, and the handicap is usually modified an amount determined from experience.

In Europe, more attention has been given to the mathematical handicapping of automobile races, some involving elaborate methods (6). Handicapping by formula (7) is applied to power-boat racing. Golfing, horseracing, sailboat races, and motor-cycle races have received attention in handicapping. It is therefore not surprising to find the most modern of sports, the aircraft contest, conducted upon some form of handicapping, with the method similar to that in other automotive events, but developed to meet the characteristics of the airplane, such as take-off, speed, landing run, and rate of climb.

In aircraft competitive events, the National Air Races and the National Air Tour are major contests which have received the attention of handicapping committees and judges. The events in both contests have gained in prominence from year to year, yet seldom has either been conducted under the same rules for succeeding years. The rapid development of the equipment entered in these events has been the primary factor dictating such changes.

In 1921, in the Air Races at Omaha, the handicapping formula for the John M. Larsen Efficiency Trophy was in the form:

$$FM = \frac{(W - T) \times S}{G}$$

and can be seen to have no particular significance if reduced to the form:

$$\frac{W_u}{C \times P \times t} \times V = \frac{1}{C} \frac{W_u}{P} \times \frac{V}{t}$$

where V/t appears to have no relation to the performance characteristics of the airplane.

FM = figure of merit
G = fuel consumed = $C \times P \times t$
C = specific fuel consumption
$S = V$ = average speed
t = time in hours
$(W - t) = W_u$ = useful load
P = bhp of engine.

Subsequent efficiency contests modified this formula variously but again in another year it is found in almost the same form, and given as:

$$FM = \frac{W_u \times V \times 3}{\text{gas consumed}}$$

The similarity to the 1921 formula is obvious, if we substitute for gas consumed $C \times P \times t$.

In other years, the winner in the efficiency contests of the air races was determined by various handicapping formulas, all of them possessing certain merits and most of them stressing particularly the ratio of useful load to the power consumed, but very few giving any consideration to the safety or reliability of the airplane. In one case, we find the winner determined by the formula:

$$FM = \frac{\text{average speed} \times \text{constant}}{\text{piston displacement}}$$

On analysis, this formula does not appear to have any practical or theoretical basis, but evidently served some purpose for which it was intended. In another instance, the handicap was applied by the formula:

$$FM = \frac{\text{weight}}{\text{gas consumed}}$$

And so on, other contests employing such formulas in many different forms. If we substitute in the latter formula for gas consumed its equivalent given by the product of $C \times P \times S/V$, with the terms having the same significance given before, we obtain:

$$FM = \frac{W \times V}{C \times P \times S}$$

Further, if the contest is conducted over a course which is of the same length for all contestants, then S is constant and

$$FM = \frac{W \times V}{K \times C \times P}$$

which is a familiar form and quite popular in many contests such as the automobile economic races. The figure of merit is a function of the specific fuel consumption, a factor difficult to measure accurately even under the best of conditions and particularly in contests in which a large number of airplanes are entered.

A handicap used for several years in the Detroit News Efficiency Contest of the National Air Races is:

$$FM = \frac{W \times V}{P}, \quad \text{or} \quad \frac{W \times V}{\text{piston displacement} \times K}$$

differing from the other in that the specific fuel consumption has been eliminated. These formulas do not contain any factor governing the rate of climb or stalling speed of the airplane. Under this method of handicapping, it is entirely possible to win the contest by loading up the airplane, provided a large enough field is available for take-off. In one case it was possible to overload an airplane 50 per cent without decreasing the maximum speed more than 2 per cent and resulting in an increased figure of merit of over 100 per cent, all accomplished at the expense of increased stalling speed, decreased rate of climb, and increased take-off run, the latter factor jumping from about 400 ft to 1600 ft, or 300 per cent. Therefore, since take-off distance and the other factors affected by high-wing loading are not accounted for in the formula, winning the contest was a "walk-away" for this particular airplane. This condition will appear obvious if one examine the factors involved in the formula. For a given airplane, the power and wing area are constant, and on the basis of Warner's formula (8) for maximum speed, where $V = K \sqrt[3]{\frac{P}{S}}$, it can be seen that the speed is also constant and independent of the weight. Therefore the figure of merit becomes a direct function of the weight of the airplane, and its magnitude depends largely on the size of field available for take-off. Of course, the formula $V = K \sqrt[3]{\frac{P}{S}}$ assumes constant propeller efficiency and rpm, an assumption which is not entirely correct. However, the variation in these factors is small.

The 1931 National Air Races adopted the 1930 National Air Tour formula for its efficiency contest. This formula was de-

veloped from the experience and data obtained in the National Air Tours from 1926 to 1929, and is the result of the combined efforts of the Rules Committee of the tour under the chairmanship of Mr. Wm. B. Mayo and the suggestions and constructive criticisms from contesting pilots and members of the aircraft industry. In 1929 and some previous years, the method of handicapping in the National Air Tour was applied by the formula:

$$FM = \frac{W \times V \times K}{(S/2 + US) \times \text{piston displacement}}$$

By this formula, it was attempted to remove the objectionable features of the efficiency formula $FM = K \times (WV)/P$, so often used in the National Air Races, by introducing in the denominator the factor one-half stick time plus unstick time, where stick time was the time in seconds required to stop the airplane after landing, measured from the instant the airplane touched the ground to the instant it stopped rolling, and unstick time was the time in seconds required for the airplane to take off, measured from the instant the wheels began to turn to the last time that the wheels touched the ground. These terms will be referred to as S and US, respectively.

By the inclusion of the factors of stick and unstick time in the older formula of $FM = (W \times V)/P$, the figure of merit at once became an index to not only the weight-carrying efficiency and speed but of safety and reliability as well. The weight-carrying efficiency is represented by the ratio of the useful load to the horsepower, the speed enters directly in the term maximum speed, the reliability through the length of the tour and penalty imposed for forced landings, repairs, etc., and safety is excellently represented by a liberal reserve of power and low landing speed, both of which enter into the determination of the term of stick and unstick time (10).

Yet at the end of the 1929 tour, practically all contestants clamored for a change of some kind. It is true that the formula contained all the essential factors necessary for a just and fair

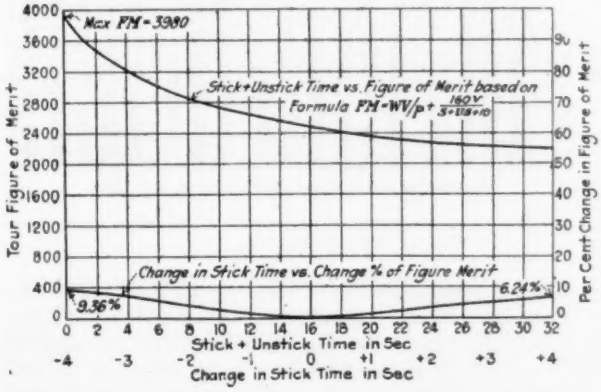

FIG. 1 EFFECT OF SMALL DIFFERENCE ON FIGURE OF MERIT FOR EACH TOUR FORMULA DUE TO ERRORS IN TIME OR SKILL OF PILOTS

handicap and considered all the factors pertaining to both aerodynamic and structural efficiency, but it was questioned whether these factors were in exactly the correct form and with each given its proper credit.

The terms of useful weight per horsepower and maximum speed were accepted without argument, but not so with the term of stick plus unstick time. The effect of this term on the total figure of merit is of primary interest. It appears that an unduly large percentage of the credit is given to this factor, and is shown by Fig. 1. In this is plotted the figure of merit against stick plus unstick time, on the assumption that the term $(W \times V)/P$ remains constant. The intention is to show the effect of changing values of stick plus unstick time on the final score as a result of the improvement of brakes, changes in landing angle, and the condition of the use of brakes and no brakes. It will be seen that the curve is asymptotic and that if the term $S + US$ could be made to approach zero, the figure of merit would approach an infinite value, although the useful load would be very small. While it is improbable that the term $S + US$ would ever be zero, yet it is clear that for small values of this term the figure of merit is unduly influenced by it. This is also shown by Fig. 2, where is plotted the percentage increase in figure of merit due to small changes in the term $S + US$. A decrease of 1 sec changes the figure of merit about 9 per cent. Primarily, this chart indicates the effect of small errors on the part of the timers and either poor

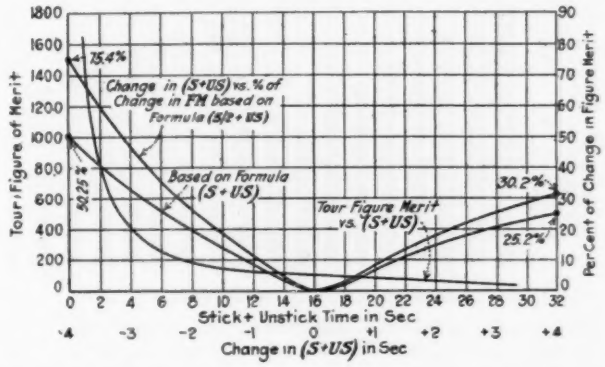

FIG. 2 EFFECT OF SMALL DIFFERENCE ON FIGURE OF MERIT FOR EACH TOUR FORMULA DUE TO ERRORS IN TIME OR SKILL OF PILOTS

judgment or bad brakes on the part of the pilot. In general, this effect is too great and the penalty paid by other contestants is too large compared to the questionable fact of the additional safety obtained by a decrease of 1 sec in either the stick time or the unstick time, which might sometimes easily be accounted for by error in timing.

In an attempt to eliminate some of the objectionable features, the stick time in the formula for 1929 was changed to one-half stick time. This, however, instead of improving conditions, actually made them worse. The term $S/2 + US$ was now smaller than $S + US$, and thus the effect of small differences such as 1 sec or less became even more pronounced. A decrease of 1 sec in $S/2 + US$, whether due to error or otherwise, now resulted in a change of about 11 per cent in the figure of merit.

However, what is true for the low values of the term $S + US$ is not the case at high values. The conditions are entirely reversed.

If we again assume the factor $(W \times V)/P$ as constant and take into account the effect of changes in the term $S + US$ due to pilot's error, poor brakes, timer's error, etc., we can see from the curve that increasing the value $S + US$ has a much smaller effect on the figure of merit of the airplane. In other words, the penalty paid at high values of $S + US$ is considerably less than at low values.

The desire on the part of any one faced with the problem of eliminating the objectionable feature of this method of handicapping or the development of some other method would naturally be to set up conditions to be fulfilled and determine as accurately as possible how the various factors in the formula obey these conditions and whether they are arranged in the order in which particular stress will be laid upon those items which the contest is aiming to develop. It is axiomatic that no contest is conducted unless some specific good is to be obtained from it. In speed contests, it is the refinement of design to obtain increased speed without increasing power; in efficiency contests,

it is the improvement in performance for a given structural weight and power; in safety and reliability contests, it is the ability in the former to land and take off safely in and from restricted areas; and in the latter, to reduce the occurrence of forced landings to a minimum.

From what has been stated, it is obvious that the tour formula as used up to 1930 laid particular stress on the effect of the factor $S + US$, and it did this well and is indirectly responsible for the development of efficient wheel brakes on commercial aircraft.

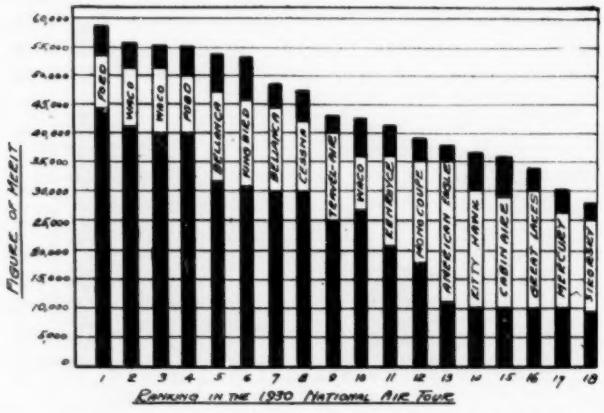

FIG. 3 RANKING IN THE 1930 NATIONAL AIR TOUR

Now that this has been accomplished, it is logical that its effect in the formula should be reduced. Hence, this would form one of the first factors to be considered in changing the present formula or adopting a new one.

Other factors of paramount importance to be considered in this case or any other are:

1 The formula should be simple for computation and simple in appearance and should be easily handled by the average pilot.

2 All factors should be easily obtained in the field and should involve a minimum chance of hazard due to crashes. Factors involving dimensions of the aircraft which are difficult to measure accurately on different types of airplanes should be avoided. Factors which require maneuvers close to the ground should be avoided for the sake of safety and adverse public opinion in the case of a crash.

3 Every factor in the formula should be effected by the variation in the airplane speed along the route in the case of a derby or tour and by every lap in the case of a closed-course event.

4 When a formula has the necessary factors to accomplish the desired results of the contest but not arranged in the proper order, the new formula should not differ materially from the old one. In some cases, however, conditions sometimes warrant new factors and a complete new formula. This is particularly true where the old handicaps have outlived their usefulness.

5 In order to develop a competitive spirit along the whole route of a tour or derby or on each lap of a closed-circuit contest, it is essential that the factors of the formula should be so arranged that the grouping of the contestants be so close that the standing of each entrant may vary from lap to lap, without of course neglect of aerodynamic or structural efficiency.

6 Due consideration should be given useful load, maximum speed, power, take-off time, landing time, reliability, and in the case of a tour passenger comfort.

7 The effect of any factor, such as take-off time, on the final score should not be excessive, except in such contests where it is highly desired to lay stress on this particular factor.

8 The value of any factor in the formula should be permitted to approach zero without the final score approaching infinity.

9 The formula should be as theoretically and fundamentally correct as simplicity will permit.

10 The factors in the formula should be so arranged that the winner will not be known until the end of the contest.

From these requirements the tour committee evolved the following 1930 formula, which was approved by the majority of the manufacturers and is believed to approach very closely to the specifications outlined:

$$\text{Figure of merit} = \frac{\text{Contest load} \times \text{Speed}}{\text{Horsepower}} + \frac{160 \times \text{Speed}}{\text{Stick} + \text{Unstick} + 10}$$

Contest load is the Department of Commerce allowable contest load, equal to the gross weight of the airplane minus the weight empty and corrected for cabin accommodations and amphibian landing gear

Speed is the actual average measured speed on each leg of the tour

Horsepower is the Department of Commerce rated horsepower for each airplane and corrected in the case of the multi-motored airplane

Stick is the time required to stop the airplane from rolling after landing

Unstick is the time required for the airplane to leave the ground during the take-off.

It should be noticed that the formula is divided into two parts, the first relating to weight-carrying efficiency and speed and the

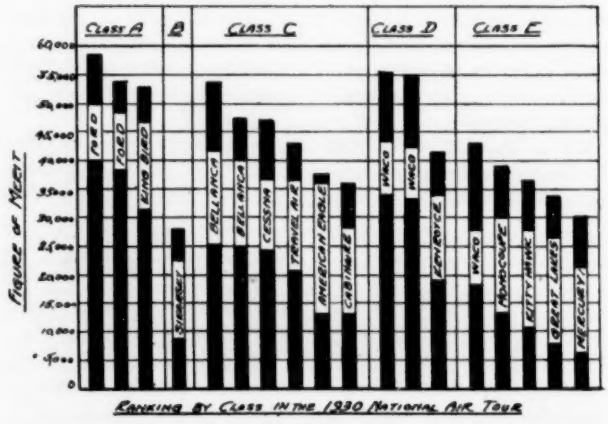

FIG. 4 PER CENT OF BRAKE-HORSEPOWER WITH MOST EFFECTIVE MOTOR STOPPED

second to reliability and safety in landing and take-off in restricted areas, as well as being somewhat connected with speed range. Proof that this formula has accomplished the results requested by the majority of the contestants is in the records of the 1930 tour. For instance, among the airplanes winning from first to tenth place is found a representation of every type of airplane, from a tri-motored Ford and twin-motored Curtiss to the small 90-hp Waco and Cessna. The competitive aspect is seen by the difference in standing between contestants and is illustrated in Fig. 3. Second place was only 5 per cent behind first, third place only seven-tenths of 1 per cent behind second, and fourth place only one-half of 1 per cent behind third. As a flying laboratory, the tour cannot be excelled. New designs are tested under actual service conditions, and old designs show up their faults, such as poor reliability of engine, airplane, and propeller. One manufacturer stated that the tour brought forth a fault in his design which otherwise might have taken six months to determine. The tour is to the airplane what the proving ground is to the automobile.

Further analysis of this formula in the light of additional performance figures seems to indicate that while the formula is fundamentally sound, yet the additional handicaps given to multi-motor airplanes should receive further attention. The multi-motor handicap, as given in the rules for 1929, 1930, and 1931, is as follows:

Multi-Motor Handicap, 1929: An entrant of a multi-motored ship will be allowed a lower cubic inch displacement figure than that which actually exists and that used in the formula providing he can demonstrate to the satisfaction of the contest committee that his plane is capable of performance as follows: (*a*) it will be required that the pilot of a three-motored ship climb from 1000-ft altitude to 2000-ft altitude as indicated on a calibrated altimeter carried by the contest committee observer as follows: With the center engine dead, he shall climb from 1000 ft to 1400 ft; with the right engine dead, he shall climb from 1400 ft to 1700 ft; and with the left engine dead, he shall climb from 1700 ft to 2000 ft level. If he shall accomplish this to the satisfaction of the contest committee observer, he will then be allowed a cubic displacement figure of two-thirds of the actual cubic displacement of all motors. (*b*) Where a twin-motored ship is employed, the pilot must climb from 1000 ft to 1300 ft with one motor dead and from 1300 ft to 1600 ft with the other motor dead. If successful, he will be allowed a cubic displacement figure of one-half of the actual cubic displacement of the two motors. In the event of failure to do this in either case to the satisfaction of the contest committee observer, the total cubic inch displacement of all engines will be taken as the displacement figure in the formula.

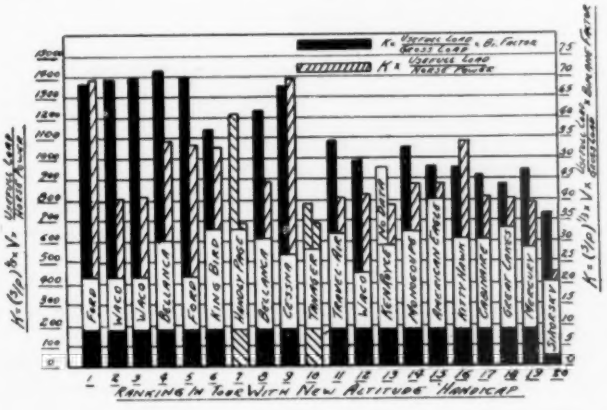

Fig. 5

Multi-Motor Handicap, 1930 and 1931: An entrant of a multi-motored ship will be allowed a lower horsepower figure than that which actually exists, and this will be used in the formula providing he can demonstrate to the satisfaction of the contest committee that his plane is capable of performing as follows: (*a*) A multi-motored ship will be required to climb immediately on all engines to 6200 ft above sea level with full contest load, and during the next 15-min interval the plane must not descend below 6000 ft when flying with the most effective engine dead. If this is accomplished the total rated horsepower of the remaining motors will be used in the formula. The most effective engine of any combination will be determined by the contest committee. (*b*) In the event of failure to do this, the total horsepower of all engines will be taken as the horsepower figure in the formula.

From the rules of 1929, it can be seen that a multi-motored airplane is required to demonstrate its ability to climb to certain altitudes, but no stipulations are made on the time required to reach these altitudes. In other words, the airplane which is heavily loaded with gasoline, usually about 30 per cent of its useful load, could take ten minutes or an hour to gain the desired altitude by climbing at a very slow initial rate and thus use up enough gasoline to reduce its weight sufficiently to enable it to reach the handicap altitude with any engine stopped.

The effect of reducing weight in the multi-motored handicap also involved the fact that no definite gross weight was specified with which the altitude tests were to be conducted. It was

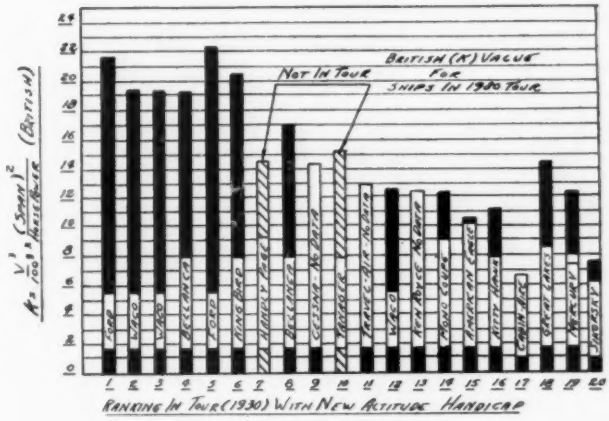

Fig. 6

possible to reduce the useful load in certain airplanes a sufficiently small amount to materially increase the absolute ceiling for performance with any engine stopped and receive a much greater benefit in the final score due to this handicap than that lost due to reduction in useful load. In the case of a twin-motored airplane this might represent a net gain of about 45 per cent.

The multi-motor ruling of 1930 and 1931 attempted to avoid this condition by setting a time limit on this performance and specifying the weight with which it was to be demonstrated. In addition, the handicap was changed from the previous basis of ability to climb on part power to the basis of settling ceiling on part power. Although the new requirements were an improvement, the factors involved worked a hardship on certain airplanes and insufficient credit was given to others. For instance, the airplane either had to complete the performance test successfully or forfeit the handicap credit entirely. Other airplanes which had ample reserve power at the settling ceiling were not given additional credit for it.

Additional investigation indicates that the multi-motored handicaps should be altered, and the following changes have been suggested:

1 The handicap credit allowed multi-motored airplanes should be based on a sliding scale. A method based on experience gained from previous contests and tempered by fundamental considerations is shown in Fig. 4, and has been suggested for future tours.

2 A standard method of correcting altitude readings for temperature and pressure changes should be adopted. For this, Diehl's correction has been suggested, where $h = h_p - k(h_p - h_d)$, where h_p and h_d are the pressure height and density height, respectively, and K has an average value of 0.36.

3 The credit allowed multi-motor airplanes should be reduced. A suggested reduction is shown in Fig. 4.

The effect of these suggested changes (as shown in Figs. 5 and 6) indicates the change in position of the contestants produced by these revisions.

Another change of importance often suggested is to divide the contestants entered in the tour into different classes, the divisions to be based on the type of airplane and its power rating. A defi-

nite plan of this type proposed for future tours or derbies is as follows:

1 Multi-motored land airplanes, any gross load, any power.
2 Amphibians, single or multi-motored, cabin or open cockpit, any gross load, any power.
3 Single-motor cabin airplanes, engine 160 hp or greater.
4 Single-motor open-cockpit airplanes, engine 160 hp or greater.
5 Single-motor cabin or open-cockpit airplanes, engine 80 to 159 hp inclusive.
6 Single-motor cabin or open-cockpit airplanes, engine 10 to 79 hp inclusive.

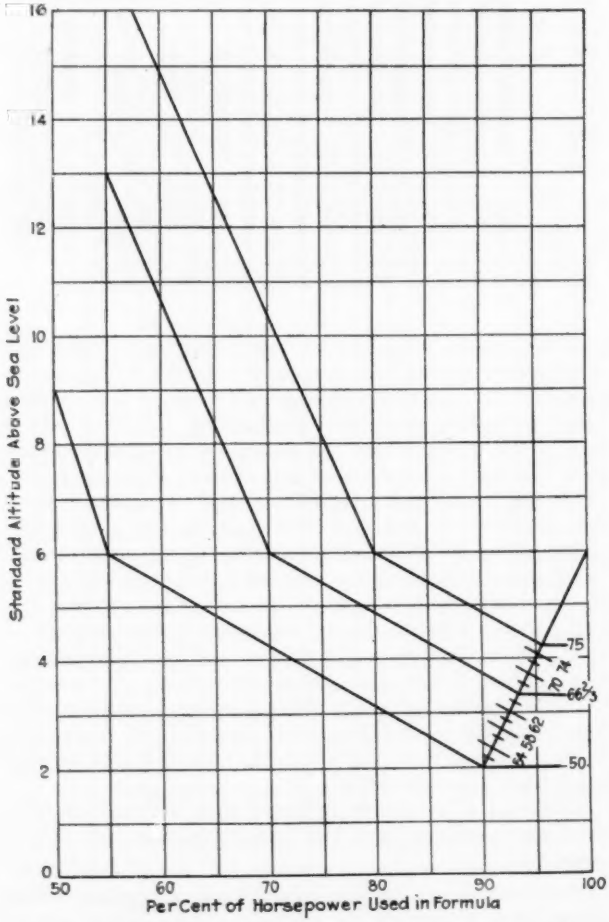

FIG. 7 RANKING BY CLASS IN THE 1930 NATIONAL AIR TOUR

The effect which this change would have had on the 1930 Tour contestants is illustrated in Fig. 7. From the arrangement of the classes, it will be seen that there are more divisions according to power in the lower powered classes than in the higher ones. This division is based on a study of the results of previous tours, arranged in a manner suggested by Warner (12), and illustrated in Fig. 8, where is shown the winning figure of merit and winning speed plotted against the corresponding horsepower of the airplane for the entrants in the 1930 tour. In addition, Warner's (12) curve of winning speed against horsepower for the A.T.C. airplanes in the 1931 National Air Races is also shown. From this chart, it will be seen that the division is fair and should result in a very interesting contest between the airplanes in each class.

A performance chart developed by the author to study the possible characteristics of new airplanes which might be entered in the tour is shown in Fig. 9. A solution for the figure of merit for any airplane by the Tour Formula is shown by the dotted line on this chart, for which the procedure is as follows:

(*a*) Obtain the values of the gross weight, wing area, and power of the airplane and also the ratio of the useful load to the gross load. If the last factor is not shown, it can be assumed to have an average value of 45 per cent of the gross weight.

(*b*) Calculate the maximum speed by the formula $V = K\sqrt[3]{P/S}$, using a conservative value of K (135 to 150).

(*c*) Enter the chart at the value of weight/horsepower (*a*), and project horizontally to the corresponding value of W, then vertically upward from (*B*) to the unstick scale S, and continue to the intersection (*C*) of the curve in the upper right-hand section of the chart. From this point, project horizontally to the intersection of the corresponding value of Useful load/Horsepower or W_1/HP (*D*), then drop vertically to the correct value of maximum speed (*E*) and horizontally to the figure of merit (*F*).

The section of the chart for unstick time is based on Diehl's formula for take-off run in a calm which is given by the equation (3):

$$X = KV_s^2 (W/P)$$

By assuming constant acceleration and substituting $X = V_s t/2$ and $V_s = K\sqrt{W/S}$, we get:

$$t = K_1 \sqrt{\frac{W}{S}} \cdot \frac{W}{P}$$

where

K and K_1 = constants and were checked by actual values measured in the tour
t = unstick time
V_s = stalling speed taken equal to landing speed
W = gross weight of the airplane
X = take-off run in feet
S = wing area in square feet
P = brake-horsepower of the motor.

The upper right-hand section of the chart is simply the ratio of $S + US + 10/US$, which appears to have a very constant value, as will be seen from the plotted points.

The curve is obtained by plotting the term $(S + US + 10)$ as ordinate and US as abscissa from data obtained in the 1929, 1930, and 1931 tours.

The rest of the chart consists of simple addition and multiplication curves, which are necessary to obtain the solution of the equation

$$\left(\frac{W}{P} + \frac{160}{S + US + 10}\right) V = FM$$

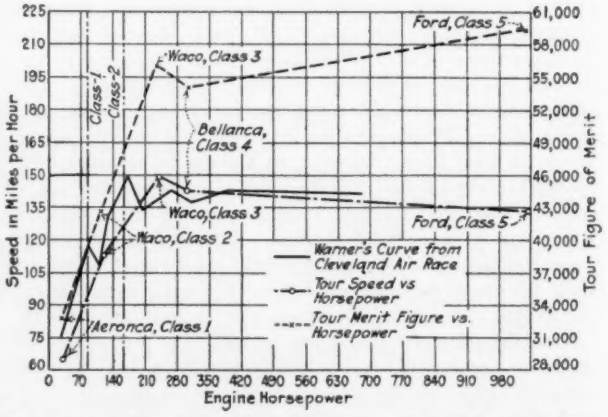

FIG. 8 CURVES FOR FIGURE OF MERIT AND SPEED VERSUS HORSEPOWER

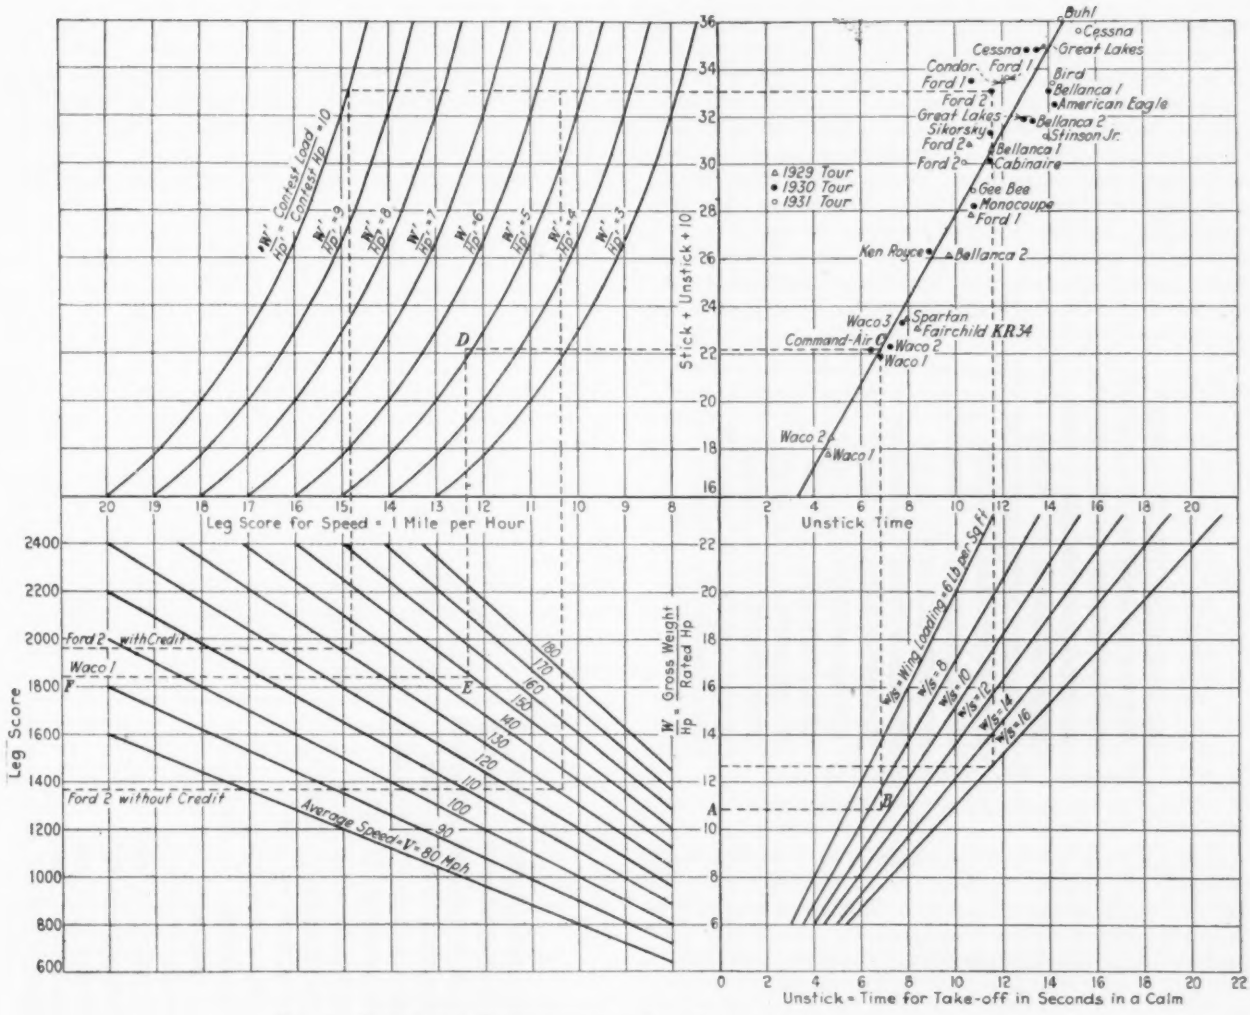

FIG. 9 CURVES FOR COMPUTATION OF LEG SCORE IN NATIONAL AIR TOUR

(Formula: $\frac{W}{HP} + \frac{160}{\text{Stick} + \text{Unstick} + 10} \times \text{Leg speed} = \text{Points.}$)

Other methods of handicapping have been suggested from time to time for both the National Air Tour and National Air Races. Most noteworthy of these has been a proposal to adopt Warner's formula for maximum speed as a handicapping formula. This appears to have considerable merit to it, from both a theoretical and practical viewpoint. The formula 8 as presented by Warner is:

$$V_{max} = K \sqrt[3]{P/S}$$

where

V_{max} = maximum speed of the airplane; the units can be either feet per second or miles per hour

P/S = the ratio of rated brake horsepower to the wing area of the airplane

K = assumed as a constant for all aircraft (14).

This constant is really a function of (*a*) the drag coefficient of the whole airplane, (*b*) the propeller efficiency, and (*c*) the maximum lift coefficient of the airplane. Thus the better the streamlining, the higher the propeller efficiency, and the higher the value of the maximum lift coefficient, the greater will be the value of K. If the maximum speed is measured and the ratio of the horsepower to wing area is known, then this value of K should be a good index to improvement in design and performance, and in this form could be used as the figure of merit in such airplane contests as tours, derbies, and even speed events. The fact that the formula considers the stalling speed of the airplane through the wing-area factor, as well as accounting for the weight, power, and speed, should make it well suited for these events. In events open only to A.T.C. airplanes, the value K computed on the basis of horsepower per unit of area is probably the best suited for the purpose. But in events open to group 2 and experimental racing airplanes, the value of K should be based on engine displacement per unit of area, to avoid the questionable amount of the power of the engines with which these airplanes are equipped and to afford a ready means of checking in the case of a protest.

However, the value of any formula for handicapping can only be judged from the results which it produces. To obtain a comparison of this formula with others, values of K have been calculated from data obtained in the National Air Tour and are shown graphically in Fig. 10, where the ranking according to K is plotted against the ranking according to the tour formula. It appears that the ranking obtained by the two methods do not agree very closely. One obvious reason for this condition is that the tour formula is based on the useful load, while the value of K is based on the gross load of the airplane. Since one of the requirements of the tour is efficiency, the useful load should govern instead of

the gross load. New values of K based on the ratio of useful load to gross load were calculated by multiplying the first value by this ratio, and are shown graphically in Fig. 11. The agreement by the two methods is now better throughout a great part of the range, but the ranking still differs in the first part of the range and seems to favor the biplanes. This is probably due to the wing-area factor in the formula, which for biplanes is higher for the same take-off and landing speed than for monoplanes. Correcting for biplane interference further improves the agreement, and replotting the ranking based on the new values of F against the ranking under the proposed new Tour rules shows a remarkably good agreement between the two methods. The correction for biplane effect is a function of the induced drag, and since the induced drag is small in magnitude at high speed, it would seem at first that this correction is unnecessary, and this is so if maximum speed is the only criterion. But where high speed is desired in combination with a good cruising speed, the induced drag is an important factor, and in speed efficiency contests its effect should be accounted for in the handicap. The formula in its final form, then, is:

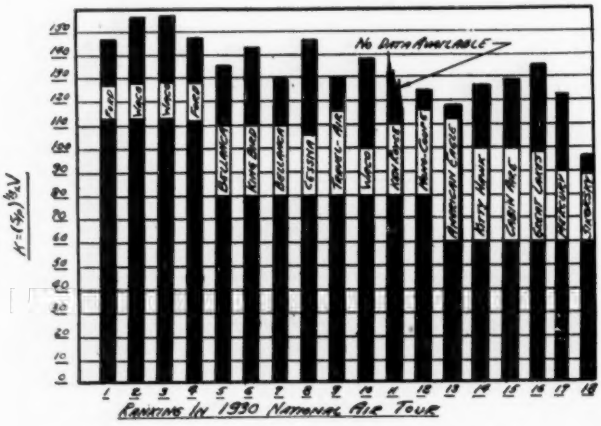

Fig. 10 Ranking in 1930 National Air Tour

$$K = V\left(\frac{S}{P}\right)^{1/3} \times \frac{W_u}{W_g}$$

where W_u is the useful load, Wg the gross weight, and S the equivalent monoplane area. Due to the simplicity of this formula $K = V \times (S/P)^{1/3}$, it would appear that it could be substituted for the tour formula and other efficiency handicaps. However, its very simplicity makes it rather difficult to apply, which is caused primarily by the work involved to obtain the correct wing area of all the types of aircraft that may be entered in a contest and for which wind-tunnel data are not available.

Consider, for instance, the case of a monoplane with lift struts of large area and perhaps in addition a stub wing at the fuselage. Here the determination of the equivalent monoplane area would present quite a problem; consider also the case of the various possible arrangements of the biplane as well as the effect of large tail areas and different fuselage shapes. All these complicate the problem and form the primary reason why a wing-area factor was not included in the tour formula. Another factor which would militate against the use of K as a tour or derby handicap would be that it does not allow any credit for the use of efficient wheel brakes. The method, however, is highly recommended in such cases where the equivalent monoplane area could be accurately determined and effect of landing run is not desired.

Another method of correcting the value of K for the weight-carrying efficiency of the airplane consists of multiplying the value of K by the ratio of the useful load to the total horsepower instead of the useful load to the total gross weight. The latter is a function of the structural efficiency, while the former is an index of the efficiency on the basis of horsepower. Both methods have their merits, and it has been suggested that the product of both ratios be used.

Expressed in symbols having the same significance as before, the formulas now become:

$$K_1 = V_{max}\left(\frac{S}{P}\right)^{1/3} \times \frac{W_u}{W_g} \quad \ldots\ldots\ldots\ldots [1]$$

$$K_2 = V_{max}\left(\frac{S}{P}\right)^{1/3} \frac{W_u}{P} \quad \ldots\ldots\ldots\ldots [2]$$

$$K_3 = V_{max}\left(\frac{S}{P}\right)^{1/3} \frac{W_u}{W_g} \cdot \frac{W_u}{P} \quad \ldots\ldots\ldots\ldots [3]$$

Values of K have been calculated by all three methods and are shown plotted against the tour ranking in Figs. 11 and 5. The relationship between the methods using the tour as a standard is self-evident from the charts. These formulas were compared with the tour formula, not because the author believes that the latter should be used as a standard of comparison, but for the simple reason that more accurate data were available for this event than any others with which the author is familiar.

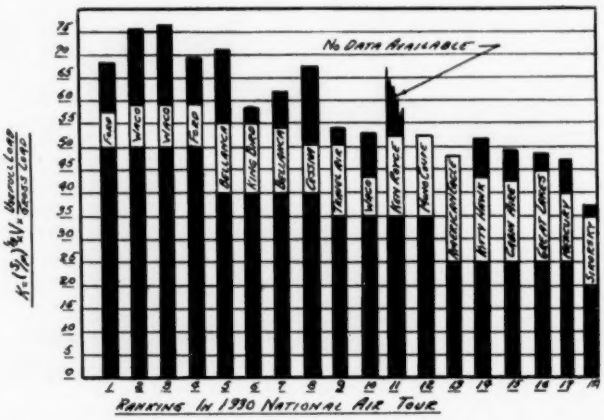

Fig. 11 Ranking in 1930 National Air Tour

In 1926 and 1927, the King's Cup Race was conducted in England on handicapping formula (*15*), somewhat similar in form to the one proposed by Warner except that wing span was used instead of area. The handicap speed is given by the equation:

$$V = 100\sqrt[3]{K \times \frac{P}{b^2}}$$

where b is the equivalent monoplane span and for biplanes of equal span was equal to 1.265 times the span of the biplane; V is the maximum speed in mph, P the brake horsepower of the engine, and K a constant. The span-correction factor used in this formula is actually an area-correction factor, so that the term P/b^2 becomes, as mentioned before, similar to P/S.

In this formula, as in Warner's, K could be made the index factor of figure of merit, but a study of this formula in comparison with other methods indicates very definitely, as shown in Fig. 6, that it unduly favors the monoplane and is subject to the criticism that correcting the span of a multiplane airplane to that of a monoplane is at best a difficult problem.

The point system of handicapping in which characteristics of

a contesting airplane are compared with a set of requirements of a hypothetical airplane has received considerable study both in America and Europe. Noteworthy of the European events was the German Seaplane Contest (3) of 1926, which was based upon such characteristics as maximum speed, take-off speed, rate of climb, fuel consumption, and endurance. In America, the outstanding event of this kind was the Daniel Guggenheim Safe Airplane Competition, in which were stressed such factors as low landing speed, gliding angle, take-off run, and useful load.

The method has considerable merit for certain contests, but depends largely on the experience of the handicappers in allotting the proper number of points for each performance factor. In addition, it usually involves factors which are very difficult to obtain in the time available for such measurements. To illustrate the effect of credit allowed for certain factors, the figure of merit for the airplanes winning first and second place in the Guggenheim competition was calculated according to the tour formula and Warner's K factor and are shown plotted with the tour airplanes in Figs. 5 and 6. It is to be noticed that although these airplanes possessed some excellent characteristics, yet the fact that certain unusual performance factors were required of them, placed them at a disadvantage with respect to other airplanes in such events as a tour, derby, or efficiency contest.

A method of handicapping proposed for the 1932 Transcontinental Derby and which has been used in other contests (5) with considerable success, consists of starting the fastest airplane an interval of time after the departure of the slowest airplane, so that with given equal conditions, both should arrive at the end of the lap at the same time. A similar procedure is to be followed for the second fastest, third fastest airplane, etc. The time in seconds in which the contestant arrives at the end of the lap ahead of his schedule is to be the figure of merit.

The maximum speed of each airplane is to be determined at the start of the derby by disinterested pilots, who will fly each airplane over a speed course with the machine in the same condition in which it will be flown in the contest. This method requires a tremendous amount of speed testing before the derby leaves, and the test, unless corrected for atmospheric conditions, is subject to error from this source in addition to other errors.

Since the length of each lap is a function of the distance between good airports on the route, it is obvious that the length of laps will vary from point to point and will thus require a new handicap figure for each lap. However, the speed of each airplane will be known before the contest starts, and it should therefore be a simple matter to compute the handicap for each lap before the derby actually leaves the first control point.

A large number of the airplanes will be closely matched on speed, which will necessitate very close starts and require extreme alertness on the part of both the timer and pilot, not only at the start of the lap, but even more so at the finish. The proposed handicap can be expressed as:

$$\text{Handicap} = \frac{\text{Length of lap}}{\text{Speed of airplane}} - \frac{\text{Length of lap}}{\text{Speed of slowest airplane}}$$

This system of handicapping is of course applicable only to such contests where the skill of the pilot is the primary factor in determining the winner. No attempt is made to allow for aerodynamic or structural efficiency or even safety, the object being almost entirely a close and spectacular finish between contestants. The factor of reliability does receive some consideration, but only from the fact that the route is a long one and motor trouble on any lap would severely handicap the contestant concerned.

A factor of paramount importance in any method of handicapping is the requirement that the condition of the aircraft remain exactly the same during the whole contest as it was during the handicapping trials. Propeller-blade setting, carburetor adjustment, type of fuel, position and amount of ballast, streamline fairings, and throttle position for maximum speed should not be altered. The throttle position for maximum speed refers of course only to airplanes equipped with supercharged engines, a type which is becoming quite popular on commercial aircraft. Airplanes equipped with these engines are required by the Department of Commerce to install throttle spots, which limit the speed of the engine on the ground and also at different predetermined altitudes. It is entirely possible, and the act can be easily carried out with such an installation, to pull the throttle beyond the spot while the airplane is either on the ground or at low altitude and thus obtain an increase of about 20 per cent or more in the horsepower of the engine. The exact amount depends on the degree of supercharging and the type of fuel used.

It is therefore possible to obtain a substantial increase in speed or decrease in take-off time by such a procedure. Where the tests on flights are to be made at low altitudes, three possible procedures present themselves as a solution of the problem, and they are:

(*a*) Handicap the airplane having this installation an arbitrary amount.

(*b*) Seal the throttle position at the carburetor at the point at which the tests are to be conducted.

(*c*) Conduct the flight tests with the throttle at its maximum open position beyond the spots and base the handicap on the speed obtained under this condition.

Of the three methods suggested the last one is recommended, due to its simplicity and ease of application. However, the procedure to be followed should be decided upon by the contesting pilot.

In all three methods and also for all other speed trials the propeller-pitch position should be sealed immediately after these trials, except in the case of propellers whose pitch can be adjusted automatically from the cockpit. The sealing can best be accomplished by marking the propeller hub bolts with a paint of special color.

The correct determination of maximum speed presents a problem of great importance in a contest in which speed is the factor deciding the winner and where these speeds are measured over a short straightaway or closed course. The accuracy and the method employed depend upon the magnitude of the speed to be measured and the length of the course on which the trials are made.

For instance, for a 1-mile course an error of 1 sec at speed of 100 mph corresponds to an error in speed of 2.78 per cent, while for a speed of 300 mph a difference of 1 sec corresponds to an error of 8.34 per cent. For longer courses, the error is reduced proportionately, so that the difference in time of 1 sec in the latter case on a 2-mile course produces an error of 4.17 per cent and corresponds to a distance of 220 ft traveled by the airplane. It is therefore obvious that stop-watch timing is not applicable to such speeds, and some more reliable and accurate method is required which is less subject to the human element. Various methods have been employed for this purpose, all of which have been a combination of photographic and electric timing. Noteworthy among these is the method employed in timing of the Schneider Cup Race (16) of 1931 and the method of timing in use on the French official speed course (17). A modification of the latter method has been employed in America in the timing of high-speed events, such as the Bayles trials to set a new mark for the world's speed record for landplanes.

This method consists essentially of two high-speed cameras, each mounted on a base located to one side of the start and the finish pylons of the course, respectively. The position of the base is arranged on a line perpendicular to the course and passing

through the center of the pylon and is perpendicular to the line of the course. In the shutter of the camera is included a circuit breaker which forms part of an electric circuit connected to an accurate electric timer. Thus it is possible to photograph the airplane as it passes over the pylon and the position of the airplane with respect to the pylon at which the photograph was taken and the corresponding time printed on the timer. This procedure is repeated at the end of the course, with the electric circuit of both cameras connected to the same timer.

While this method eliminates the human element in correcting by means of the photographs for exactly the point at which the time was taken, yet unless the operator at the camera has had sufficient experience with this method, he is likely to miss the airplane entirely and therefore obtain no photographic record at all.

For this reason, the British method in which continuous photographs are taken by means of a motion-picture camera is to be preferred. In such contests where take-off or landing time are factors in the handicap the effect of head wind on these factors should receive due consideration and corrections should be made for the magnitude to this effect on each test.

In conclusion, the writer wishes to make clear that in this presentation it was not attempted to solve the problem of handicapping for aircraft nor to advocate that handicapping by formula is the only feasible method available, but the intention was simply to present such information with which the author is familiar for the good which others might get from it for future work in this direction.

It must be remembered that any handicap determined by formula will favor the airplanes of better aerodynamic performance and structural efficiency and usually does not consider the effect of the pilot's skill. Whether this should be so depends entirely upon the character of the contest.

Formulas which depend upon arbitrary constants are subject to the criticism that the constants do not provide for the case of the "freak" airplane or one specifically designed for the event by taking advantage of the weak features of these constants through special arrangement of the design. If such constants are necessary and cannot be eliminated from the handicap formula, then they should be made a function of the handicapper's judgment and should not be published before the event, except in a very general form.

Discussion

E. W. CLEVELAND.[3] There is but one reason for handicapping, and this is for competitions. The handicap permits a larger number of competitors to enter an event.

In previous years the racing events scheduled by the National Air Races were based on cubic inch of piston displacement. This could not be entirely equitable to the motor manufacturers, and in free-for-all events, after scheduling a 1000 cu in. event, the others above that were practically duplicates. In 1932 an attempt was made to group the A.T.C. races according to top speeds. The races grouped in accordance with the advertised top speed proved that the pilot is an important factor in handicapping, and coincides with Mr. Edward P. Warner's ideas on handicapping. However, one would be at a loss as to a method of working this factor into the handicap.

The National Air Tour supplied experience in handicapping and had the appearances of being a fair formula, but due to the wide range and purpose of the airplanes involved, it could not satisfy all competitors. Putting the formula into words: "The airplane which can take off the quickest and land the slowest, fly the fastest, with the most load and the least amount of horsepower." This approaches an ideal. However, the tour was supposed to have a semblance of reliability; therefore speed trials were run before the start, in the earlier days of the tour, and a schedule was set up requiring but 85 per cent of the speed obtained on the speed trials for cross-country flying. This was abandoned later as most of the pilots ran their motors wide open, and the tour took on a racing aspect, as it became a case of not only maintaining the schedule, but a direct competition as to which pilot could get to the next scheduled stop first. This again brings up the fact that, regardless of the formula, the pilot plays an important part. On all tours with which the writer has been associated, there have been contestants who were prone to wander off the course. This wandering about after the adoption of the leg speed into the formula resulted in the airplane losing points through no fault of its own. There were cases where an airplane with an earth inductor and compass would be followed by others whose pilots knew that the craft ahead was so equipped, and therefore could not be wrong as to direction, and were thereby led astray. Then there were cases where the pilot would miss the airport, although in sight of it, by enough to affect the total score. This comes under the heading of navigation, but in cross-country events it plays an important part, as usually the course is laid down without taking into consideration present-day facilities furnished by the airways.

The tour formula is more of an efficiency formula than one to demonstrate reliability, although a remarkable degree of reliability was obtained. Only on rare occasions was the scheduled take-off deferred, and with but few exceptions all contestants finished, and in two or three cases the finish was in the face of adverse weather.

It is too bad that Professor Altman could not have accompanied the tour on its various trips—an explanation as to why the speed in 1930 was greater and also the stick time in seconds greater might have been forthcoming. The writer's explanation as to why the 1930 tour showed a superiority over the 1931 tour in speed was favorable winds over most of the distance flown. Variables are bound to creep into each handicap, as shown in a case where seven airplanes, all of the same make and horsepower, competed in the same event, starting from a racehorse start on a $3^1/_2$-mile course, six laps being flown, and there was a variation in range of speed of 1:46.79 between the fastest airplane and the

[3] Automotive Division, Cleveland Pneumatic Tool Company, Cleveland, Ohio; Chairman, Contest Committee, 1931-1932, National Air Races.

slowest. This proves that certain methods of mathematical handicaps are reasonably correct as to the equality of its effects on the airplanes involved. Following are the results of the purely handicap event, No. 8, flown over the $3^1/_2$-mile course, four laps, the handicap being absorbed at the start. The handicapping was figured mathematically by three people, and the values of K submitted by each member of the handicap committee were checked against each other and a compromise was reached:

Plane	Finish time
92, Taylor Cub	13:39.61
57, Waco	13:48.50
59, Monocoupe	13:50.78
70, Aero Klemm	14:05.77
23, Monocoupe	14:07.71
31, Aristocrat	14:09.71
99, Monocoupe	14:18.56
49, Heath Parasol	14:29.03
103	Out on first lap

Event No. 8 was a handicap for open or closed airplanes, carrying Department of Commerce commercial license, powered with an engine of not more than 510 cu in. piston displacement. All entries were handicapped by a handicap committee, and the announced handicap was absorbed at the start of the race.

As evidence that classifying airplanes according to the manufacturers' advertised top speed is superior to the old method of grouping according to cubic inch piston displacement for A.T.C. airplanes, there is the following comparison: Event No. 11, 1932 National Air Races, C or NC planes, 140-mph basis, 6 laps on a $3^1/_2$-mile course: The difference in speed between the first plane to cross the finish line and the fifth was 2:26.09. The corresponding A.T.C. event in 1931, based on a cubic inch piston displacement, showed a variation of 3:22.85 between the first airplane and the fifth.

In some cases the manufacturer's advertised top speed is overrated, in which case a handicap would be unfair. Also there is a variation in the speeds obtained by different pilots. From the writer's experience, the same speeds cannot be obtained from the same airplane operating under full throttle in level flight consistently, as the same airplane has been found to vary as high as 5 miles per hour when flown over a speed course on five different occasions in as many days. This variable is hard to compute and can only be reckoned with by taking the average.

One thing noticeable in the speed tests covering the 1932 Handicap Air Derby was the slight variation between the test pilots' speed as recorded by carrying a stop watch strapped to the pilot's leg and the speed as recorded by the camera. A total of 28 ships of 14 different makes were speed tested with a maximum variation in average speed of 2.3 miles per hour as the greatest difference, which is also evidence of the fact that elaborate timing apparatus is not particularly required to obtain very satisfactory results.

George B. Patterson.[4] Regarding the quoted statement that the original inclusion of stick and unstick times in the National Air Tour formula was "a stroke of genius," it is believed that the genesis of this formula was a remark by Major R. W. Schroeder, "The best airplane is the one which will carry the largest load the fastest, at the least expense, and will get off and on."

As to measuring performance for computing multi-motor handicap allowance, the writer differs from the statement that "A standard method of correcting altitude readings for temperature and pressure changes should be adopted. For this Diehl's correction has been suggested."

The methods of performance testing and computation which the writer developed in 1918 and 1919, and which are the basis of the present methods of the Army, Navy, and N.A.C.A., were designed to permit quantitative comparisons of performances measured under widely varying atmospheric conditions. In the present case, qualitative results are desired, and the tests are run so nearly simultaneously that atmospheric conditions are practically identical. A stop-watch and a sealed sensitive aneroid (the same instrument being used for all tests) should give sufficiently accurate results for handicap purposes. Of course, no high-altitude performance tests should ever be made when conditions such as temperature inversions or scattered cumulus clouds indicate the presence of vertical air currents.

In cross-country derbies and closed-course races where skill is to determine the winner, a wind allowance should be included in the handicap. Assuming all airplanes in a straightaway race to be handicapped so that all would reach the finish line together in still air, a tail wind would give the race to the slowest airplane, while a head wind means victory for the fastest. Any wind during a closed-course event favors the fastest airplane. In other words, the slower the airplane, the more it is affected by wind.

Application of the wind-correction factor can be greatly simplified by using previously prepared charts which take account of wind speed and direction and the shape of the course. This method was used for the first time at the National Air Races this year with promising results.

Carl F. Schory.[5] Handicapping is justified only where it is the desire of the race management to encourage a sufficient number of entries to warrant a contest which could not be otherwise organized on a free-for-all-class basis. Handicap contests have been generally unsatisfactory from the viewpoint of the contestants, as obviously all contestants other than the winner are inclined to the feeling that they would have won had the handicap been more favorable to their particular entry.

Author's Closure

Answering Mr. E. W. Cleveland's discussion, the author agrees that stop-watch timing is sufficiently accurate for slow-speed airplanes, but where the speed succeeds 160 mph and the trials are conducted over a mile course, a more accurate method should be used. Mr. Cleveland's reference to the close agreement between the stop-watch and elective timing in the speed trials of the 1932 Transcontinental Derby refers to tests on slow-speed airplanes. The maximum speed in these trials did not exceed 150 mph and the average speed was about 120 mph.

Mr. Patterson's statement referring to a correction for wind velocity and direction in the handicap of events based on speed is an important one and should be included in all such events. Referring to the statement that standard altitude correction for atmosphere conditions is not necessary, in the 1930 National Air Tour the multi-motor altitude tests were conducted at a temperature of over 90 deg. The specified test altitude was based on standard atmospheric conditions, and in order for most of the multi-motored airplanes to complete these tests successfully it was necessary to correct the altitude performance for temperature on a basis of an equivalent pressure altitude. After the correction was determined, the tests were conducted with a sensitive altimeter and stop-watch, as Mr. Patterson suggests. A barograph was used as a check in some of the tests. Various methods are available for this correction, but in any contest one method should be specified. When the time to conduct these tests is limited, it is not usually possible to wait for correct weather conditions.

AER-55-15

Mechanical Equipment for Handling Large Rigid Airships

By C. M. BOLSTER,[1] LAKEHURST, N. J.

The paper describes the development of the equipment used at the Naval Air Station at Lakehurst, N. J., for docking and undocking the U. S. S. *Akron*. The main feature of the plan is a stern handling beam or long horizontal girder lying athwartship beneath the stern of the airship, holding the ship from each side with a cable system from heavy trucks moving along outward-lying tracks, and a floating support resting on a castoring taxying wheel and placed under the reinforced lower fin. This stern handling beam moves out of the hangar following the mobile mast to which the airship is moored. When a circular track is reached, the airship is positioned in the proper wind direction.

THE development of the equipment used at the Naval Air Station, Lakehurst, N. J., for docking and undocking the U. S. S. *Akron* was undertaken during the fall of 1930. At that time it had been decided that the bow of the ship would be held by a mobile mooring mast of the rail type—that is, built to travel on railroad tracks. However, it was not known what type of equipment would be used for holding the stern.

Experience in the development and use of the partial mechanical handling equipment used in docking and undocking the *Los Angeles* had produced several definite ideas as to the desired features of mechanical docking equipment. These ideal characteristics were used as a guide in the development of the equipment for the U. S. S. *Akron*. Briefly, those which appeared to be most desirable at that time were:

(*a*) That when leaving the hangar the airship should be held securely from both vertical and lateral movement relative to the mechanical handling gear until the ship is clear of the hangar and the stern has been swung with the prevailing wind direction. Conversely, when entering the hangar the ship must be held securely from the time it is connected to the mechanical handling gear on the landing field and during the time the stern is hauled around against the wind to a direction parallel to the hangar and while the ship and the mechanical handling gear, including the mobile mast, enter the hangar.

(*b*) The system should be so devised that there would be no necessity for disconnecting one set of equipment and connecting up another after the stern had been hauled up against the wind. Such a condition would exist if a system were used by which the stern of the airship were hauled around by a locomotive or a winch with a long bridle and when parallel to the hangar be connected to ordinary docking trolleys. This shifting from one system to another at a time when the loads were the greatest was considered both dangerous and undesirable. Such a system also did not hold the ship from both sides while hauling up the stern, which is essential in shifting winds.

(*c*) The equipment should be of such a type that the time taken to shift from the hauling up or swinging condition to the docking condition would be as brief as possible.

(*d*) Provision must be made in the equipment for supporting the stern of the ship in such a manner that the castoring taxying wheel could be used to hold it above and clear of the stern handling equipment after the equipment itself had been disconnected. This was essential, since after the ship had been taken out of the hangar and had swung to the prevailing wind direction, it had to move across the landing field to a mooring and riding-out circle which was about 2000 ft away from the hangar.

(*e*) The height of the stern handling equipment, including the hauling-up equipment, must be kept well below the bottom of the lower fin when supported on the taxying wheel in order to avoid any possibility of the fin striking it while the ship was swinging freely before it was connected to the mechanical equipment.

(*f*) The original design of the *ZRS-4* (*Akron*) provided for six reinforced points on each side of the after part of the ship, two at frame 0, two at frame 17.5, and two at frame 35. The mechanical handling equipment had to be devised in such a manner that it could utilize these six attachment points.

(*g*) The *ZRS-4* also had been designed in such a manner that the vertical load on either method of ground handling (that is, a taxying wheel or mechanical handling attachments) had to be applied through a reinforced area directly beneath frame 17.5 in the lower fin. The equipment therefore had to support the fin at this point.

(*h*) Since this particular equipment was being devised for use at Lakehurst, it had to be so designed that it would permit docking or undocking the *Akron* with the *Los Angeles* in the hangar. Owing to the limited space available, this complicated matters somewhat.

It was fairly obvious that, whatever type of stern handling equipment was to be used, it should travel during the hauling up or swinging period on a circular track, the mobile rail mast providing the center of the circle about which the ship could swing. It was also realized that an extremely powerful locomotive of low height and delicate control would have to be available for hauling up or swinging the stern of the airship.

The first thought as to the type of equipment to use for holding the stern was to provide heavily weighted cars on each side of the ship which would act somewhat as docking trolleys, except that they would be capable of holding the side load of the airship by their weight and the flanges on the wheels. A third car was to be used to support the lower fin. It was thought that some system could be devised whereby these heavily weighted side cars and the center supporting car could be shifted or transferred from the hangar tracks to the circular or hauling-up track when the ship had reached the center of the circle and was ready to swing. During the period that these heavily weighted side cars and the center car were on the circular track, the use of long compression members tying the three together was contemplated.

[1] Lieutenant (CC), U. S. Navy; Naval Air Station.

Contributed by the Aeronautic Division of The American Society of Mechanical Engineers and presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Some time was spent on the development and study of this system, and several difficulties and complications arose. It had always appeared that the simplest and most dependable method by which these heavily weighted cars could be shifted from the hangar tracks to the circular tracks while under side load would be by means of some method of vertical jacking whereby one set of wheels would be lifted off as the other set made contact.

This immediately resulted in complications due to the fact that one car could not move vertically relative to the other without greatly altering the tension in the side cables. Another undesirable feature of this method was that it involved the construc-

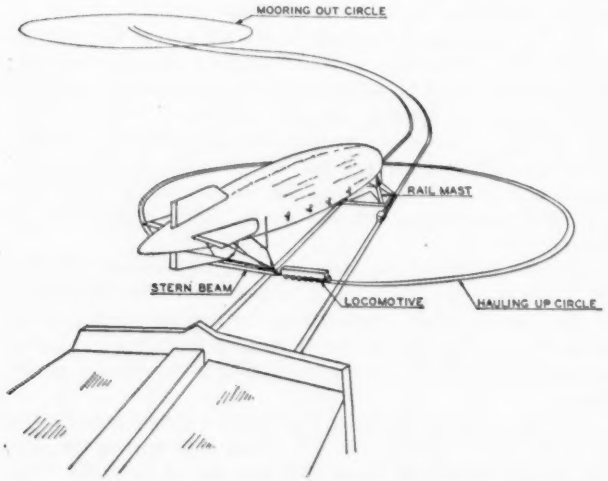

FIG. 1 GENERAL PLAN OF HAULING-UP AND MOORING-OUT CIRCLES

tion of three more standard-gage railroad tracks completely through the hangar and for a distance of about 1200 ft out on the landing field. In other words, our trackage system would have consisted of five sets of standard-gage railroad: one in about the center of the ship's path on which the lower fin support would travel, the two which already existed at a gage of $64^1/_2$ ft on which the rail-type mobile mooring mast was to travel, and two more—one at the extreme edge of the hangar on the side of the *Akron* berth and one on the other side as far over toward the *Los Angeles* as possible on which the heavily weighted side handling cars or trolleys were to travel. The expense and the difficulty of laying these three additional railroad tracks were considerable. It also appeared that there might be a dangerously high concentrated side load on the rails which supported the side handling trolleys under the 63,000-lb side load upon which the design was based.

It was while trying to improve on this system in such a manner as to permit the use of the two tracks through the hangar on a $64^1/_2$-ft gage which already existed that the idea of the stern handling beam was evolved.

Basically, the stern handling beam consisted of a long beam which reached out to the two end points where the side handling trolleys were intended to travel while utilizing the two railroad tracks which already existed through the hangar. It also gave the desired center support without the necessity for a track at that point. It thus provided the three points, two end and a center point, without the cost of laying any more track through the hangar. In order to investigate the possibilities of such an arrangement, a model was made of the proposed stern handling beam, and a small section of hangar track and a circular track were constructed on the same scale as this model. The whole arrangement was used with a small airship model that we had at Lakehurst. Work with this model showed that the stern handling beam system was perfectly feasible and that it should provide a suitable type of mechanical handling equipment for the stern at relatively low cost.

There was one interesting complication, however. It was found while checking back with models that it would be impossible to bring the *Akron* in the hangar with the stern and bow concentric to the existing hangar tracks without the tail of the *Akron* striking the *Los Angeles*. This was solved by moving the stern of the *Akron* 10 ft 3 in. off the center of the existing tracks. The *Akron* could then enter or leave the hangar and still have ample clearance between the hangar wall and the *Los Angeles*.

Such an arrangement meant that a beam must be provided for supporting and holding the ship at two possible points each 10 ft 3 in. from the center line of the existing hangar tracks. This was necessary because the ship set toward one end of the beam when entering the hangar stern first, while when entering bow first the beam had to be swung 180 deg, and the stern therefore had to be moved toward the other end of the beam. This complication meant a dual installation of the stern supporting points and of the two side handling points. It did not, however, destroy the feasibility of the beam arrangement.

In checking back on the characteristics which were deemed most desirable for the stern handling equipment, it was found that the stern handling beam adequately met all of them:

(*a*) It held the airship securely from both vertical and lateral movement relative to the mechanical handling gear until such time as it was desired to disconnect it. (*b*) Having once connected the ship to the stern handling beam, there was no further necessity for connecting or disconnecting any other system. (*c*) The period of transfer from the hauling-up circle to the hangar tracks was reduced to a relatively short time. (*d*) The castoring taxying wheel was attached to the ship throughout the operation and was available for use in holding the ship clear of the mechanical gear whenever required. (*e*) The height of the stern handling equipment, both beam and locomotive, could probably be kept within the 6-ft over-all height required. (*f*) The six attachment points on the ship itself could be utilized in holding the ship. (*g*) The vertical load from the ship to the stern handling beam was applied through the reinforced point at frame 17.5. (*h*) The equipment permitted docking or undocking with any direction of the ship in the hangar, with any wind direction, and with the *Los Angeles* in the hangar. Thus all of the requisite features were adequately met and preliminary drawings and specifications were prepared.

The stern handling beam was constructed by the Wellman Engineering Company, of Cleveland, Ohio. Complete with all winches, trucks, and miscellaneous equipment, it weighs about 178,000 lb. The main strength member consists of a steel built-up girder of two heavy I-sections, with ample section modulus for the bending loads involved. These I-sections are 42 in. deep and are mounted parallel to each other about 7 ft apart. The sections are tapered at the ends and suitably braced laterally. The resulting girder is 186 ft 6 in. long and lies horizontally in such a manner that the 42-in. dimension is vertical.

When traveling in and out of the hangar, the beam is supported on four four-wheeled trucks, two toward each end, each pair traveling on one of the two railroad tracks laid through the hangar on a $64^1/_2$-ft gage. These trucks are well braced to take the side load and are rigidly mounted. The wheels themselves are of a roller-bearing type and are only 14 in. in diameter. Special flanges are used on the wheels for taking the side load, the flanges being machined from rolled steel.

For traveling on the circular track, the beam is supported by

two four-wheeled trucks located outboard of the hangar trucks and built to conform to the curvature of the circular track of 650-ft radius on which they travel. The axles which carry these wheels are supported by a power-driven screw linkage mechanism which permits the axles and wheels to be moved vertically 8 in. relative to the beam. This movement is so arranged that while the beam is traveling on the hangar tracks the circular track wheels are in their top position, or are 4 in. above the level of the ground and hangar tracks. When the beam has reached the circular track and it is desired to shift from the hangar track to the circular track, the circular track wheels are jacked from their top position to their bottom position. In so doing the circular track wheels have landed on the circular track at the mid-point of their travel and have then lifted the beam, ship, and hangar track wheels 4 in. upward. The beam has thus been transferred from one set of tracks to the other and is perfectly free to swing on the circular track. This operation is performed with brakes on the circular track wheels and with the hauling-up locomotive connected up in order to prevent the side load on the airship from running away with the beam as soon as the hangar track wheels have disengaged. This jacking operation is done by a gasoline engine and requires less than a minute.

While traveling in and out of the hangar, the beam is pulled by the ship itself through suitable towing cables. The ship is moved by the mobile rail mast, which is provided with a gasoline-electric locomotive. The decision to tow the beam in this manner was based on extensive towing tests conducted with flanged wheels under side load and towing tests of the beam itself under high side load. These tests showed that the pull required to start the beam under extremely high side load was about 5000 lb, and that the running load was only about half this amount. Although this method has functioned satisfactorily, it is considered desirable to remove all unnecessary loads from the ship's structure, and at the present time a system of interconnecting members traveling on small trolleys is being developed which will rigidly connect the beam to the mast.

When swinging on the circular track, the beam is connected to a gasoline hydraulic locomotive especially designed for the purpose which controls the beam and the ship during this period. This locomotive is a most interesting mechanism. It was designed and built by The H. K. Porter Company, of Pittsburgh, Pa., and is probably capable of exerting a greater drawbar pull than any locomotive in the world of comparable size and power. It is 35 ft long, 6 ft overall in height, and conforms to the standard railroad requirements as to width. It weighs 266,000 lb and is driven by a 250-hp Leroy engine, which drives the wheels by siderods and gears through a Waterbury hydraulic transmission unit. In low gear this locomotive develops a drawbar pull of 63,000 lb at 94 ft per min. and due to the hydraulic transmission it has remarkably delicate control, speed being capable of reduction to such a creep that the motion is hardly perceptible.

The original design of the *ZRS-4* (*Akron*) provided six reinforced attachment points on each side of the after part of the ship for attachment of the side handling cable system. Suitable bridles were made up which would secure to these points, the bight of the bridle hanging down to where it could be reached from the ground. Large snatchblocks were procured which could be quickly attached to these side handling bridles, and a cable system was provided which connected the beam to the ship's bridles by means of a continuous cable anchored at one end and rove back and forth between the snatchblocks and sheaves on the beam and then to a power-driven winch on the beam. The motors which drive these winches are mounted on the after side of the beam out of the way of the taxi wheel and cradle. A $^{9}/_{16}$-in.-diameter extra-flexible cable having a breaking strength of about 30,000 lb is used, and the system is so arranged that each side of the ship is held by from six to eight strands of this cable, the tension in each strand being approximately the same except for the slight friction in the sheaves and snatchblocks. The sheaves which restrain these side handling cables are mounted on removable pins placed at two possible locations on each end of the stern handling beam. Two of these locations are at the extreme ends of the beam and the others are 20 ft 6 in. in from the ends, thus providing the two possible attachment systems required by the necessity of moving the stern of the *Akron* off the center of the beam itself.

In connecting up or disconnecting the beam cables with the ship's bridles, the beam cable is slacked by the power-driven winch until the bridles can be reached from the ground, at which

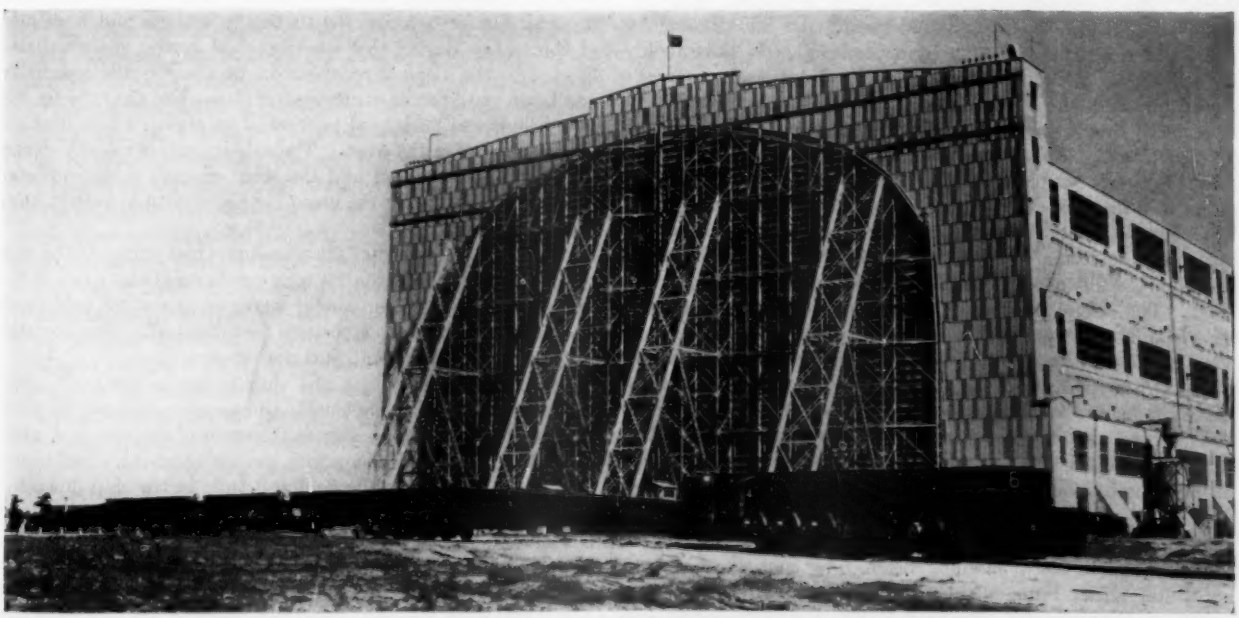

FIG. 2 STERN HANDLING BEAM AND LOCOMOTIVE

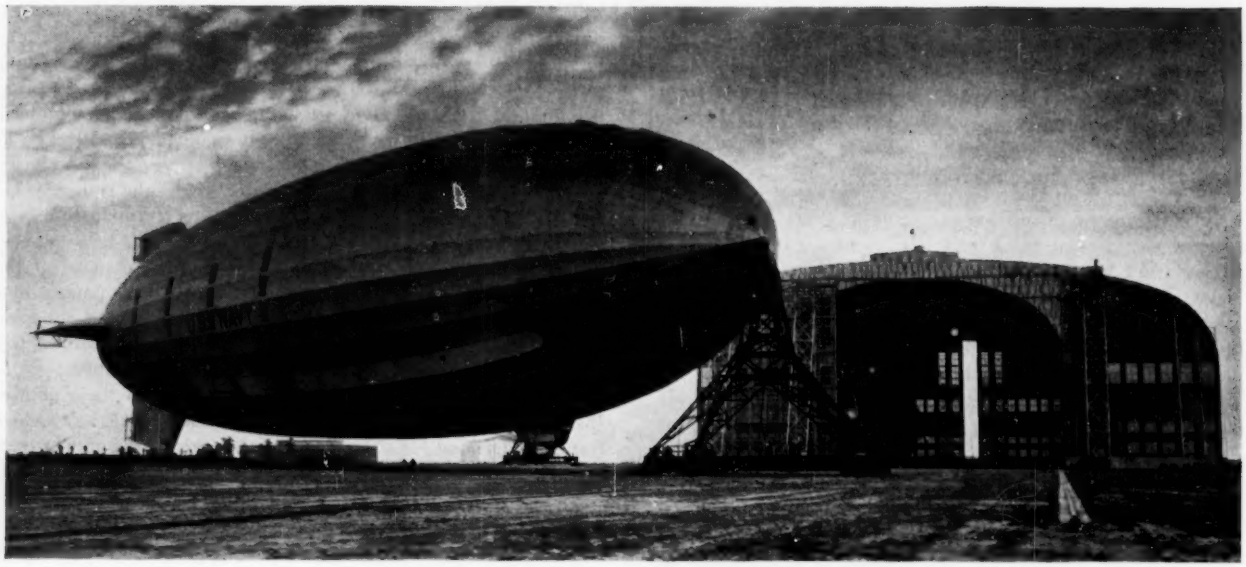

FIG. 3 THE "AKRON" BEING HAULED UP TO ENTER THE HANGAR

time the snatchblocks are removed. Quick-release devices are also introduced into the cable system between the ship's bridles and the beam cable in order to permit rapid disconnecting of the side handling cables in gusty weather. Due to the whipping action of the cables under tension, these quick-release devices are normally never released until the cable has been slacked down. It will be noticed that this cable system, when connected up, holds the ship from both sides, and that once the ship has been placed on the beam and the side handling cables are set up, the ship is held from any side movement relative to the beam. The ship, however, is not restrained from rolling.

In providing the support for the lower fin, two objectives were carried out. The first was that the support for the lower fin should be so arranged that the castoring taxying wheel could be left in place on the ship while the ship was attached to the beam. This attachment is made in such a manner that the beam support can be moved underneath the fin attachment point and raised mechanically by a powerful jack, thus avoiding any necessity for lifting the ship by hand during the connecting-up period. The support for the lower fin is so made that it is perfectly free to move laterally in order that the ship could be free to roll. This is essential in order to avoid side loads on the bottom of the lower fin. The support also is free to move 36 in. in a fore-and-aft or radial direction relative to the beam. This fore-and-aft freedom is necessary in order to allow for inaccurate centering of the mast relative to the circular track and to allow for inaccuracies in the radius of the circular track itself. The lateral freedom of the fin support removed all side load from the bottom of the fin, the ship absorbing the rolling effect from the side load by rolling over until the couple due to the static stability of the ship equals the rolling moment of the wind load. Actually this rolling is not as great as might be supposed and should normally not exceed 4 or 5 deg. The actual connection between the supporting trolley and the lower fin is made by clamping a swiveling yoke on the beam trolley to a cradle which has previously been secured to the lower fin. The castoring taxying wheel is secured to this same cradle.

The complete stern handling beam thus consists of a long horizontal girder lying athwartship beneath the stern of the airship, holding the ship from each side with a cable system and supporting the ship on a floating support through the reinforced portion of the lower fin. This girder or stern handling beam moves out of the hangar with the airship, and when the mobile mast reaches the center of the circular railroad track it stops. The beam is connected to the stern locomotive, and with brakes on is transferred to the circular track by means of the jacking trucks. The stern of the airship is then swung around until the ship is headed approximately into the prevailing wind. It will be noticed that the airship may be swung in this manner through any required angle, and the ship may leave the hangar either bow first or tail first with any wind direction and can be swung through any angle up to or beyond 180 deg if required.

When headed approximately into the prevailing wind, the stern cables are partially slacked off, and it is immediately apparent whether or not the ship is actually in the wind by movement of the ship relative to the beam. This is most evident by lateral movement of the fin-supporting trolley along the beam. A signal device is connected to the fin trolley, and movement of the trolley during this slackening off period is immediately relayed to the locomotive operator, who moves the locomotive and beam until the signaling system shows him that the fin support has moved back to the center of its travel, which indicates that the ship is in the wind. The cables are now rapidly slacked down and disconnected and the stern support is disconnected, the locomotive moving the beam back and forth to keep it under the ship in gusty weather.

As soon as disconnected, the taxying wheel supports the after part of the ship, and the beam is run around the circle out of the way as the mast and airship move on across the field to the mooring-out circle or to a position for taking off. The operation for docking is, in general, just the reverse.

During the period that the ship is being "walked" across the landing field, a single handling-line spider, manned by about 30 men, is used on each side of the stern of the ship. A group of about 12 men walk along with the after taxying wheel to help it over rough spots in the field and to hold the ship down if it becomes light. These men also assist in holding the ship while it is being connected or disconnected from the beam. They perform no function during the hauling up and docking operation, and this may truly be said to be entirely a mechanical operation, since the only personnel involved are the eight men on each side who connect the side handling cables, the group

mentioned who connect the lower fin support, the three winch operators, and the locomotive operator.

Actual use of the stern handling beam and rail mast in docking and undocking the *Akron* required the solution of several incidental problems. The most important of these were:

(*a*) When leaving the hangar how best to stop the mast so that the beam wheels could be lined up with the circular track rails. An automatic stop-light system was first tried, but did not work satisfactorily. Experience showed that a hand-operated stop light at the beam and seen by the locomotive operator at the mast gave a better control, and such a system works fairly well. The beam usually stopped within 3 or 4 in. of the required point and is moved along the track by suitable equipment through this distance before the jacking operation is begun. Further improvement of this feature is now under way and will be included in the improved type of towing equipment.

(*b*) In hauling up the stern it is necessary to stop the beam when the hangar trucks are lined up with the hangar rails. Due to the ease with which the hauling-up locomotive can be controlled, this operation is a simple one. It has now been improved to the point where the locomotive operator stops his locomotive at a predetermined point which automatically lines the wheels up as required.

(*c*) One of the most difficult features of the beam handling operation is that of connecting up and disconnecting the side handling cables, especially in gusty weather. This operation makes it essential that the beam be kept fairly well centered under the ship during the period that the side handling cables are slacked. The signaling system which controls the locomotive operation by movement of the fin and fin trolley relative to the beam has proved to be the solution of this problem and has worked out fairly well. A system of automatic control would be even better and can undoubtedly be included in future designs. Actual connecting and disconnecting of the snatch-blocks themselves is a matter of experience, and with properly drilled personnel can be performed very rapidly. Under such conditions it requires about 2 min to disconnect the blocks and from 4 to 5 min to connect them up.

Several important lessons have been learned during the relatively brief experience with this handling equipment. Undoubtedly many more will be learned in the future. Briefly, these lessons may be summarized as follows:

(*a*) Mechanical docking and undocking is entirely feasible, and the stern handling beam and rail-type mobile mast provide suitable equipment for this purpose. However, as shown by the accidental breaking away of the *Akron* from the stern handling gear on February 22, 1932, there are definite limitations as to safe docking and undocking conditions imposed by the strength of the airship structure. Present indications are that the maximum permissible cross-hangar wind velocity for docking and undocking the *Akron* is about 20 miles per hour. This is of course a great improvement over non-mechanical docking methods. However, this limitation must be just as carefully adhered to as was the old limitation of 5 to 6 miles per hour for manual handling in former days. Such a limitation will always depend on the strength of the ship's structure, for the mechanical handling gear can be designed to withstand any loads that the ship can carry.

(*b*) Apparently a quartering wind imposes greater loads on the stern handling gear than a beam wind. Accurate confirmation of this fact will be obtained in the future. At any rate, undocking stern first in a quartering wind probably requires the best weather conditions of any maneuver.

(*c*) The stern handling equipment should be permanently equipped with suitable dynamometers to indicate the load imposed on the ship at all times. Loads existing at any time can then be observed and the maneuver be stopped before dangerous conditions arise. At all times, but especially in gusty weather, there seems to be little relation between observed wind velocities and loads imposed on the ship. A dynamometer will give the true story as to the load which the ship is carrying, which is the important feature of the operation, the wind velocity of course serving as a guide as to whether such an operation should be begun.

(*d*) Although actual breaking away of an airship from mechanical handling gear should normally be a rare occurrence, it seems desirable that every precaution be taken to minimize the danger to the ship when such an accident occurs. To accomplish this it would probably be desirable to have the pendants which secure the side handling bridles to the ship's structure the weak link in the system, so that these pendants will break before the ship's structure will fail, and at the same time any whipping of the heavy cables against the ship's structure will be avoided.

(*e*) It would be desirable to have fewer attachment points on the airship, and thus fewer bridles and less equipment to connect up and disconnect. This is a matter of airship design and local reinforcement of the airship structure. Undoubtedly, considerable progress toward reduction of the number of these attachment points can be made in future ships. If this means a reduction in permissible loads which the ship can withstand while being handled mechanically, it would not be desirable, for the slight advantage gained in making the handling operation an easier one would not be sufficient to warrant a reduction in the strength of the ship and equipment.

(*f*) The use of a type of handling equipment such as the stern handling beam, in which all parts are below the ship, is still considered a vital feature. Use of vertical booms or masts which would attach to reinforced points well up on the side of the hull on each side has been proposed several times, but it would seem that in case of unexpected high winds which cause the ship's structure to fail, the damage resulting to the hull would be much more severe in the case of the side masts than in the use of cables, since they would cut completely through the hull at that point. It may be feasible to design such booms so that they will fall down out of the way when a breakaway occurs. However, at the present moment it is difficult to see how such a boom can be relied upon to hold in tension from one side and in compression on the other and at the same time release itself should the ship's structure break. Any type of manually operated quick-release equipment for such an emergency is of little or no value since the break will occur before any one can act. Danger of damaging the ship while connecting and disconnecting would also be ever present unless the booms were used in combination with a cable system. A most desirable improvement in the low type of equipment such as the beam, which holds entirely in tension from the windward side, would be to have the fin-supporting trolley and leeward cables automatically releasing under conditions when the ship breaks away. Such features are believed to be perfectly feasible.

(*g*) It would be desirable to have the hauling-up locomotive built into the stern handling beam as an integral part of it to avoid the unnecessary complication of coupling and uncoupling it and to reduce the necessary pieces of equipment. Such a design was considered when the beam was designed, but at that time it was felt that due to the experimental nature of the whole project it was much more conservative to procure the locomotive and beam separately, since the locomotive could be used for hauling up the stern whether the beam worked properly or not.

(*h*) The improved towing methods, removing all towing loads from the ship's structure, are considered desirable.

(*i*) A two-ended hangar with circular tracks at each end would be desirable for an ideal arrangement. Undocking of an airship stern first out of the windward hangar door is a difficult and hazardous operation, the danger of which would be considerably reduced if the ship could go out of the leeward door and swing on a circle at that end of the hangar.

Based on our experience thus far, it appears that the ideal stern handling equipment for handling large rigid airships should consist of a stern handling beam much like the present one except improved in arrangement, as already outlined. At a location where meterological forecasts can be relatively accurately made (that is, where desirable weather conditions for docking can be depended upon for an hour or so) it would be desirable to move the hauling-up circle a considerable distance from the hangar and combine the hauling-up circle and mooring circle into one circular track. The beam for such a layout would be changed to permit the fin-supporting trolley to travel directly upon the top of suitable trackage along the top of the beam, and when the ship had left the hangar and had been swung into the prevailing wind, transfer of the ship from the beam to the riding-out car could be made entirely a mechanical one by movement of the trolley along the top of the beam to the top of the riding-out car. In this case the trolley which supported the lower fin would have to permit some movement of the fin relative to this trolley, and this movement would in turn automatically control the movement of the beam and would thus move it out from underneath the ship as the trolley transferred from its position on the beam to the riding-out car.

For locations where weather conditions are changeable and difficult to forecast, it seems very desirable to have the hauling-up circle as close to the hangar as possible in order that the period during which the ship is held against the side-wind load will be reduced to a minimum. For such locations, a beam like that now used at Lakehurst except for the slight improvements mentioned would be preferable. Such an arrangement, of course, will always require a small ground crew, since during the period that the airship is being "walked" across the landing field a small detail of men will be required to hold and control the after part of the ship.

Thus it appears that at an airship base where relatively good meteorological conditions exist (namely, where maximum winds of 20 mph or less can be assured for an hour or so) the docking and undocking operation can be made almost completely a mechanical one with only a few (perhaps 20 or 30) men required for mooring, riding out, or entering the hangar. For unfavorable locations, although the undocking itself can be made mechanically, a small ground crew will always be required for "walking" the ship across the field.

Discussion

W. Klemperer.[2] The docking and undocking of large rigid airships by man-power has been looked upon by many as not in keeping with the trend in mechanization in this machine age. Although it may be argued that even the docking and undocking of ocean liners between piers with the aid of tugs and a considerable number of men handling ropes on shore is even today not completely mechanized, there is no doubt that substitution of machines for man-power in handling large rigid airships will increase the safety for men and equipment, the reliability of operation, and the economy of commercial application of airships.

The motorization of the bow mast has been accomplished for some time. However, the holding of the aft part of the ship by mechanical means offered considerably greater problems, and it has been extremely gratifying to all interested in lighter-than-air craft to watch the remarkable progress made at the Naval Air Station at Lakehurst, where undoubtedly the greatest experience along this line has been concentrated.

One is impressed that one of the most ambitious parts of the problem is to maintain the proper distance between the bow mast and the stern handling gear without throwing stresses into the ship's structure, considering the gear having the mass of 180,000 lb.

The author has pointed out that mechanical links connecting the tail beam with the bow mast have been considered, and mechanical links have already been successfully used between individual docking trolleys in handling the U. S. S. *Los Angeles*. However, the alternative idea of providing the stern handling gear with a power drive and servo-control obviously has also suggested itself. It is understood that any such device is looked upon as too delicate and dangerous to be relied upon entirely. However, one may visualize the power drive being servo-controlled with or without the aid of a human element from a moderate permissible movement between the beam proper and the ship's support substructure, any displacement of the two movable parts, fore and aft, activating the beam motors in such a direction as to reduce this displacement. Such an arrangement would act as a brake as well as a reversible motor.

Evidently the system would have to be fully operative with the servo-control drive out of operation, and the latter would only serve to keep the routine stresses away from the airship. Whether the expense involved in this motorization would be justified by this limited usefulness is a matter of opinion and experience.

It is of course of great interest to accumulate data of actual handling forces in order to compare them with those assumed under more or less fictitious meterological conditions. So long as airships were handled mainly by man-power, the introduction of dynamometers was always a disagreeable complication of a delicate operation. Now with mechanical means measuring is greatly facilitated, and it is noted with great gratification that the introduction of permanently installed force recorders in all of the important load-carrying members is contemplated by the Navy.

Although the author has vividly pointed out the disadvantages of any stern handling structure with solid parts extending high above the ground, there is one such alternative which has been given serious attention. This is a single stern mast on which the stern of the ship would be moored somewhat similarly as the bow is on the bow mast. In this case, our studies have shown that the stern attachment could possibly be worked out so that it permits some relative motion and so that, in case of breakaway, the stern could swing clear of the structure. Then the mast need not be collapsible.

Of course, a mutual fore-and-aft tow system with provision for ample permissible relative motion or an efficient and reliable servo-drive equipment must again be worked out. Neither solution seems to offer insurmountable difficulties. A stern mast equipment requires some strengthening of the stern of the ship, which investigations have shown would not necessarily be prohibitive in weight.

Most of the difficulties in docking or undocking large rigid airships arise from sudden wind shifts encountered more or less against anticipation during the docking operation. Obviously it will mean much for the elimination of unnecessarily high handling loads when elaborate automatic wind-shift warning systems are installed at airship ports. A number of automatic wind velocity and direction recorders placed at strategic distances around the airport, especially on the weather side, sufficiently far away to give at least a quarter of an hour's warning, will enable the docking officer to change his plans before a sudden emergency arises.

[2] Goodyear Zeppelin Company, Akron, Ohio.

Author's Closure

The suggested motorization of the stern handling equipment to provide movement in and out of the hangar, keeping it properly spaced away from the mast by some type of servo-control, is not considered a safe solution to the problem. It is believed that one of the most important basic principles for safe operation is that while going in and out of the hangar there should be only one source of power. The soundness of this principle has been demonstrated twice at Lakehurst, when use of such a servo-control might have resulted in damage to the ship.

Since the original paper was written a system of interconnecting tension and compression members has been designed and built which rigidly holds the beam a fixed distance from the mast and is stronger than the full tractive effort of the mast locomotive. On one occasion while the ship was being walked out of the hangar, the beam fouled on a protruding part of the hangar floor and was definitely stopped against further motion. Using the interconnecting spreader-bar system of towing, this merely resulted in stopping the mast and airship, the locomotive spinning its wheels but doing no damage to any part of the ship or handling apparatus. On another occasion while operating in a snowstorm, the tracks were partially coated with ice and the locomotive wheels turned with no motion of mast, beam, or ship. Under such a condition the beam wheels might be properly controlled and receive ample torque, but no movement would result, although at that moment the mast wheels might be taking hold. This would result in movement of the mast relative to the stern equipment, with resultant damage to the ship. The spreader-bar system is simple and relatively inexpensive and is considered to be the safest arrangement.

The use of a single stern mast which would secure to a suitably reinforced point on the stern, much as the bow is secured forward, is considered to be an excellent alternative to the beam. The *Akron* and *Macon* are not provided with such a point, and the beam was designed to utilize the strong side handling points available. The stern mast probably would require some added structural weight in the tail of the ship and would be a more costly unit in itself in addition to the added trackage required. It has the important advantage, however, that it removes all handling stresses from the lower fin. Such a stern mast, if used, should be on a track radius large anough to insure that it would be well clear of all parts of the airship as soon as disconnected.

AER-55-16

The Economics of Air Transport

By LOUIS BREGUET,[1] PARIS, FRANCE

In this up-to-date analysis of the economic problems of aerial transportation, the author presents a revision of the basic formula for calculating the net cost of air transport, gives examples of its application, and discusses the following problems: (*a*) Application to a simple case; (*b*) the importance of overhead expense; (*c*) the influence of speed on net cost; and (*d*) flight at high altitudes.

IN A PAPER read before the Fourth International Congress of Aerial Navigation, held at Rome, Italy, in October, 1927, the author presented a formula which permitted the calculation of the net cost of aerial transportation; he also discussed several examples of the application of this formula.

It now appears advisable, after an interval of four years, to raise the question again and bring it up to date, taking into account the progress made in the operation of air lines and the changes in the economic situation. Advantage will also be taken of this occasion to complete to a certain degree the main formula which the author previously proposed for the calculation of the net cost of aerial transportation.

I—REVISION OF THE BASIC FORMULA FOR OBTAINING NET COST

This formula gives the net cost X per *ton-kilometer of pay load available*. For scheduled operations with an efficiency of 100 per cent, the net cost is obtained by dividing the total expenses charged to each flying hour by the pay load and by the cruising speed per hour in kilometers.

For practical operation with an efficiency less than 100 per cent, the net cost is obtained by multiplying the cost of 100 per cent operation by a coefficient i, which takes into account irregularity of operation and sundry incidental expenses. This coefficient varies appreciably with operating conditions and the type of traffic available. Some years ago i had a value of approximately 1.30 on most routes, but it is now more usually between 1.0 and 1.10 for air lines which are efficiently operated and well patronized.[2]

The main formula in question has reference to the operation of an air line in stages of a practically uniform length E, flown by airplanes of the same type fitted with the same engine. The supply parks, exclusive of the supply of spare parts which are in stock at the main repair depots, will carry the following classes of spares:

Airplanes, excluding engines and their fittings
Fittings, accessories, and spares attachable to the bare airplanes
Engines, including their accessories, spares, and propellers.

A distinction is drawn between current maintenance, comprising cleaning, washing, and occasional repairs needed to keep the airplane in service, and major overhauls made at intervals as required.

Similarly, one should distinguish between repair or overhaul work done by the operating company (or by a third party paid by the company) and not covered by insurance, and the repair work caused by accidents and covered by insurance. The cost of the second type of repair work is covered in the coefficient i, being an irregular or incidental expense. The different categories of material include the equipment in regular service, the equipment "out of action," and the equipment in reserve to meet emergencies.

The depreciation of the material in each category (airplane or engine groups with their accessories and spares) should be calculated differently for equipment in regular use and for equipment "out of action" or in reserve. Equipment in use should be depreciated on a flying-hour basis, while that not in use should be written off on the basis of age in months or years, to cover obsolescence.

It should be appreciated that the same material passes by successive stages through the phases of active use, out-of-action, and reserve, the whole being the useful life of the equipment. The complete depreciation of equipment can be calculated from the numbers allotted to these different stages without considering individually the items themselves, which are for simplicity assumed to be all of the same type. It is admitted, on the other hand, that the initial cost value to be placed on an airplane or engine group for depreciation purposes must include the cost of accessories and spares; it should also include the financial charges incidental to purchase, e.g., the interest on capital locked up (either paid up or tied up) in the equipment.

Repairs or overhauls are made at intervals of H_p or H_m hours of running for planes and engines, respectively, and entail an expenditure which may be represented by a fraction K_p or K_m of the purchase price.

To sum up, the equipment costs can be broken down into:

a The cost of amortization of the purchase price, including interest on capital
b The expenses of repair or periodical overhaul (not covered by insurance) including the total expenses of the repair shops, and/or payments to third parties for repair work.

To these expenses must be added the costs of running the service, which comprise:

a Fuel and oil
b Pilots and crew, including salaries, flying pay, insurance, uniforms, etc.
c Airports, including ground personnel, executive, clerical, mechanical and accounting; hangar charges, radio, lighting, etc.

These expenses can be considered on an annual basis as proportional on the one hand to the tonnage of the fleet, and on the other hand to the product of the number of flights per annum multiplied by the pay load of the aircraft employed.

Finally, we must add to the foregoing the administration expenses, including legal and insurance costs, plus the expenses of the traffic department. The total of these last two categories of expense can be termed general charges, and will depend on numerous factors.

---

[1] Director General and Founder, the L. Breguet Aviation Works.

[2] The net cost per ton-kilometer available, designated by X, does not take into account the actual pay load carried. Airplanes do not by any means always fly with a pay load equal to their maximum capacity; the pay load actually carried should be considered in the calculation of actual operating receipts to be set off against X, the net cost per ton-kilometer for operation at maximum capacity available.

Contributed by the Aeronautic Division and presented by the translator, C. H. Biddlecombe, New York University, before the Metropolitan Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., November 22, 1932.

In the case of a specific air line using specific equipment, we can consider these general charges as comprising two parts: one constant and the other proportional to the traffic. The latter will vary linearly with the number of trips flown annually on the scheduled service, the coefficients of the linear function depending principally on the number of stopping points on the route and the useful tonnage of the aircraft employed, or, more simply, of the total tonnage of these aircraft.

The sum total of the foregoing items represents the cost of operating an air line. Regarding the pay load FP of the aircraft employed, this is obtained by using a coefficient $(1 - a)$ where a represents the fraction of the disposable load absorbed by the cabin fittings and furnishings; the disposable load being the difference between the "all-up" weight P of the airplane fully loaded, and the "dead weight" represented by the sum of the weights of the bare airplane structure, the power plant group or groups, the crew, the flying equipment and/or instruments not otherwise included, and the fuel and oil with tanks and pipe lines. Finally, the cruising speed over the ground, as an average of all flights made over the length E of the trips, is generally a little less than the air speed V; it can be represented by γV, γ being a coefficient slightly less than unity, and which allows for head winds and the time lost in taking off and landing. The variable winds encountered in flight have very little effect on this coefficient, but it may be noted that in the formula the amount of fuel and oil needed for a given operation is calculated by using a factor v, representing an average wind always deducted from the air speed V.

Taking into account all the foregoing remarks, the formula which the author presented in 1927, now suitably revised, can be written in the manner, shown in the adjoining column, X being the actual cost of the ton-kilometer of pay load available, expressed in French francs as defined by the stabilizing law of 1928.

$$X = i \times \frac{100}{\lambda V}\left[\left(\frac{1}{M_p} + \frac{(n-n_1)\lambda V}{A_p N E} + \frac{K_p}{H_p}\right)x_p + \left[\frac{r}{M_m} + \frac{(n'-n'_1)V}{A_m N E} + \frac{rK_m}{H_m}\right]\frac{\chi V \tan\varphi'}{r \cdot 270}x_m + \left(\frac{100}{P} + 0.035\right) + \frac{V}{270}\tan\varphi' \cdot mx_c + p + \frac{\lambda V}{E}\left[g\frac{n}{N} + g'f\right] + \frac{\lambda V}{E}\left[\frac{G}{NP} + G'f\right]\right]$$

$$\text{Payload Capacity} = (1-a)\left[1 - \alpha - \chi\frac{V}{270}\tan\varphi' \cdot q - \frac{m}{270}\tan\varphi'\frac{V}{V-v}E - \left(\frac{130}{P} + 0.03\right)\right]$$

Purchase, Depreciation, and Overhaul of Equipment — Airplanes With Spares and Accessories — Depreciation — Service: $\frac{1}{M_p}$; Reserve: $\frac{(n-n_1)\lambda V}{A_p N E}$; Overhaul: $\frac{K_p}{H_p}$ — x_p

Engine Groups, Spares, Propellers, Etc. — Depreciation — Service: $\frac{r}{M_m}$; Reserve: $\frac{(n'-n'_1)V}{A_m N E}$; Overhaul: $\frac{rK_m}{H_m}$ — $\frac{\chi V \tan\varphi'}{r \cdot 270}x_m$

Operating Expenses — Flying Personnel: $\left(\frac{100}{P} + 0.035\right)$ — Fuel and Oil: $\frac{V}{270}\tan\varphi' \cdot mx_c$ — Running Maintenance: $p + \frac{\lambda V}{E}\left[g\frac{n}{N} + g'f\right]$ — Airport Expenses: $\frac{\lambda V}{E}\left[\frac{G}{NP} + G'f\right]$ — Administration and Traffic Expenses

Relative Weights — Cabin Fittings: a — Airplane Without Power Plant: $1 - a - \chi\frac{V}{270}\tan\varphi' \cdot q$ — Power Plant: $\frac{m}{270}\tan\varphi'\frac{V}{V-v}E$ — Fuel and Oil With Tanks: $\left(\frac{130}{P} + 0.03\right)$ — Crew and Equipment

France per Ton-Km Available

The letters and symbols employed in the formula are as follows:

- i = coefficient of increase to allow for irregular operation and certain incidental expenses, including insurance costs. The value of this coefficient ranges between 1.0 and 1.5, and is at present between 1.05 and 1.10 for air lines with efficient and regular operation
- M_p = depreciation of the bare airplane and accessories in hours of flying time. Its value varies between 2000 and 5000, depending on conditions
- M_m = depreciation of engine and accessories in flying hours and varies usually from 1000 to 2000
- n = total number of bare airplanes in the supply depot
- n_1 = total number of bare airplanes in regular operation on the air line
- n' = total number of engine groups in the supply park
- n'_1 = total number of engine groups in regular operation on the line
- A_p = mean time of depreciation, in years, of bare airplanes out of action or in reserve; usually between 5 and 10
- A_m = mean time of depreciation in years, of motor groups out of action and in reserve; usually between 5 and 10
- H_p = running time in hours of flight prior to an overhaul which puts the airplane structure out of action, and of the order of 300 to 1000
- H_m = running time in hours prior to overhaul of the engine group; usually from 200 to 600.
- x_p = purchase price, increased to take care of interest on and liquidation of capital invested in the plane and its accessories, spare parts and equipment, expressed in francs per kilogram of total weight of bare airplane. This specific price x_2 so defined is at the moment be-

tween 100 and 200, and varies according to the construction (wood, duralumin, or steel) of the plane

x_m = same as x_p, but for the engine group (i.e., power plant), expressed in francs per nominal hp. This specific price so defined is at the moment between 300 and 500 francs, according to the type of engine and quality of construction.

K_p = a fraction of the original purchase price of an airplane (minus engines) which represents total cost of periodic overhaul, including all the charges of the workshops and spare-parts depots doing the work. It varies from about 0.15 to 0.25

K_m = the same as K_p, but for the engine group, and varying from about 0.15 to 0.25

r = number of engine groups in each airplane

V = mean air speed of flight in regular service in kilometers per hour

λV = effective commercial speed (with regard to the ground and as an average of all flights) of aircraft in service; λ is of the order of 0.92 to 0.99

$\tan \varphi'$ = "fineness" of the aircraft at nominal flight speed, and equal to the aerodynamic "fineness" $\tan \varphi$ of the plane divided by the efficiency n of the propellers.

χ = relation between the nominal horsepower and the mean horsepower, $PV \tan \varphi'/270$, actually developed by the engines in service and at the normal altitude of flight

m = actual consumption of fuel and oil in kilograms per actual horsepower-hour. m is of the order of 0.23 to 0.28, and varies with the type of engines and the speed (i.e., rpm) at which they are operated in service

x_c = specific price of fuel and oil in francs per kilogram, taking into account all supplementary expenses such as distribution, storage, insurance. In France this is about 3 francs per kilogram for aviation spirit, and in the French colonies about double this figure. Conventionally the price should be increased by a small amount added to the actual cost to take care of additional casual consumption, such as during test flights

p = cost of line service and running maintenance of the airplane expressed in francs per hour of flight and per kilogram of all-up weight P. p ranges in value from about 0.07 to 0.12. Actually the expense of current maintenance is clearly proportional to the duration of flight and to the size of the airplane. The costs of line service for the planes (cleaning, inspection, etc.) and of their storage for the night are proportional only to the tonnage of the aircraft and to the number of flights, and not to the length of flights, so that one could break down the term p into two parts, one constant and the other varying inversely with the length of the stage. In practice, and to avoid unduly complicating these calculations, one can take a global figure p, fixed for a definite operation

g, g' = coefficients of the annual general airport expenses (other than expenses otherwise specifically enumerated). For air lines of the type in general operation today (i.e., with more than 10,000 flying hours a year and 2 to 6 airports), one can take $g = 8$ to 10 and $g' = 0.3$ to 0.5

E = length (taken as uniform) of the stages expressed in kilometers and assumed to be between 400 and 1500 km

N = total number of trips run per year on a scheduled service

F = pay-load ratio; FP = actual pay load

G, G' = coefficients for the total annual costs of the administrative and traffic departments. For the average air line, with more than 10,000 flying hours a year, one can take G as 1,000,000 to 3,000,000 and G' as 0.8 to 1.8

a = fraction of total disposable load devoted to the necessary fittings, etc., for the transportation of passengers. This fraction varies between 0.2 and 0.3 for passenger-carrying planes according to the comfort, etc., provided

α = relation of the weight of the bare airplane (without engine groups, tanks, fittings for the cabin, or special equipment for pilotage or navigation) to the total weight P. α varies from 0.25 to 0.35 according to the type, size, and construction of the plane

q = specific weight of the engine groups expressed in kilograms per nominal hp. q varies from 1.1 to 1.4 or from 1.0 to 1.3 for engine groups, water- or air-cooled, not supercharged, and of a capacity greater than 250–300 hp. This specific weight increases slightly as the hp of the engine decreases, and on the other hand decreases when the normal hp is increased by supercharging

v = speed (in kilometers per hour) of the contrary wind agreed on in order to determine the weight of fuel and oil to be carried.

In addition, the number of airplanes and engines necessary for a given service can be determined by formulas as follows:

The total number of airplanes

$$n = n_1 + n_2 + n_3$$

where n_1 = airplanes in regular service
n_2 = airplanes out of action for repair or overhaul
n_3 = airplanes in reserve to meet the emergencies of the service.

In the same way the total number of engines n' includes n_1', engines in regular service, n_2' engines under overhaul, and n_3' engines in reserve. The number n_1 of airplanes in regular service is equal to N/N', where N is the total number of trips budgeted for per year on scheduled service and N' is the number of trips which each airplane should fly per year in regular operation.

The number n_1' of engines in regular service is equal to the product $n_1 r$, i.e., the number of planes n_1 in regular service multiplied by the number r of engines in each plane.

The numbers n_2 and n_2' of airplanes and motors out of action for repair and overhaul are given by the formulas

$$n_2 = \frac{J_p N \lambda V}{365\,EH_p}; \qquad n_2' = \frac{J_m N \lambda V}{365\,EH_m}$$

where J_p and J_m represent the average time in days per year during which a plane or engine is out of commission for repair or overhaul.

As for the numbers n_3 and n_3' of airplanes and engines held in reserve, they depend essentially on the disposition of the stops and the nature of the traffic, as well as on the actual variables more or less unforeseeable. As a general rule, at least one complete airplane and one engine group ought to be held in reserve at each regular stopping point.

II—EXAMPLES OF APPLICATION—DISCUSSION OF CERTAIN PROBLEMS

1 Application to a Simple Case

Let us take an air line with two 400-km stages, each of them traversed three times a day in each direction; i.e.,

$E = 400$ km
$N = 12 \times 365 = 4380$ trips a year.

Assume that there are 6 single-engined planes ($r = 1$) running regularly on this line; i.e., $n_1 = 6$; $n_1' = 6$, that the air speed is 200 km per hr ($V = 200$), and that the commercial effective speed is reduced 5 per cent ($\lambda = 0.95$, or $\lambda V = 190$).

The "flying life" in service is taken as 3000 hr for each airplane, ($M_p = 3000$), obsolescence is reckoned at 5 yr ($A_p = 5$), the interval between overhauls is taken at 500 hr ($H_p = 500$), and finally the elapsed time between overhauls is 120 days ($Jp = 120$). Under these conditions the number n_2 of airplanes regularly out of action for overhaul is

$$n_2 = \frac{120 \times 12 \times 365 \times 190}{365 \times 400 \times 500} = 1.37$$

or, roughly, $n_2 = 2.0$.

One plane is held in reserve at each terminal, and one at the intermediate stop, i.e., $n_3 = 4$.

In the same way for the engines, $n_2' = 2$, and $n_3' = 4$.

The supply park then has:

$n = n_1 + n_2 + n_3 = 12$ airplanes, of which $n_1 = 6$, are in regular use

$n' = n_1' + n_2' + n_3' = 12$ engines, of which $n_1' = 6$, are in regular use.

Let us now calculate the pay-load ratio F, taking the relative bare airplane weight as 32 per cent ($\alpha = 0.32$), the specific weight of motors installed as 1.4 kg per hp ($q = 1.4$), a coefficient of excess power of 2/3 or ($\chi = 1.666$), a specific consumption of 0.26 kg per hp-hr ($m = 0.26$), a contrary wind of 40 km per hr ($v = 40$), a relative commercial fineness of 13 per cent ($\tan \varphi' = 0.13$), the relative weight of fittings in commercial flight as 20 per cent of the whole disposable load ($a = 0.2$), and finally a total weight of 4000 kg ($P = 4000$).

With these conditions, we calculate the nominal (rated) capacity of the engine at 640 hp, and the weight distribution of the plane is as follows:

		Weight, kg		Relative weight
Airplane		1280		0.32
Engine group		890		0.223
Crew and equipment		249		0.0625
Fuel, oil, and tanks		251		0.063
Total disposable load		1330		0.3315
being	cabin fittings 270		0.0665	
	pay load 1060		0.265 = F	
		4000		1.0

For the engine groups let us allow a service life of 1800 hr ($M_m = 1800$), an obsolescence life of 5 yr ($A_m = 5$), an interval between overhaul of 400 hr ($H_m = 400$).

For the cost of material let us allow a specific price of 150 francs per kg for the airplane ($x_p = 150$), of 300 francs per hp for the engine ($x_m = 300$), of 3.20 francs per kg for fuel and oil ($x_c = 3.2$), and finally a depreciation figure of 1/5 of the cost price for the airplane ($K_p = 0.2$) and 1/4 for the engine ($K_m = 0.25$).

Let us further decide on a coefficient for line service and running maintenance for the equipment of 0.075 franc per hour of flight and per kilogram of airplane weight ($p = 0.07$) and on coefficients $g = 8$ and $g' = 0.35$ for the general service expenses of the airports, and finally on $G = 1{,}000{,}000$ and $G' = 0.08$ for the costs of the administrative and traffic departments.

We have thus defined all the elements for the calculation of the net cost for an ordinary service on a short and easy line with very regular operation, using airplanes and engines corresponding to the present-day normal construction of commercial airplanes of moderate size and good quality. Speaking generally, all the conditions assumed are, although realizable, rather optimistic at the moment.

We can now calculate the net cost X per ton-kilometer *available*, taking into account incidental expenses of operation by giving the coefficient i a value corresponding to anticipated irregularities and the incidents and accidents common to average airplane operation. Including insurance costs and other incidental expenses for a sanely planned line, we may take the value of i as being about 1.06.

We then obtain (Table 1) the elements of actual expenses referred to either the ton-kilometer available or to the kilometers flown (with an available load of 1060 kg).

TABLE 1

			Total Expenses: Francs per ton-km	Francs per km	Per cent	
Equipment						
Airplanes	Depreciation	In use	0.990	1.05	8.60	22.22
		In reserve	0.387	0.41	3.34	
	Maintenance and overhaul		1.191	1.26	10.28	
Engines and propellers	Depreciation	In use	0.530	0.56	4.56	10.75
		In reserve	0.123	0.13	1.06	
	Maintenance and overhaul		0.595	0.63	5.13	
Operations						
Flying personnel			1.191	1.26	10.28	45.17
Fuel and oil			1.582	1.68	13.68	
Line service and running maintenance			1.385	1.47	11.97	
General airport and other expenses			1.065	1.13	9.24	
General administrative and traffic expenses			2.531	2.68	21.86	21.86
Total			11.57	12.26		100
Allowance for contingencies such as extraordinary repairs and insurance costs			0.69	0.72		6
Grand Total			12.26	12.98		106

2 Importance of General Expenses

In the foregoing example the author has assumed that the hypothetical service is operated economically, particularly with regard to administrative, traffic, and airport costs. In other words, he has assumed that this 800-km line laid out in 2 stages of 400 km each (i.e., 2 terminal airports and 1 intermediate landing ground) was established under very favorable operating and traffic conditions.

Such is not the case for the majority of the services being run today. Very often air lines operate between several different countries, and this fact involves complications in the running and additions to the general expenses which are easy to understand. On the other hand, air-transport companies, in spite of the development of air lines, have relatively small fleets and little traffic as compared with the great railway or shipping companies. The fact is that commercial aviation is still only in its early stages, nevertheless the organization of each company must include a considerable number of departments to study the numerous problems, technical, economic, legal, and otherwise, which are encountered in operating an air line. These problems can only be solved by incessant experiment, research, and practical operation. The expense of maintaining these departments is generally found to be heavier than has been assumed in the preceding example.

In order to keep in our minds the importance of these general charges in the actual state of commercial aviation, let us modify the assumptions made in the example so that these expenses will conform to all intents and purposes to the figures realized in 1930 on a French air line.

For the general expenses of the airports we can then substitute for the values of g and g' (viz., 8 and 0.35) the values 9 and 0.40; as regards the general expense of the administrative and commercial services, we should double the figures for G and G', that is, instead of 1,000,000 and 0.8, call them 2,000,000 and 1.6.

In these circumstances, if all the other factors were unchanged, Table 1 of the net cost of transportation would appear in its revised form as Table 2.

TABLE 2

			Total Expenses: Francs per ton-km	Total Expenses: Francs per km	Per cent	
Equipment						
Airplanes	Depreciation	In use	0.990	1.05	6.71	17.42
		In reserve	0.387	0.41	2.62	
	Maintenance and overhaul		1.191	1.26	8.09	
Engines and propellers	Depreciation	In use	0.530	0.56	3.57	8.43
		In reserve	0.123	0.13	0.84	
	Maintenance and overhaul		0.595	0.63	4.02	
Operations						
Flying personnel			1.191	1.26	8.09	37.67
Fuel and oil			1.582	1.68	10.73	
Line service and running maintenance			1.385	1.47	9.38	
General airport and other expenses			1.396	1.48	9.47	
General administrative and traffic expenses			5.385	5.71	36.48	36.48
Total			14.755	15.64		100
Allowance for contingencies such as extraordinary repairs and insurance costs			0.878	0.94		6
Grand Total			15.633	16.58		106

We can conclude that the increased expense estimated for the general charges translates itself into an increase of 28 per cent on the net cost. Such an increase is altogether in accordance with the actual influence which peculiarities of the organization and running of a line can exert on the net cost of operation independently of the equipment used. It is clear that an increase in these general charges of every kind has the effect of reducing the relative importance of the purchase price, and the maintenance and operating costs of the flying equipment. It follows that the importance of technical progress will be felt the more as the general costs of air transport can be reduced with the development of more profitable air lines.

3 Influence of Speed on the Net Cost

Let us go back to the formula which is the basis of our calculation and look into the influence of V on the different figures.

Consider the numerator only, of which the figures represent the costs in relation to each hour of flight and to each kilogram of the gross weight of the airplane (or to this weight in tons when one considers the coefficient 1000 used as a common factor of the numerator).

These figures fall into two categories; those in the first class are independent of V because they represent hourly expenses (such as obsolescence and maintenance of the airplanes, crew expenses, ground expenses, and maintenance) which are independent of the distance covered by the airplane in any given time of flight.

Those in the other class are proportional to V because they represent hourly expenses which are either exactly proportional to the power of the engines (partial obsolescence, overhaul, and fuel and oil consumption of the engine group) or inversely proportional (obsolescence of material in reserve, other expenses of airports, expenses of administrative and traffic departments) to the length of the stages because the corresponding annual expenses are either fixed by or proportional to *the number of trips flown* and do not essentially depend on the duration of those trips.

Divided by the factor λV which appears at the left of the denominator, the figures of the numerator then represent the costs in relation to the kilometers flown and to the gross weight of the airplane in kilograms (or tons if we multiply the figures of the numerator by the common factor 1000).

In accordance with the foregoing, we see that the figures in the first class decrease as V grows larger, while those of the second class become independent of V, that is to say, they are constant, always excepting those which depend on the rated or effective horsepower of the engine. For these latter χ, $\tan \varphi'$, and even m can vary more or less as we increase V. However, this last influence is inconsiderable, and if we neglect it we can make the statement that in general the total of the expenses per kilometer decreases with increasing speed, at least up to a certain limit.

As for the denominator (the factor λV having been dealt with), it represents the pay-load ratio F.

In this, the increase of speed of flight entails an increase in the rated and used horsepower of the engine and can bring about a modification of the manner of flight. It follows that the relative weight of the engine group varies not only because it is directly proportional to V but also by reason of the variation which may have to be made to χ, $\tan \varphi'$, and q.

As for the relative weight of fuel, oil, and tanks, it is affected only by the influence of the possible variation of $\tan \varphi'$ and by the influence (favorable in sign) of the lessening of the quantity $V(V - v)$ which takes care of the increased factor necessarily affected by the importance of contrary winds.

Therefore, in general, the pay-load ratio diminishes as V increases, and this effect is opposed to that which we have seen above for the expenses per kilometer.

The result is, therefore, that the net cost affected by these two opposing influences can vary but little with the speed, and can exceed a very small minimum only when the speed is very high. This particular property of the airplane, *eminently characteristic of its fitness for economic transportation at great or extreme speed*, can be specially developed if we increase the speed of flight by adding as little as possible to the weight of the engine while increasing as much as possible the effective power which it can give.

In order to study this problem we can consider two kinds of flight, namely, at low and at high altitudes; we can consider flight at 1000–2000 meters, which is normal in commercial aviation today, or flight at an altitude much higher, e.g., above 4000 meters.

In the latter case, remaining at such a height for a long flight involves the provision of special arrangements for the crew and passengers, and in consequence we can equally well consider regular flight at heights already reachable by commercial airplanes (4000 to 6000 meters) or at much greater heights (6000 to 12,000 meters, for example). The influence of high-altitude flight on the net cost will be considered later.

For flight at ordinary heights an increase of V involves, for any given airplane, an increase of $\tan \varphi'$, for the speed actually employed by commercial airplanes is already somewhat higher than the so-called "economic" speed which corresponds to the minimum of the apparent "fineness," $\tan \varphi'$.

One can nevertheless see the possibility of an appreciable increase of V without alteration of φ', either by increasing the weight per square foot (progress in this direction is soon stopped by the increase in landing speed and the risks such increase brings) or by "cleaning up" the airplane, particularly by reducing all forms of parasite drag.

To show the influence which the increase of V may have on the net cost, let us take the first example given above and vary only the factor V, giving successive different values to $\tan \varphi'$. We can then plot a suitable graph from which to ascertain the influence of the variation of V, both when supposing V constant and when an arbitrary law of variation is given to $\tan \varphi'$ as a function of V.

We then obtain, with all the assumed figures of the previous example (see Art. 1 of this section), for the pay-load ratio F the values given in Table 3, and for the net cost X per ton-kilometer available those in Table 4. These results are shown by the curves for $\tan \varphi'$ in Figs. 1 and 2.

The graph of Fig. 1 shows very clearly that the variation in net cost X (as a function of speed), with $\tan \varphi'$ constant, decreases with lower values of $\tan \varphi'$. In the example in question, when $\tan \varphi'$ has a value of 0.13, X only increases about 22 per cent when the speed increases from 160 to 320 km per hr. If $\tan \varphi'$ is 0.11, the extreme spread in the net cost falls to 5.5 per cent, which is practically insignificant.

TABLE 3

V, km per hr	tan φ' = 0.11	0.13	0.15	0.17
	Values of F			
160	0.329	0.297	0.267	0.237
200	0.300	0.265	0.230	0.195
240	0.271	0.231	0.191	0.150
280	0.242	0.197	0.152	0.106
320	0.214	0.162	0.112	0.062

TABLE 4

V, km per hr	tan φ' = 0.11	0.13	0.15	0.17
	Values of X			
160	11.08	12.37	13.86	15.75
200	10.77	12.26	14.17	16.79
240	10.79	12.67	15.34	19.50
280	11.13	13.57	17.71	24.97
320	11.70	15.18	21.69	39.00

The decrease in the net cost X obtained, for any given speed V, by reducing the value of tan φ', either through "cleaning up" the airplane or improving the power plant, is also clearly visible on the diagram. In order that it may be better appreciated, the author has added a curve for the ideal and unrealizable case where tan φ' would be nil. This curve also shows the absolute low limit possible for X. It is seen that if tan φ' is taken as low as 0.10 to 0.12 (which can be expected from really good modern aircraft, at least at normal speed of the order of 200 km per hr), we already approach closely to the theoretical limit of X.

Moreover, we must not look alone to technical progress in the design of flying equipment for a reduction of the net cost. Such reduction will in fact depend above all on the improvement in the

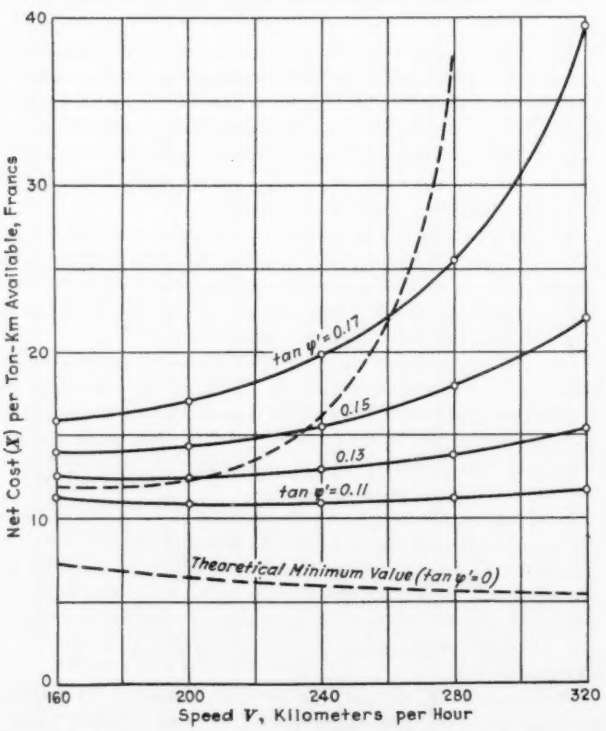

FIG. 1 NET COST PER TON-KILOMETER AVAILABLE (IN FRANCS)

life of the equipment, on the reduction of wear in service, on a decrease in initial and maintenance costs (all qualities more or less compatible), and finally on the reduction of general charges of all kinds, including organization and traffic costs.

As outlined above, for any given airplane, tan φ' increases with V when the economic speed is exceeded, which has already been done in the commercial speeds in common use today. Returning to the preceding example (tan $\varphi' = 0.13$; $V = 200$) we may admit that the variation of tan φ' with V for the airplane under consideration will be as follows:

V, km per hr	200	240	280	320
tan φ'	0.13	0.153	0.187	0.240

In accordance with these values of tan φ' we can trace by extrapolation a curve showing the variation of X as a function of V (upper broken line in Fig. 1). We get the following values of X:

V, km per hr	160	180	200	220	240	260	280
X, francs	11.7	11.7	12.26	13.4	15.9	21.3	36.7

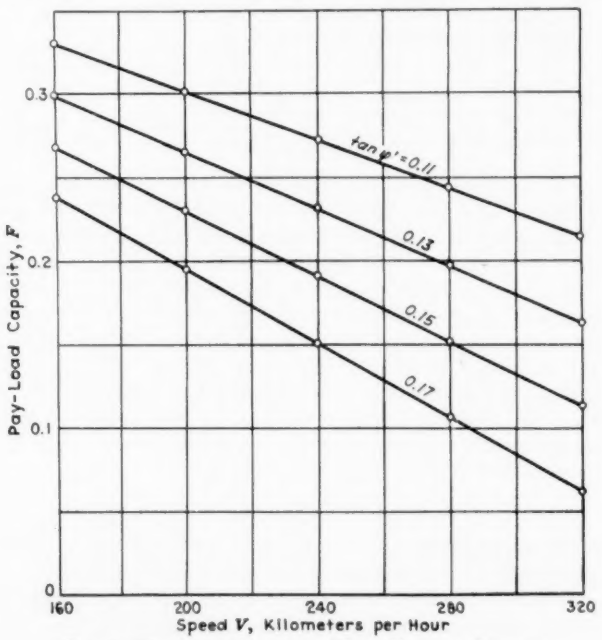

FIG. 2 PAY LOAD CAPACITY (F) AT VARIOUS SPEEDS

which show the very rapid growth of the net cost when V exceeds, under the assumed conditions, 220–240 km per hr; this results from the rapid growth of the values of the fineness tan φ'.

We see clearly then from this example that *the problem of economic flight at very high speeds is absolutely bound up with the realization of very small values for tan φ'*. These small values must be at such speeds (outside of the cleaning up of the airplane and the improvement of the power plant) as will allow us to lower tan φ' at a constant load or speed, or to reduce the load and increase the speed at a constant tan φ'. An increase in the altitude of flight will permit increasing the speed at a given load, and this without impairing tan φ', if the propeller efficiency is maintained.

We shall now examine the question of flight at high altitude.

4 FLIGHT AT HIGH ALTITUDE

Let Z be the normal height in commercial flying. Let us allow that, thanks to supercharging, the engine can maintain a constant thrust up to the altitude Z. In principle, the nominal hp of an engine of this kind is the power which an ordinary engine would have developed at ground level, where thrust at altitude Z would have been reduced by the natural falling off with height to the value estimated above.

Instead of the nominal hp, which here becomes altogether imaginary, let us consider the basic hp or the maximum power actually obtainable at all altitudes between zero and Z.

The effective power necessary at altitude for commercial flight at a speed V is always PV tan $\varphi'/270$ (hp) and the basic hp is equal to this multiplied by a certain factor of increase which we shall call χ_z.

This factor is not of the same order as the coefficient χ used earlier for a normal engine and for flights at low altitude.

In the first case, the value given to χ should be sensibly larger than unity—for example, of the order of 1.5 to 2, so that the excess of power over that required for commercial cruising will give the airplane a quick take-off, rapid climb, and sufficient ceiling to insure safety in flight. This would allow us, while cruising, to reduce the strain on the engine, which works considerably below full power, and from this again we get more freedom from engine trouble and a decrease in corresponding costs (the engine life M_m and the interval H_m between overhauls are increased).

This reduction in costs again tends to compensate, and sometimes more than compensates, for the loss of pay load which results from an increase of the engine power.

On the contrary, in the present case, even if we give to χ_s the lowest value ($\chi_s = 1$), the airplane must necessarily have a ceiling at least equal to Z, and in consequence, if Z is large enough, sufficient climbing speed. But in that case an engine would be working at Z at full throttle and thus be liable to excessive trouble. To avoid these conditions it is necessary to give to χ_s a value larger than unity, between 1.2 and 1.4 for example.

On the other hand if the basic hp, which is defined below, is taken as a term of reference, the specific weight q and specific price x_m of the engines have no longer the same values as for a normal engine for which one takes them in reference to nominal hp.

Let q_s and $(x_m)_s$ be the coefficients to employ in the case of a supercharged engine. Let us compare them with the coefficients q and x_m of a similar engine not supercharged and of a nominal power equal to the basic power of the first one.

Obviously supercharging adds to the weight of an engine and increases its price, but to a moderate degree. For the purposes of approximation we can consider that we have for different values of Z the approximate value shown below for the relations q_s/q and $(x_m)Z/x_m$:

Z, meters..	0	5,000	10,000	15,000
q_s/q.....	1	1.2	1.4	1.6
$(x_m)_s/x_m$...	1	1.3	1.6	1.9

Let us take these figures and review the assumptions of the first example studied above on the supposition that the cruising speed is made at the same efficiency (tan $\varphi' = 0.13$), which again obviously presupposes the employment of a variable-pitch air-screw, the extra weight of which is included in the increase of the specific weight just fixed for the engine groups.

Let us assume, on the other hand, that the increase in the basic power be taken at the low value $\chi_s = 1.2$ for each altitude Z above 5000 m.

Finally, the special equipment needed to make an airplane habitable during flight in rarefied air increases the weight of the cabin fittings. Instead of expressing this increase in cabin weight as a constant fraction $a = 0.2$ of the total disposable load, it will be assumed for clarity that, in a passenger plane, the total disposable load should be reduced by a constant amount increasing linearly with the height. This amount is 200 kg when $Z = 5000$ m, and 300 kg when $Z = 10{,}000$ m. We should also increase the value of the coefficient a to 0.3.

The author will consider separately the case of a mail plane, allowing the same fixed increment for the weight of fittings, but reducing the value of the coefficient a to zero. In these circumstances, we can calculate that there can be no pay load when $Z = 12{,}000$ m, which is the altitude at which the speed V reaches 395 km per hr.

The speed, the pay load, and the cost X for high-altitude flying between 5,000 and 12,000 m is as given in Table 5.

The cost thus calculated is represented as a function of V by the two curves in Fig. 3 representing high-altitude flying by passenger and mail planes, respectively.

TABLE 5

Altitude (Z) in meters..	5,000	7,000	9,000	10,000	11,000	12,000
Speed (V) in km per hr..	258	288	324	345	369	395
Pay-load ratio (f) of airplane:						
With passengers.....	0.179	0.142	0.095	0.0668	0.033	0
With mail.....	0.257	0.206	0.138	0.0958	0.05	0
Payload (kg) of airplane:						
With passengers.....	716	569	380	266	132	0
With mail.....	1,025	823	552	382	200	0
Cost (X) in francs per ton-km:						
With passengers.....	13.0	16.4	22.25	29.05	....	....
With mail.....	10.8	12.75	17.30	21.50	32.75	....

A third curve has been traced on Fig. 3 by the author which corresponds to flight at low altitude with the same value of tan φ' (0.13), which is supposed to be constant. He has also traced on the same figure a curve corresponding to an airplane with a constant speed having a "fineness" factor tan φ' equal to 0.13 at a

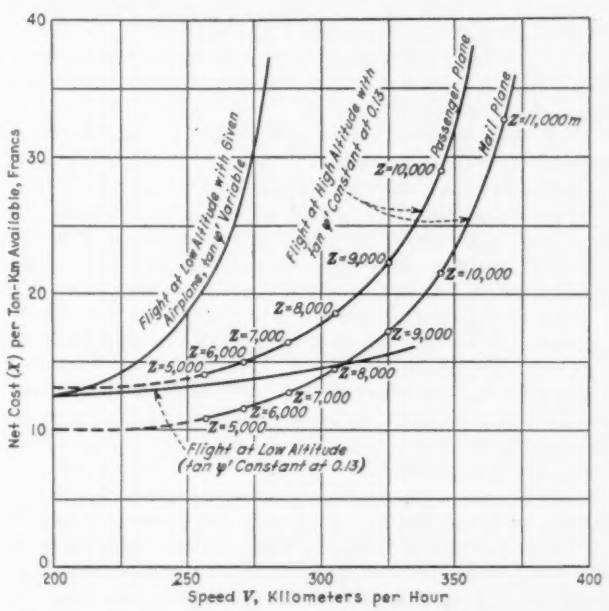

FIG. 3 NET COST PER TON-KILOMETER AVAILABLE (IN FRANCS)

speed V of 200 km per hr. It can be seen that tan φ' varies with the speed.

For example, if we take a passenger airplane for which $X = 12.26$ francs per ton-km, when $V = 200$ km per hr, and increase the speed to 260 km per hr, we obtain the following results:

(*a*) X becomes 21.4 francs per ton-km (an increase of 74 per cent) if we increase the horsepower in order to attain 260 km per hr, while still flying at low altitudes.

(*b*) X would not become greater than 13.2 francs per ton-km (an increase of only 8 per cent) *if* we could *at low altitude* increase the speed from 200 to 260 km per hr without changing tan φ'.

This would necessitate increasing the landing speed by 30 per cent (by reducing the lifting surfaces 41 per cent) or else decreasing the parasite resistance and profile drag by 36.5 per cent without changing the wing load or aspect ratio. The third alternative would be a compromise between the two methods, but all these suggestions are impossible in practice.

(*c*) X would reach 14.1 francs per ton-km (an increase of 15 per cent) if without changing the airplane or the rated sea-level speed, we could attain a speed of 260 km per hr by flying at 5100 m with a supercharged engine.

(*d*) X would *decrease* to 10.9 francs per ton-km (a *decrease* of 11 per cent) if we adopted solution (*c*) but carried only mail or freight and no passengers.

It is evident that it is advantageous and relatively easy to in-

crease the speed of flight from 200 to 260 km per hr by flying at 5100 m with a supercharged engine.

Let us go further and consider a speed of 320 km per hr; the curves of Fig. 3 show that solution (*a*) become absolutely prohibitive, X reaching an enormous value. On the other hand:

(1) X would not exceed 15.2 francs per ton-km (an increase of 24 per cent) if we could at low altitude increase the speed from 200 to 320 km per hr without changing tan φ'. This would mean either increasing the landing speed 60 per cent (by reducing the lifting surfaces 61 per cent) or reducing the parasite resistance and profile drag 56.5 per cent without changing the wing loading or aspect ratio. A third alternative is a compromise between these two, but all three are again impossible in practice.

(2) X would not exceed 21.1 francs per ton-km (an increase of 72 per cent) if without changing either the airplane or the rated sea-level speed, we reached a speed of 320 km per hr by flying at 8700 m with a suitably supercharged engine.

(3) X would not exceed 16.3 francs per ton-km (an increase of 33 per cent) if we flew at 8700 m, but carried only mail or freight and no passengers.

From these observations we can conclude that as soon as we consider commercial speeds above 300 km per hr, the efficiency of air transport is dependent on high-altitude flying.

This involves the use of supercharged engines, variable-pitch propellers, and special arrangements for making the airplane habitable for the crew and the passengers in the rarefied atmosphere.

Flight at high altitude can appreciably affect the reduction coefficient φ, by which we must multiply the average air speed to obtain the ground speed. In effect, the ground speed is reduced during the climb to high altitudes, but on the other hand we must consider the increase in frequency and intensity (at least up to 11,000 m) of the so-called "regular" winds encountered at high altitudes.

It seems generally agreed that these regular winds of from 60 to 100 km per hr velocity can be expected at altitudes of from 6,000 to 10,000 m. Nevertheless, in the foregoing calculations the author has allowed for all flights a value of 0.95 for λ, which can easily be modified if regular favorable winds can be relied upon in future high-altitude flights.

Discussion

JEROME LEDERER.[3] The formula appears to be involved, but actually it reduces to the well-known fact that the cost of operating an airline equals the sum of overhead plus operating expenses. This total is then divided by the total available pay load and by the miles flown to get the cost per ton-kilometer. However, some items in the overhead will vary with mileage flown, and this formula offers the advantage over usual rule-of-thumb methods by providing for variation in overhead with miles flown. Unfortunately, several factors in the formula would have to be obtained by actual operating experience, and by the time the operator obtained this data he could find out what his costs were by simply referring to his books. However, the formula, with simplifications and assumptions, might be used to make comparisons of different types of aircraft flying over the same route.

One's first reaction to the formula is that it goes into too much detail; for example, why should the weight of cabin fittings and of tanks be separated from the weight of the airplane. However, when one considers that the same airplane may be used for relatively long or short hops and over high or low terrain, the justification for this becomes evident. Long hops, for example require greater cabin comfort and larger tanks; hence the weight of fittings and tanks is a variable factor.

The method of calculating depreciation seems ambiguous. What are the "numbers" referred to in the sentence reading, "The complete depreciation of equipment can be calculated from the numbers allotted to the different stages." If exactness is desired in figuring depreciation and obsolescence, the following reasoning is suggested. The value of an airplane will depreciate by obsolescence and/or by use. An airplane which is kept in a hangar continuously will be obsolete at the end of, let us say, 6 yr; an airplane in constant use might be said to have a life of 3000 flying hours. Briefly it is good for a certain number of hours, and/or a certain number of years. However, these factors of time and use are seldom combined in figuring depreciation.

It does not seem particularly difficult to take both factors into consideration. Assume an airplane worth \$6000 is good for 3000 flying hours and is obsolete at the end of 6 yr. Then it will depreciate at the rate of \$2 per hr. Whether it flies or not, it will depreciate \$1000 per yr, due to obsolescence. Consequently, if the airplane is used 500 hr per yr, it is being used to the full extent of its obsolescence—that is, \$1000 (\$2 × 500)—and its value would be \$5000 at the end of the first year.

If the plane were used less than 500 hr, its depreciation would still be \$1000, due to obsolescence. If it were used more than 500 hr, say 1500 hr, its depreciation due to obsolescence would be \$1000 as before, and for use would be (1500 — 500) × \$2 = \$2000, or a total of \$3000. The minimum depreciation is fixed by obsolescence; the maximum depreciation is fixed by obsolescence plus use. Expressed in general nomenclature, let D = value of plane less engine, in dollars; H = life of plane, in hours; Y = life of plane, in years; and h = number of hours it is used per year. Then D/H = rate of depreciation due to use in D/hr; and D/Y = rate of depreciation due to obsolescence in D/yr.

When $h \times D/H = D/Y$, the plane is being used to the full extent of its obsolescence, or H/Y hr per yr. If h is less than H/Y, the depreciation is D/Y dollars per yr. If h is greater than H/Y, by say A hr, the depreciation is $(D/Y + A \times D/H)$ dollars per yr.

This method automatically takes care of the depreciation of an airplane due both to use and to obsolescence, and determines the minimum number of hours a plane should be used to obtain full advantage of its growing obsolescence.

AUTHOR'S CLOSURE

The author sympathizes with the feeling of dissatisfaction which Mr. Lederer expresses—i.e., that the proposed equation contains certain conditions of which the numerical value cannot be supplied otherwise than by practical experience. But any formula for the precalculation of net cost price will be exposed to the same criticism, because the elements of the price to be calculated are naturally of an empirical kind and cannot be known with certainty before real expenses have been incurred for the case under consideration.

No great importance should be placed on this remark, however. Every human "prevision" always supposes a certain extrapolation of the required results. This is an extrapolation which can be safely made. Moreover, my equation is for the purpose of making intelligent comparison possible, and likewise it is for the study of variations of the net cost price by changing its principal factors at will. The observations presented by Mr. Lederer with regard to effects of age, use, and depreciation value of a piece of equipment are entirely correct. His remarks furnish a useful comment on a point that I have purposely omitted to discuss in order to make my explanation simpler and shorter, and in which I have made each of these elements of depreciation to bear only on the material in reserve or on that which is in regular service.

AER-55-17

Shaft Drives for Airship and Airplane Propellers

By J. L. GOLDTHWAITE,[1] INDIANAPOLIS, IND.

General recognition of the possibilities of gear and shaft transmissions would free the designer from the limitations imposed by the fixed-unit power plant and appreciably broaden the field of aircraft design. Against these advantages are the weight and many engineering problems. The author discusses the most important problems from the standpoint of transmission design and suggests methods of meeting them. Working stresses, torsional vibration, dynamic balancing of long shafts, flexible couplings, and splines receive attention.

A UNIT POWER PLANT consisting of a propeller closely coupled to the nose of a heavy engine fits the typical airplane of today. It seems a perfectly natural arrangement, until some one asks, "What would you think if the designer of a ship put the propeller in front to throw the water back over the hull, impeding its progress, and if he put the motors out in the water instead of inside the hull?" And then one begins to suspect that the arrangement appears natural only because the airplane has developed around that kind of a power plant.

There are several types of aircraft for which the conventional arrangement is distinctly awkward. Amphibians and other watercraft properly take geared engines with large propellers, but it is difficult to secure sufficient clearance above rough water, particularly with flying boats; and engines over the wings are objectionable because of drag and interference, not to mention structural problems. A better arrangement would be to place the engines in the pontoons or floats, with shafts running up to the propellers. One engine can drive two propellers, or two engines can be geared to one propeller. By this plan the engines are entirely enclosed, noise and exhaust are far removed from the cabin, and the struts are relieved of the weight of the engine in landing.

In large multi-engine monoplanes, the thick wings provide free and frictionless space for the engines, but it is then necessary to provide shaft extensions to the propellers. The latest Ford plane has two such wing engines; the advantages are obvious.

Several years ago our company built for the Army a four-motor gear designed to drive one very large propeller with four Liberty engines. It passed a successful test on the stand, about 80 hours at full power, but the test consumed 15 Liberty engines, which perhaps explains why the transmission was never actually used.

In all large airships before the *Akron*, engines were hung outside in power cars. Streamlining of the cars and the necessity of clutches and brakes required shaft extensions several feet long. The *Shenandoah* drives included also reduction and reverse gears.

The *Akron* introduced an entirely different and very elaborate power plant. The eight engines are mounted inside the ship proper—an arrangement made possible by helium. From each engine a shaft more than 20 ft long extends laterally to a reduction bevel-gear head, which is supported on an outrigger and arranged to swivel so that the propeller may be pointed downward; and as the engines are reversible, the propeller may be used to exert thrust up or down, forward or backward. Two flexible couplings are used to allow for weaving of the ship structure, and a clutch and brake are provided at the inboard end. The gears are spiral bevels mounted in four bearings, and adjusted for reversible operation. The tilting device is a worm and quadrant in the drive-gear head, hand operated from the engine room.

Engineering Problems

The airplane designer, as an individual, has in many cases had the vision to wish for a separation of engine and propeller, but very generally has been appalled at the engineering problems involved, such as the question of weight when a propeller shaft weighs one or two pounds per inch; the matter of those 15-lb bearings and their housings; flexible couplings are unavoidable; few engineers have had experience with propeller gears; there are serious problems of whipping shafts and torsional vibration.

General recognition of the possibilities of gear and shaft transmissions would appreciably broaden the field of aircraft design. A considerable number of successful transmission systems have been built in the past several years, but experience in this field is built up slowly and cautiously, and the early designs, to be successful, must necessarily tend to be over-conservative. The author wishes to point out the most important problems and difficulties, to suggest methods of studying and meeting them, and above all to plead for further study and research, so that the airplane designer may be freed from the limitations of the fixed-unit power plant.

Stresses

Modern alloy steels are readily heat treated to an ultimate strength in shear of 100,000 lb per sq in. Presumably the fatigue strength bears the same relation to the ultimate in reverse shear as in reverse bending, and if torsional vibration is limited to an amplitude that just doubles the mean stress at peaks (greater amplitude would cause torque reversal, which is intolerable), then a design stress of 25,000 lb against nominal full-power torque should be permissible. But experience points to about half that figure as the safe limit for crankshafts; the discrepancy, of course, lies largely in the extremely complex nature of crankshaft stresses, which makes accurate analysis impossible. A simple drive shaft is free from such uncertainties; yet we have never dared go to a stress as high as that just suggested, for there is too much at stake in each new design. Eventually some one must take the chance, with his eyes open;

[1] Assistant Chief Engineer, Allison Engineering Company. John L. Goldthwaite was born at Marion, Ind. He attended Purdue University, and after an interruption in war service was graduated in 1921, with B.S. in Chemical Engineering. Following several years of general plant and maintenance engineering, he went to the Allison company in 1927.

Presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

meanwhile the conservative course is to keep below 12,000 lb and take the weight penalty. There is much need for more research work, both in the laboratory and in service, on the fatigue strength of steel in torsion.

Torsional Vibration

In a simple engine-propeller system resonance occurs ordinarily only in single-noded vibration, and is substantially independent

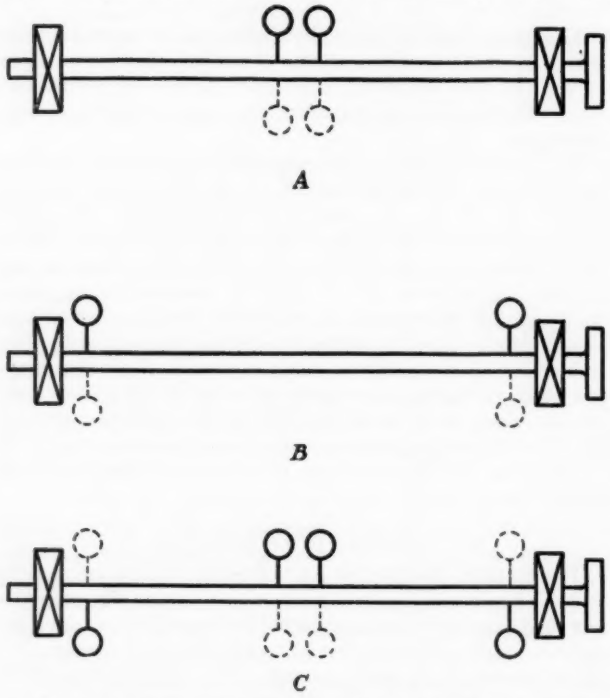

Fig. 1 Examples of Unbalance, With Corrections Shown by Dotted Lines

of the mass of the propeller. In other words, there is only one resonant frequency, and that one is inherent in the engine, although it of course may come in at several different engine speeds, excited in turn by different orders or harmonics of the torque curve. But as soon as a gear or extension shaft is interposed, the picture becomes more complex. In the first place, the natural frequency bears no relation to that of the simple power plant; an engine which is free from serious vibration throughout its operating range when direct connected to a propeller may run into dangerous periods when driving a shaft, and vice versa. Furthermore, a shaft always involves flexible couplings and sometimes gears, additional masses, so that vibration may be encountered in two or more nodes. In the *Akron* a 12-cylinder engine with at least eight measurable harmonics in its torque curve was coupled to a shaft system capable of vibrating in three or more nodes, so that there were at least 24 possible resonant speeds.

The five engines of the *Graf Zeppelin* are connected to their respective propellers through spring couplings and short extension shafts, almost exactly like those of the *Los Angeles* and other earlier ships. In tuning up the engine for the transatlantic flight, after many hours of successful operation, a slight change was made in the springs of the coupling. Shortly after starting on her trip, the *Graf* lost four engines in rapid order and was barely able to make her way back to a safe port. The apparently slight change in the coupling had brought the natural period directly into the operating range, and the crankshafts failed by fatigue.

The transmissions for the *Shenandoah* were built before the importance of torsional vibration was generally realized. They were designed for use with the 12-cylinder Liberty, and were entirely successful on the stand. But the engines finally selected for the ship were 6-cylinder motors, exceptionally rough, which set up vibration so severe and so sharply tuned that the shafts actually turned blue at the nodes. The difficulty was solved by the use of friction clutches set to slip just below the danger point.

A satisfactory analysis to predict dangerous torsional vibration is likely to be extremely difficult and involved; gears and couplings introduce considerable uncertainty at best. In many cases the best course is to build the transmission after only an approximate study and then explore its characteristics in actual running tests with the aid of a torsiograph. The characteristics of the system may be very materially altered, if necessary, by changing the diameter, i.e., the moment of inertia, of couplings, clutches, or gears; by changing the stiffness of shafts and couplings; or, as on the *Shenandoah*, by the use of a slipping clutch.

Speaking of torsional vibration, is it too much to ask some practical mathematician to develop an analysis without the use of differential equations? Put the problem of the simple pendulum before an engineer who is not familiar with the ritual of vibration, and he will regard it as a simple mass acted upon by a force. He will start it on a swing and will calculate directly how far it will go and how long it will take, and so derive its natural period and amplitude. His reasoning is straightforward and direct, and involves only purely physical concepts, unhampered by mathematical manipulations. But put the pendulum in the hands of a vibration specialist, and he catches it at some random point on its path and reasons backward to find where it must have been, how long ago, how it got there, how it got here, and what it will do next; he expresses all this in a mathematical code, eliminates the constants of integration, decodes the message, and discovers the natural frequency. The author does not question the value of the mathematical method, but the subject of vibration is so very important that its treatment should not be restricted, as it is now, to specialists. The designing engineer is likely to be a bit rusty in his code work.

Dynamic Balance of Long Shafts

A long extension shaft cannot be rigidly supported in an airplane, and if it is economically designed, it is likely to be operating above its critical whipping speed. And as the rigidity of the bearing supports is indefinite and variable, an unbalanced shaft may find resonant response, not only at the theoretical point, but at almost any speed, within itself, at one or both bearings, in a vertical, horizontal, or intermediate direction, unless it is perfectly balanced.

But balancing a long, slender shaft is a difficult task, involving factors that do not appear in the ordinary balancing problems. The usual methods and the familiar machines, based on reactions at the ends, do not apply; for the shaft can assume a different shape at each speed. The effect of flexibility is perhaps best illustrated by the cases of simple static unbalance illustrated in Fig. 1. Shaft *A* has two units of unbalance at the middle; shaft *B* has likewise two units, divided between the ends. If these shafts are rigid, as a turbine drum, or rigidly supported, as a crankshaft with intermediate bearings, or if the speed is low, so that distortion does not enter, then the end reactions of the two will be exactly the same, and a balancing machine would not distinguish between them. Shaft *C* would show perfect balance. But if the pieces are long and flexible, it is obvious that *A* and *B* would behave quite differently, and that *C* would be entirely out of balance because of distortion. For distortion balance not only must all forces be balanced, but all

internal couples as well; and from this standpoint the only possible complete corrections are those shown by the dotted lines. It will be noted that *C*, which from the ordinary standpoint is completely balanced, requires more correction than either *A* or *B*.

The longest single drive shaft in the *Akron* transmissions is some 13 ft long, 5 in. in diameter, with $^3/_{16}$-in. walls. Its critical speed in whip lies within the operating range. The first step toward balancing was to explore it inside and out with a dial indicator while turning it slowly by hand, measuring the amount and phase of eccentricity every 6 in. of length. Counterweights were calculated and applied to correct for unbalance due to eccentricity and variation in wall thickness; for this computation the shaft was considered as being made up of four short lengths, and each length was calculated for complete static and dynamic balance. These corrections left the shaft in very good approximate balance, so that the final corrections were small; but, more important, they left it substantially free from internal couples that would cause distortion at speed.

For final balance the shaft was mounted in three ball bearings on a long, level bench weighing several tons, with clamps so arranged that any bearing could be rigidly fixed or allowed to move horizontally; the mass of the bench prevented vertical movement. It was driven through a quillshaft by a variable-speed motor. Running at fairly high speed, two bearings were clamped and the vibration at the third or free bearing was reduced to a minimum by counterweights applied by systematic trial and error. This was done at each of the three bearings in turn; then starting at the first bearing, the course was repeated several times over. When finally released, the tubes were so closely balanced that no critical speed could be detected, whether running on two bearings or three, and the maximum vibration

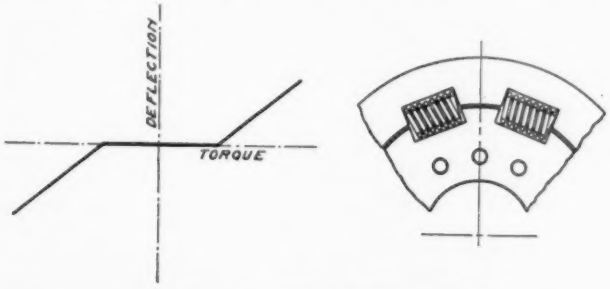

Fig. 2 Preloaded Spring Coupling

at any speed was less than 0.0015 in., or within the probable errors of the bearings and their mountings.

Flexible Couplings and Universal Joints

The influence of spring couplings on vibration has been mentioned. In many cases an elastic coupling is not required, but it is necessary to allow for angular misalignment due to weaving of the structure; probably the lightest coupling for this purpose is the internal-external gear type, sometimes known as Fast's coupling. It is sometimes objected that this type is noisy, for its flexibility is due entirely to loose fitting; but as the teeth cannot separate under load unless vibration is so severe as to cause torque reversal, the noise of the coupling might very well be regarded as a useful danger signal.

Among the elastic couplings there are several types available. In one form, Fig. 2, the drive is through compression springs preloaded in such a manner that no torsional deflection occurs until the torque reaches a certain predetermined value, the theory being that when vibration approaches a dangerous value the springs come into play and entirely change the elasticity of the system, thus destroying resonance. It can happen, however, that at certain other speeds a sudden accidental disturbance will momentarily bring the springs into play and throw the system into resonance. Once deflected, there is no appreciable change of stiffness with amplitude, so that resonant vibration once established can become dangerous. There is no friction.

The Falk or Bibby coupling, Fig. 3, depends on the deflection of flat spring elements. It has a considerable amount of free play or backlash, but its stiffness increases with increasing deflection. It may respond to a large range of frequencies, but

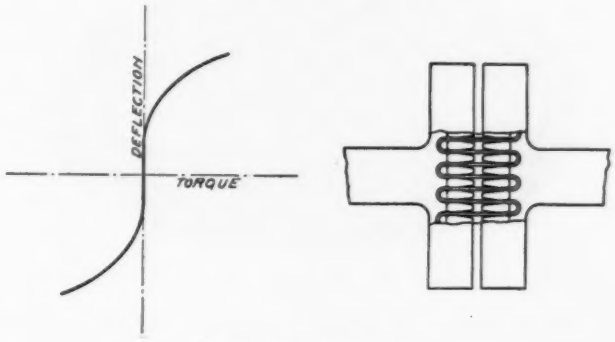

Fig. 3 Falk Coupling

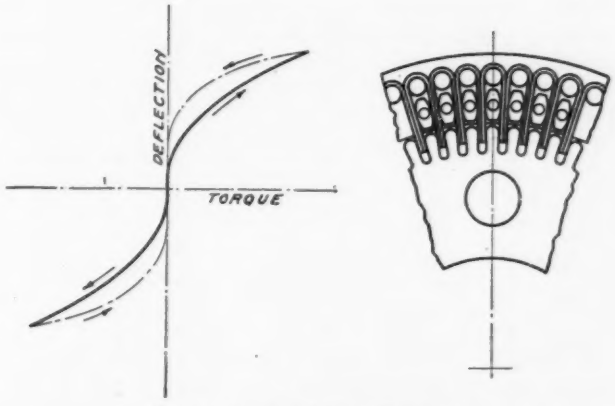

Fig. 4 Allison Spring Coupling

the amplitude at any given frequency is definitely limited. There is no friction and therefore no damping action.

The Allison spring coupling, Fig. 4, resembles the Falk in principle and in elastic characteristics, but interleaf-spring friction gives it a very considerable damping action, the hysteresis amounting to 10 to 15 per cent of each torque cycle. Consequently, although it responds to a wide frequency range, it possesses a powerful damping action. It has been used successfully in hundreds of geared transmissions and is an important element in the control of vibration in the *Akron*.

A very ingenious coupling is the Kirchbach, Fig. 5, also used on the *Akron;* it is of the familiar type that employs pins connected by links. The links are elliptical loops of flexible steel cable entirely embedded in rubber. Under tension, the loops tend to straighten out, putting the rubber in compression. Thus they combine the valuable damping feature of rubber with the strength and safety of steel.

Splines and Riveted Couplings

In view of the major importance of splines in all engine and power-plant design, it is really surprising that they have received so little attention. Except for well-placed emphasis on accuracy,

the design of splined joints has scarcely progressed beyond the rule of thumb. The author offers the following observations, although without complete proof except that the principles have been used in successful designs:

With a steady load in one direction, any reasonably well-made splined joint will distribute its load safely, because if one part is overloaded beyond the yield point, it will yield until the load is better distributed. But in aircraft power plants, with their inevitable vibration, failure by fatigue may occur at

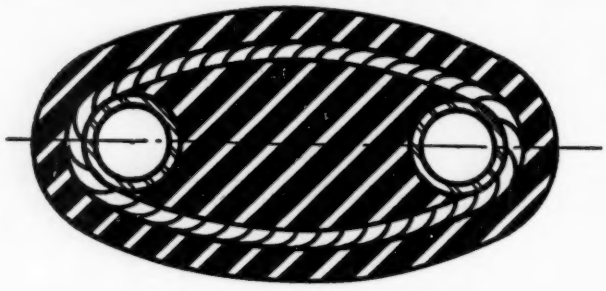

FIG. 5 KIRCHBACH COUPLING LINK

stresses far below the elastic limit. What is the fatigue strength of a perfect spline, of an ordinary good one, of a long spline, of a short one? These questions are only partially answered at present. Of two well-known geared engines, one drives its pinion successfully through a spline only $^1/_2$ diam in length; the other, with a spline length of nearly $1^1/_2$ diam, had a record of repeated spline failure; the difference, of course, was one of accuracy, affecting load distribution. It might well be pointed out that a perfect spline theoretically need be only $^1/_4$ diam long.

The importance of precision is obvious, but the influence of elasticity of the parts is not generally realized. Within the length of any joint the two members, shaft and hub, share the torque load in direct proportion to their relative stiffness. Now in the typical case of a slender shaft driving a heavy pinion or hub through a long spline, the hub is quite stiff and the shaft comparatively flexible; and it is quite obvious that the portion of the shaft within the hub cannot be carrying any load, for the shaft cannot carry torque without twisting. It follows that all the load is transferred to the hub at the point where the shaft enters it. Examination of splines in service will confirm this; they are overloaded at the point of entry, and the rest of the length does nothing.

Now suppose the hub and shaft are made to be equally stiff. Similar reasoning shows that they share the load equally. It follows that half of the load is transferred to the hub at the point where the shaft enters; throughout the length of the joint the load remains equally divided, and so there is no transfer; at the opposite end, the remaining (half) load is transferred. And so, by this simple expedient, the concentrated load on the splines is cut in half. A further step can be made by tapering the hub, whereby the load can be distributed in any manner desired; but of course such refinement is entirely out of place unless the splines are very accurately cut.

Clearly, the length of a spline as a rule has no influence on its capacity. Excessive length is a handicap; a long spline is likely to be cut with a slight twist or taper, so that it seems tight when in reality only a few points are bearing; short splines, conversely, are an aid to close inspection.

AER-55-18

Torsional Vibration of Aircraft Engine Crankshafts

By W. G. LUNDQUIST,[1] PATERSON, N. J.

Results of the study of torsional vibration of aircraft engine crankshafts are presented. Almost all engines have one or more easily detectable critical speeds for torsional crankshaft vibration. If one such critical speed should fall in the operating range of the engine, it is likely to cause trouble. Many apparently unrelated failures of engine parts can be traced to crankshaft vibration. It is therefore important that the vibration characteristics of every engine model be known so as to intelligently develop its design for maximum reliable power output.

THE subject of torsional vibration of crankshafts is certainly not new. Neither is the mathematical analysis of natural frequencies and critical speeds as much of a mystery to engineers as it was some years ago. Almost all phases of the subject have been discussed in the technical literature of recent years, and it therefore becomes difficult to present any new data which will be of interest to any one who has studied this source of trouble in internal-combustion engines. However, since aircraft engines appear to hold a popular interest and since they are by no means immune to the malady under consideration, a short presentation of some of the results of such vibration studies may be in order.

Almost all engines have one or more easily detectable critical speeds for torsional crankshaft vibration. If one such critical speed should fall in the operating range of the engine, it is very likely to cause trouble. There is a popular misapprehension to the effect that if the crankshaft of an engine does not break during operation, the engine must necessarily be free from serious crankshaft vibration. Such is not always the case. A long list of apparently unrelated engine-parts failures can be traced to crankshaft vibration, because such vibration besides overstressing the crankshaft also induces abnormal stresses in crankcases, connecting rods, valve gear, and accessory drives—particularly supercharger drives. It is therefore of great importance that the vibration characteristics of every engine model be known in order to intelligently develop its particular design for maximum reliable power output.

Present-day conventional aircraft engines can be classified roughly under two headings: first, in-line engines and, second, radial engines. Most of the engines under the first classification will be found to be liquid cooled, while the majority under the second classification are air cooled. However, as far as this study goes the method of cooling is of no great importance and will be given only little attention. The vibration characteristics of the engines under these classifications are as distinct as the classification to which they belong, and it is this point and the reason therefor that we wish to consider among other things.

Before taking up any specific phase of this subject, however, let us review briefly the underlying cause of torsional vibration in any engine in order to direct our attention intelligently and in order to give us a consistent method of attack in all cases.

Every crankshaft and connecting-rod system has at least one natural mode of vibration, the frequency of which can be determined. The calculation of natural vibration frequencies has been treated so thoroughly in technical literature of recent years that it need only be mentioned here. Any one not already familiar with the subject need only refer to Professor Timoshenko's books or to F. M. Lewis's paper of 1925, in order to get the necessary information for calculation of natural vibration frequencies. Only the single-noded mode of vibration will be considered in this discussion, since that is almost invariably the one which gives trouble. Since we have at our disposal, then, ready means for determining natural frequencies of crankshaft assemblies, we need only in addition to determine the engine speeds at which dangerous resonance may occur. Again we find ample literature to help us out, and we will only consider the main points.

As we all know, torsional crankshaft vibration is caused by torque variation. Every engine has a torque curve—sometimes unfortunately so. This torque curve is made up of the summation of the turning efforts of all cylinders combined in the proper phase relation as determined by the firing order. The fluctuations indicated by this curve may be large or small, depending upon the engine; but regardless of the size of the engine, the curve will repeat itself once every two revolutions of the crankshaft in the case of a conventional four-stroke-cycle engine. Accepting the harmonic method of analysis, we can take the turning-effort curve for each cylinder unit and resolve it into its harmonic components, the magnitude of which we are able to determine. We can then combine each successive component of each cylinder with the corresponding components of all the other cylinders of the engine in their proper phase relation and determine which harmonic of the single-cylinder torque curve will have a resultant effect in the engine. Selecting from this analysis the harmonic components which are cumulative, we can easily establish the location of our critical speeds. If we are still curious and wish to try to calculate the amplitude of vibration at a critical speed, it becomes necessary to know the magnitude of the damping forces in the engine, and in our present state of ignorance we can do little better than guess at the value of this variable. If we are going to guess at one of the stages of our calculation, we might just as well guess at the final result to start with, and thus save ourselves many hours of hard work. Furthermore, there are instruments available which will tell us without guesswork what the amplitudes during critical speeds are, and if our calculations do not agree with the instruments, we will have to believe the experimental data anyway, until we know more about

[1] Project Engineer, Wright Aeronautical Corporation. Mem. A.S.M.E. Mr. Lundquist is a graduate of the Mechanical Engineering College, University of Minnesota. After graduation, was connected with the Westinghouse Elec. & Mfg. Co. at East Pittsburgh, Pa., until March, 1929, at which time he assumed his present position. His scope of work has included experimental test, stress analysis, design, and experimental development.

Presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the subject. When sufficient consistent experimental data have been obtained, it will no doubt be possible to estimate within very close limits what the damping factor of a particular engine type will be, and using this value, we will be able to predict before building any engine very closely what the vibration characteristics will be. Until such data are available, however, we will have to content ourselves with being able to predict the location of the critical speeds and will have to use our judgment, based

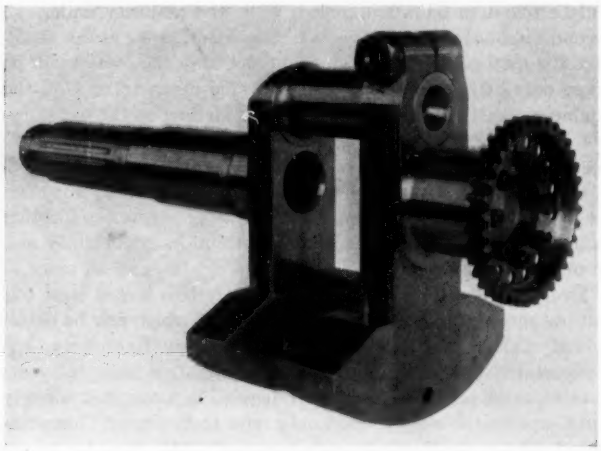

FIG. 1 SINGLE-THROW CRANKSHAFT

on experience in estimating the seriousness of any particular critical speed.

We will consider radial engines first, since they are the most orthodox in their behavior where torsional vibration is concerned. Strangely enough, radial engines show more violent vibration amplitudes during a critical speed than do line engines. Vibration torques reach almost unbelievable magnitudes in the case of some of the large engines. We will try to discover the reason for this as we proceed.

Most successful radial engines of today are single-row types having single-throw crankshafts. Following in general our proposed line of attack, we will first see how the natural frequencies work out.

Fig. 1 shows a conventional single-throw crankshaft as used in Wright engines.

The natural vibration frequencies of single-row radials with such shafts will usually be found to lie between 150 and 300 cycles per second with the small displacement engines on the high-frequency end of the list. The author has found that over the conventional range of displacements the natural frequency of similar engines varies inversely as the displacement raised to the 0.30 power quite closely, or

$$\frac{n_1}{n_2} = \left(\frac{D_2}{D_1}\right)^{0.30}$$

Accepting this formula as a rough approximation, we can make a fair guess at the range of natural frequencies which may be expected with present-day single-row radials. The main difference between engines of the same displacement will be the torsional stiffness of the crankshaft. If we assume certain extreme proportions for the dimensions of possible shafts, we can locate approximately the limiting curves as shown by Fig. 2. Curve *A–B* will pertain to engines having relatively stiff crankshafts (usually short nosed), while curve *C–D* will pertain to engines having relatively very flexible shafts (usually long-nosed). These curves are of interest since they facilitate the study of any particular family of engines—particularly so in the case where the design of a whole series of engines is contemplated. In such an instance the proportions of the basic design can be so determined as to preclude the coincidence of a critical speed with the operating range of any one of the models of the series.

Concerning two-row radials, few data are available. In general, however, two-row radials will be found to have higher natural frequencies than single-row engines of the same displacement. Two-row frequencies are indicated by the estimated curve *E–F* on Fig. 2. The author wishes to point out here that these curves are empirical and must be used only with considerable discretion.

After determining the natural-vibration frequency of the crankshaft assembly of an engine, the next step is to find what harmonics of the torque curve will be cumulative for a particular engine. In the case of radial engines, we discover that as we combine the successive harmonics of the torque curves of the cylinders in their firing order, all harmonics cancel out with the exception of those which are multiples of the number of cylinders. It is customary when making a harmonic analysis to assume that all connecting rods center on the crankpin. Such an assumption is not true, of course, when a master rod with articulated rods is used. Link-rod motion modifies the torque curve some-

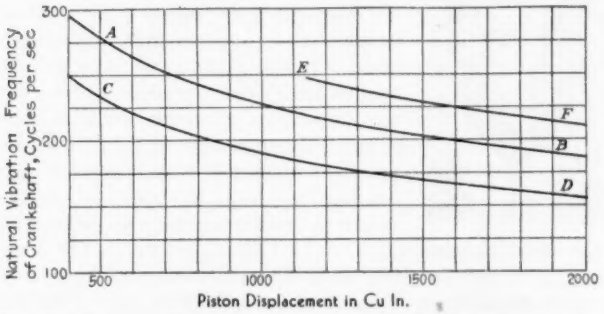

FIG. 2 NATURAL VIBRATION FREQUENCY OF CRANKSHAFTS VERSUS PISTON DISPLACEMENT, RADIAL ENGINES

what, the net result being the introduction of a second harmonic torque variation of small magnitude. This effect may be neglected when making an analysis, since the critical speed for a second harmonic is usually far beyond the normal range of the engine. From the preceding, then, we may make a tabulation of the engine-torque components which may give trouble. (See Table 1.)

TABLE 1

Engine types	Critical harmonics
5-cylinder radial, single-row	2, 5, 10, 15, 20, etc.
7-cylinder radial, single-row	2, 7, 14, 28, etc.
9-cylinder radial, single-row	2, 9, 18, 27, etc.
11-cylinder radial, single-row	2, 11, 22, 33, etc.
14-cylinder radial, two-row	2, 14, 28, etc.

Knowing which harmonics are effective, we locate the critical speeds as follows:

$$N = \frac{n(120)}{K}$$

where N = critical speed in rpm
n = natural vibration frequency of crankshaft (cycles per second)
K = number of harmonic torque component, as per Table 1, known as harmonic coefficient.

Let us assume that we have a whole series of single-row engines whose natural frequencies lie along curve *C–D*. We will further assume that the displacements of our models are as given in Table 2.

TABLE 2

	Cu in.	Rated speed (rpm)
5-cylinder model	500	2000–2400
7-cylinder model	700	2000–2400
1st 9-cylinder model	900	2000–2400
2d 9-cylinder model	1800	1800–2200

Referring now to our frequency curve and to Table 1, we can assemble the data for Table 3.

TABLE 3

Engine model	Natural frequency of crankshaft	Critical harmonics and speeds (rpm) Harmonic	Critical speed
5-cylinder	232	5	5570
		10	2320
		15	1855
7-cylinder	211	7	3600
		14	1800
1st 9-cylinder	196	9	2610
		18	1305
		9	2145
2d 9-cylinder	161	18	1072

We notice from this tabulation that the only criticals which fall in our proposed operating range are the 9th harmonic of the nine-cylinder engine and the 10th harmonic of the five-cylinder engine. Reference to a harmonic analysis will show that the magnitudes of these two harmonics are nearly the same, and both may give trouble. Torsiometer tests verify these deductions. In addition to the harmonics which fall directly in the operating range, other harmonics may also give trouble. If a large harmonic lies just below the rated operating range, it will probably give trouble at cruising speeds. Similarly, a critical speed above the rated rpm may give trouble at diving speeds in the case of pursuit ships or diving bombers.

The torsiograms of Fig. 3 were made by a Prescott torsiometer.

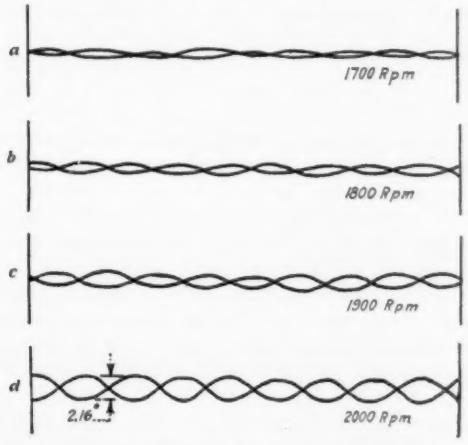

FIG. 3 TORSIOGRAMS MADE BY 9-CYLINDER SINGLE-ROW RADIAL ENGINE OF 1820 CU IN. DISPLACEMENT

(See paper, "Vibration Characteristics of Aircraft-Engine Crankshafts," by Ford L. Prescott, presented at the Fourth National Aeronautic Meeting of the A.S.M.E., paper AER-52-19.) They show the reaction of large nine-cylinder radial direct-drive engine of 1820 cu in. displacement to its critical harmonic (9th). The torque variation of this harmonic was approximately ± 9000 lb-in. The calculated critical speed for this engine was approximately 2200 rpm. The instrument was driven directly from the free end of the crankshaft. A vertical displacement of 1/8 in. represents 1 deg of torsional deflection at the crankshaft. The length of the card represents one revolution of the crankshaft. It will be noticed that two curves are recorded; these curves are two supplementary revolutions of the crankshaft, and represent a complete cycle.

From these torsiograms we can plot the curves of Fig. 4 showing the vibration torque and deflection of the crankshaft during resonant vibration. The curves represent conditions at 2000 rpm, as shown by corresponding torsiograms.

Notice from these curves the tremendous torque variation which apparently occurs during resonant vibration. Remembering that the disturbing harmonic in this case had an amplitude of 9000 lb-in., the ratio of torque variation at resonance to normal torque variation is 128000/9000, or 14.2 to 1. The damping factor (Δ) becomes 1/14.2, or 0.070.[2]

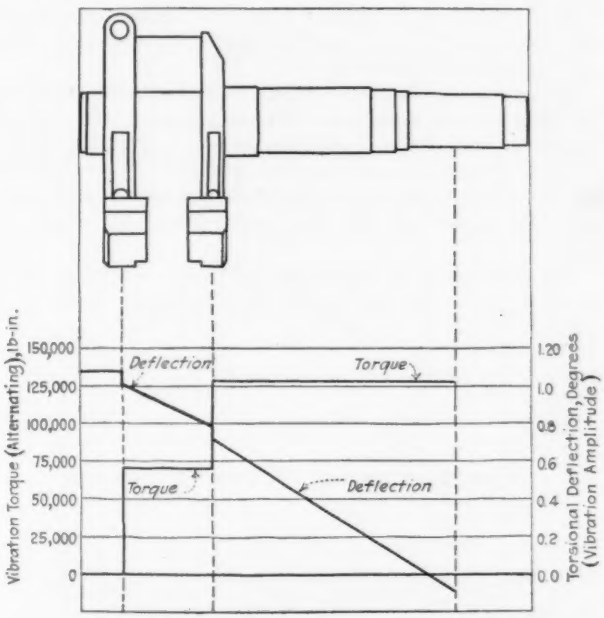

FIG. 4 TORQUE AND DEFLECTION CURVES FOR RESONANT SPEED

Major B. C. Carter states in his paper, "Dynamic Forces in Aircraft Engines," that the damping in radial engines appears to be of such an order that the torque variations in the shaft at synchronous speeds are from 5 to 10 times the normal gas-torque variations. The damping factor corresponding to this would vary between 0.1 and 0.2. It appears from the results presented herewith that the damping is less than what Major Carter suggests. The torsiogram from which our damping factor is calculated does not quite represent synchronous vibration either, being taken at a speed approximately 175 rpm below the critical speed of the engine.

Referring again to the torque curve, note the magnitude of the torque applied at the rear end of the crankpin. Mathematical analysis of the forces acting on a three-bearing crankshaft such as the one under consideration shows that approximately 38 per cent of engine torque is applied to the crankpin during normal operation. In the case of this engine the mean torque carried amounted to approximately 8300 lb-in. Due to resonant vibration we have an additional alternating torque of ± 70,000 lb-in. applied at the rear of the crankpin. The need for a good joint between the rear cheek and the crankpin is im-

[2] The resonance factor is:

$$\frac{1}{\sqrt{(1 - X^2)^2 + \Delta^2 X^2}}$$

where X is the ratio of the disturbing force to the natural frequency of the system and Δ is the damping factor. At resonance $X = 1$. The resonance factor becomes $1/\Delta$. Therefore Δ = 1 ÷ resonance factor.

mediately apparent. A well-designed clamp joint at this point will carry as much as 90,000 lb-in. torque.

It is difficult to say offhand just where the maximum actual stress occurs in a crankshaft during resonant vibration. The highest calculated stress will usually be found to occur in the section under the rear propeller cone. Oil holes and keyways, however, produce stress concentrations at other points of the shaft, and highest actual stress will usually be found in some section that is drilled or slotted. Fatigue cracks may therefore occur anywhere from the rear main journal to the propeller splines, but almost invariably do they start at some hole or sharp corner. Ample fillets, smooth holes with well-rounded edges, and careful machining operations are safety measures which must be adhered to faithfully.

We note in our fictitious analysis that the 10th harmonic of the torque curve would come into resonance in the assumed operating range of the five-cylinder engine, and we may expect trouble. This deduction is not idle speculation. Actual vibration of a five-cylinder engine crankshaft in resonance with a 10th harmonic torque variation has been recorded by torsiometer tests.

One more point should be mentioned here before we leave radial engines. We have noted that, neglecting link-rod action, the lowest harmonic of the torque curve which may cause trouble is that one whose coefficient corresponds to the number of cylinders of the engine. Furthermore, reference to a sample harmonic series will show us that the magnitude of the harmonic components decreases rapidly as the higher frequency harmonics are reached. Thus the 12th harmonic is, approximately, 25 per cent of the 6th, or again the 12th harmonic is only 45 per cent, approximately, of the 9th. If we now assume the damping factor to be constant, we know that the vibration amplitudes will be roughly proportional to the amplitude of the forcing torque. The best method of controlling vibration therefore is to use a large number of cylinders. For this reason two-row radials of 14 or more cylinders are particularly attractive. Such engines can usually be operated directly in a critical range without any observable damage.

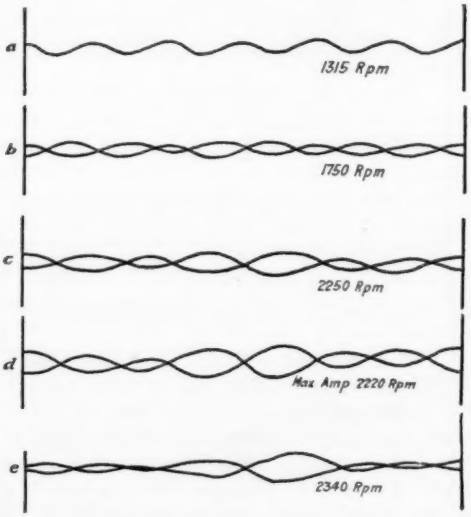

FIG. 5 TORSIOGRAMS MADE BY A 12-CYLINDER INVERTED-VEE ENGINE OF 1560 CU IN. DISPLACEMENT

The vibration characteristics of line engines are somewhat different from those of radial engines. The calculation of natural frequencies may be done in the same way as were those for single-throw shafts. It is when we attempt to determine which harmonics of the torque curve are effective that we come across some apparent discrepancies. Some actual examples will illustrate this.

The torsiogram of Fig. 5*a* is a transcript of a card made by a 12-cylinder inverted air-cooled vee engine of 1560 cu in. displacement. The card shows six cycles per revolution, or 12 in two revolutions. In other words, it represents the critical speeds for the 12th harmonic of the torque curve. If we make a harmonic analysis for such an engine as this, and combine the successive harmonics of the single-cylinder torques of the cylinders in their firing order, we discover as before that so far as resultant torque

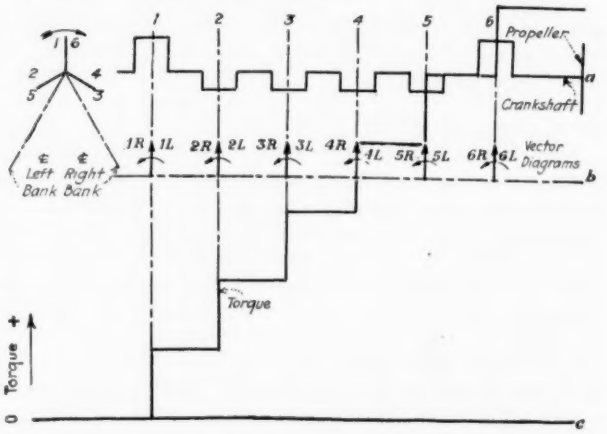

FIG. 6 SUMMATION OF 12TH HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

on the whole crankshaft is concerned, all harmonics cancel out except those which are multiples of the number of cylinders. One writer has suggested that since in a line engine we always have pairs of crank throws whose torque curves are exactly 360 deg out of phase, we may combine the turning-effort curve of each pair and let our cycle of events be 360 deg of the crankshaft instead of 720 deg. Doing this automatically eliminates all half-order criticals, which is a mistake, as will be seen.

Referring to torsiograms of Fig. 5*b* and Fig. 5*c*, both made by the same engine that made Fig. 5*a*, we find that the 9th and also the 7th harmonic of the torque curve cause resonant vibration. Our previous analysis would indicate that these harmonics should cancel out. The reason for this apparent discrepancy lies in the displacement of the points of application of the successive torque components. A simple graphical representation will show this.

Fig. 6*a* shows a line diagram of a six-throw crankshaft as used in a 12-cylinder vee engine. Assume that we have an inverted engine as just described, with the banks designated as right and left when viewed from behind the engine, then cylinders 1 right and 1 left are to the rear. The conventional firing order for this engine is: 1R, 6L, 5R, 2L, 3R, 4L, 6R, 1L, 2R, 5L, 4R, 3L.

We can now draw vector diagrams showing the phase relation of the torque components of each cylinder, considering each of the harmonics of the torque curve in order. Fig. 6*b* shows such a vector diagram for the 12th harmonic (harmonic torque of No. 1 right assumed maximum). Fig. 6*c* shows the summation of applied torque plotted against the points of application along the crankshaft. Notice that the harmonic components of the cylinders add up directly from No. 1 to No. 6 throw. Figs. 7 to 17, inclusive, show similar diagrams for each of the other first eleven harmonics of the torque curve. Notice particularly that on some of these diagrams (Fig. 9 for instance) there is a resultant average torque applied to the crankshaft

between No. 1 and No. 6 throws, although the sum of the torque is zero at No. 6 throw. In a case such as this, therefore, where No. 6 throw is very near the node, we are probably safe in concluding that the crankshaft will respond to the average torque applied along its length rather than to the algebraic sum of the torque over the whole length. Our diagrams indicate that the 12th, 9th, 7th, 5th, and 3d harmonics will produce an average torque as described, while the other harmonics show none at all or at least only a very small average torque from No. 1 and No. 6 throw. Notice that the forcing torques of the 6th harmonic cancel out at every throw. This analysis agrees with the known results as indicated by tests on this type of engine. No torsiograms of a 5th or 3d harmonic have been recorded to the author's knowledge, but such vibration probably would be encountered were it possible to attain high enough speeds to come into resonance with these harmonics. By such an analysis as this we may study the effect of various crank arrangements, firing orders, and the effect of changing the angle between banks.

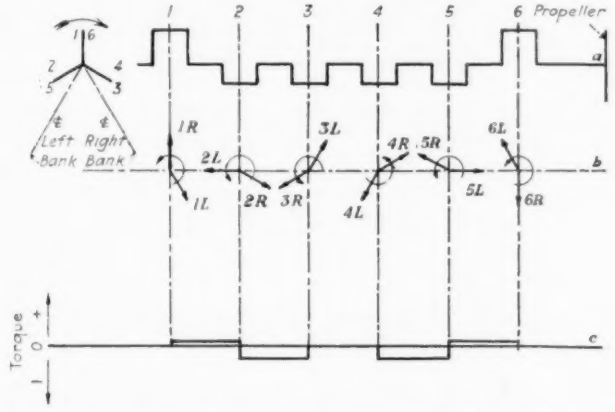

FIG. 7 SUMMATION OF 11TH HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

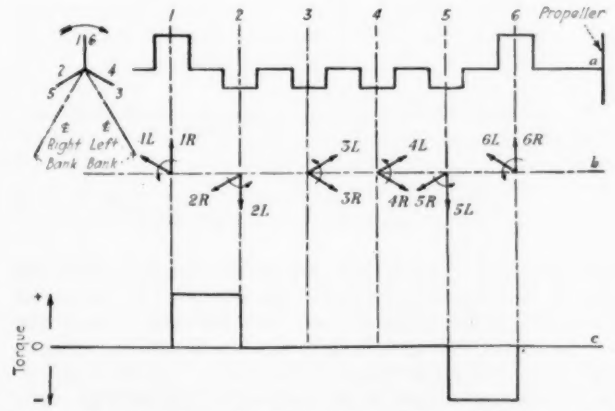

FIG. 8 SUMMATION OF 10TH HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

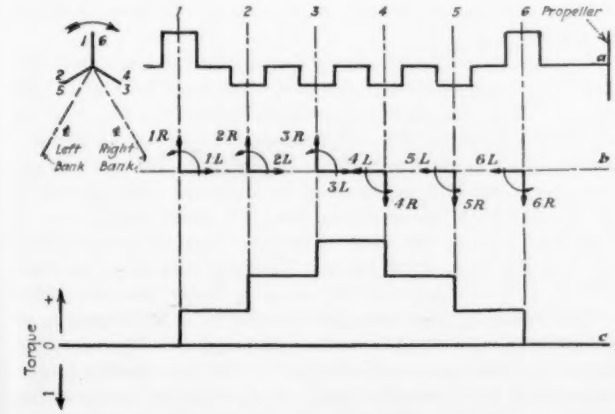

FIG. 9 SUMMATION OF 9TH HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

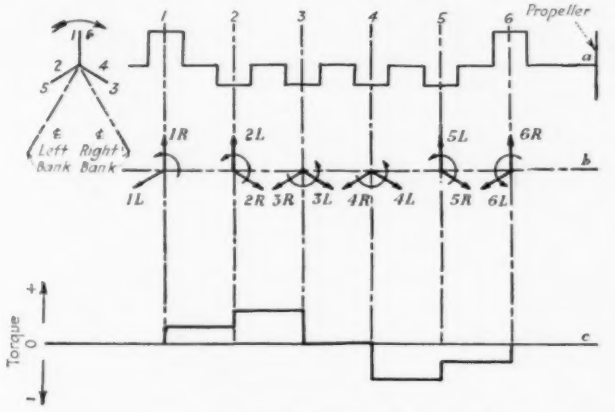

FIG. 10 SUMMATION OF 8TH HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

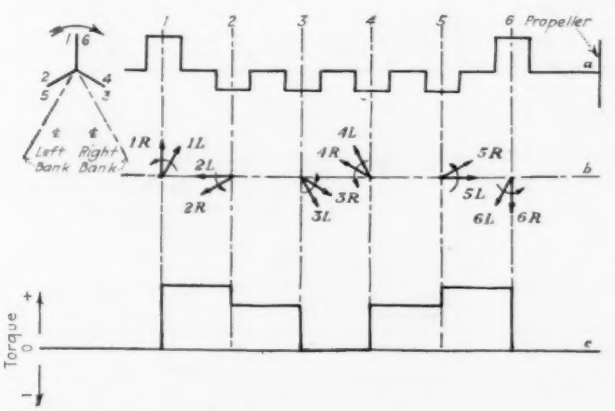

FIG. 11 SUMMATION OF 7TH HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

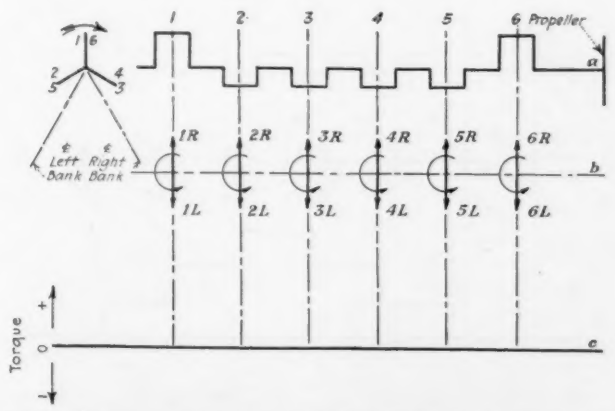

FIG. 12 SUMMATION OF 6TH HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

Referring again to the torsiograms, notice that Fig. 5c and Fig. 5d show a peculiar form having large and small waves. Before we can estimate the crankshaft stresses we must determine which portion of the deflection recorded thus is to be attributed to vibration and which to normal asynchronous torque variation. Since the power impulses in a line engine are not applied to one point of the shaft but to successively different points, the free end of the shaft will not have a steady deflection due to mean torque, but will exhibit a more complicated motion.

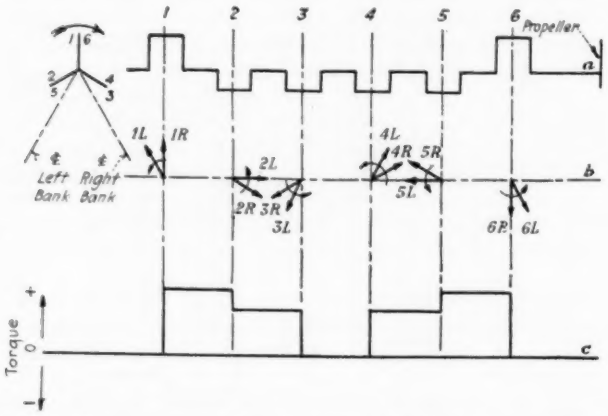

FIG. 13 SUMMATION OF 5TH HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

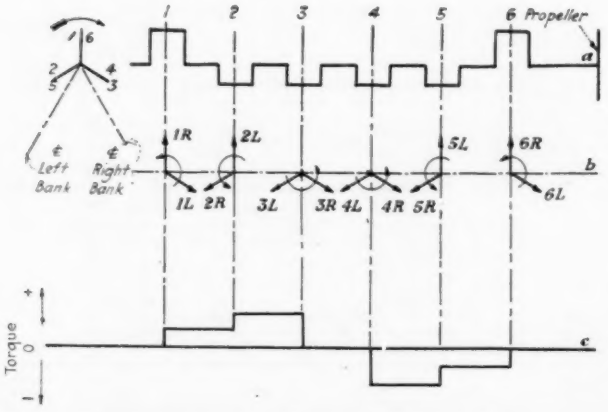

FIG. 14 SUMMATION OF 4TH HARMONIC TORQUE VARIATION OF 12-CYLINDER VEE ENGINE

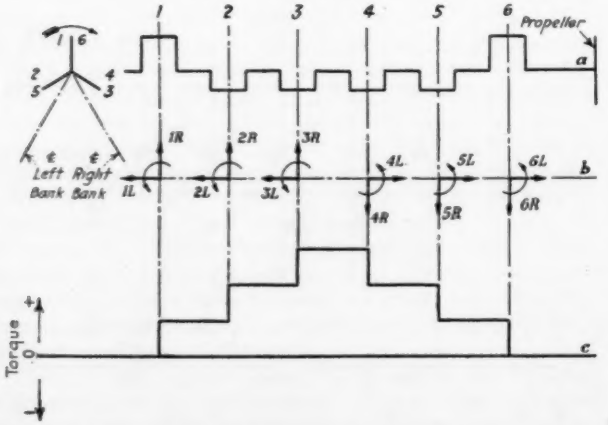

FIG. 15 SUMMATION OF 3D HARMONIC TORQUE VARIATION OF 12-CYLINDER VEE ENGINE

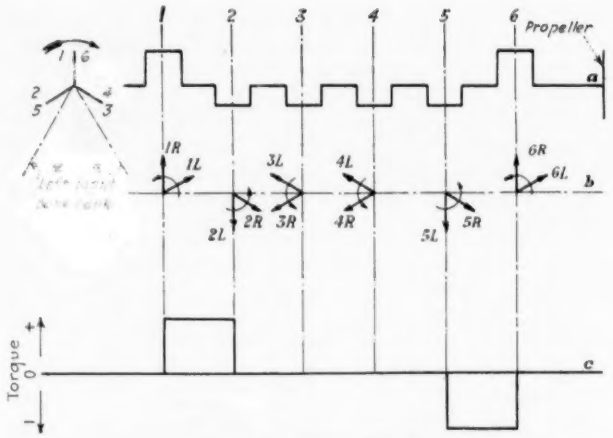

FIG. 16 SUMMATION OF 2D HARMONIC TORQUE VARIATION OF 12-CYLINDER VEE ENGINE

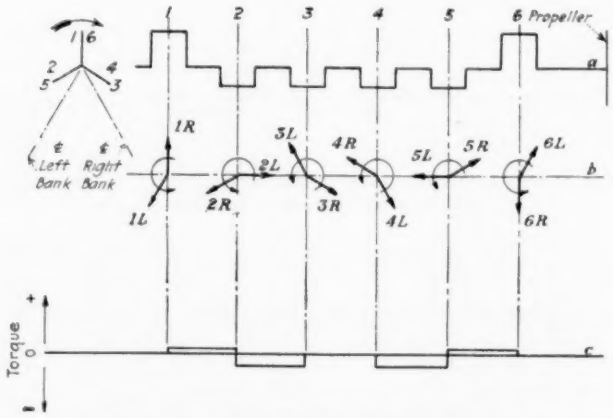

FIG. 17 SUMMATION OF 1ST HARMONIC TORQUE VARIATION OF 12-CYLINDER INVERTED-VEE ENGINE

During a critical speed there will be superimposed upon this asynchronous motion a harmonic vibration, and the torsiometer will record the resultant of these two vibrations. The easiest way to differentiate between these curves is to draw the enveloping lines of the higher frequency vibration. Fig. 18 is an example. Notice that the curve described by the envelope corresponds to the torsiogram which recorded the motion of the free end of the crankshaft at an asynchronous speed (see Fig. 18*d*).

Fig. 19 shows the elastic curve and the torque curve of a 12-cylinder engine crankshaft during resonant vibration, as shown by Fig. 5*d*.

Since we do not know exactly the resultant magnitude of the disturbing force of the 7th harmonic indicated by Fig. 5*d*, we are safer if we calculate our damping factor from the diagram of the 12th harmonic (Fig. 5*a*), because we know that all cylinder components add up directly (refer to Fig. 6*c*). The total torque variation of the 12th harmonic of the engine at 1315 rpm based on propeller-load characteristics from 600 brake horsepower at 2400 rpm was ± 620 lb-in. The total torque variation indicated by Fig. 5*a* is ± 9500 lb-in. The resonance factor becomes 9500 ÷ 620, or 15.3, and the damping factor becomes 0.065.

This would indicate that the damping in a line engine is of about the same order as that in a radial engine. The redeeming feature of a line engine in this respect is that the effective torque variation of the harmonic which usually falls in the operating range (the 7th) is small. Compare the torque summation of Fig. 6 and Fig. 11. For this reason it is not unusual to be able

to operate directly in the range of this harmonic without serious difficulty, providing that the accessories are driven from the propeller end of the engine or through some kind of flexible coupling.

Should the 12th harmonic of such an engine as described fall in the operating range, considerable trouble could be expected. Reference to Fig. 6 will remind us that the effective torque variation of this harmonic is large, and large vibration amplitudes could be expected. Crankshaft trouble, excessive bearing wear, and valve-gear failures would not be surprising. Fortunately, this harmonic usually lies in the idling range of this type of engine.

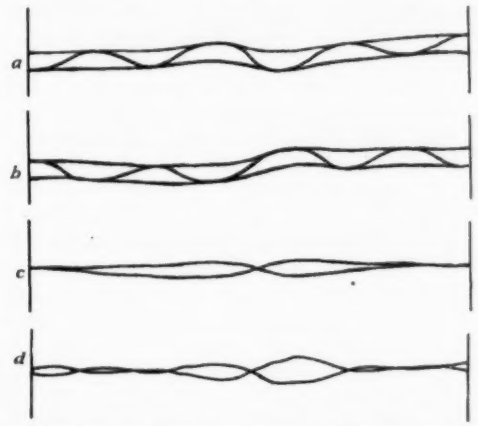

FIG. 18 METHOD OF DISTINGUISHING BETWEEN ASYNCHRONOUS AND RESONANT VIBRATION

(*a*, first revolution of Fig. 5*d*; *b*, second revolution of Fig. 5*d*; *c*, combination of enveloping curves of *a* and *b*; *d*, motion at asynchronous speed.)

In contrast with this we have previously noted that the major critical speed of a radial engine often falls in the operating range. That is why crankshaft vibration may be expected to give more trouble in a radial than in a line engine. Experience has taught us that this is true.

No discussion about torsional vibration would be complete without at least some mention of vibration dampers, and to be orthodox we will not deviate from this custom. Vibration dampers occupy more or less the position of poor relations to the aircraft-engine industry. We will welcome them with open arms if and when they come with real value in their hands, but until such a time we prefer not to be bothered with them. There are several objections to using conventional types of dampers in present-day conventional airplane engines. The three main objections are:

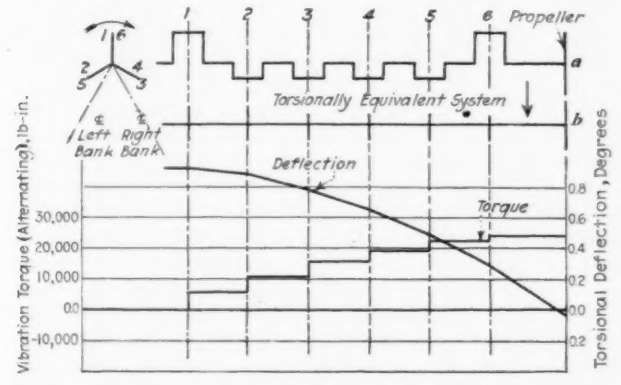

FIG. 19 TORQUE AND DEFLECTION CURVES FOR RESONANT SPEED, LINE ENGINE

1 They add weight
2 They are, in some forms, susceptible to misadjustment
3 They do not eliminate vibration; they only damp it.

Faced with these and other objections, we prefer to modify our engine designs to avoid resonance rather than to resort to dampers. However, we are open to persuasion, and perhaps some day we will make the addition of a vibration damper a further sales attraction, as do the automobile builders now.

AER-55-19a

I—The Problem of Elastic Stability

By L. H. DONNELL,[1] PASADENA, CALIF.

Increasing loading on a structure brings about "failure," either in the familiar way in which the material does not stand up at some point or by the way in which a part under compression reaches a state of instability and buckling occurs. The first of these modes of failure is a failure of material; the second is of a more structural character. The paper discusses preliminary stress calculations, independence of the two types of failure, characteristics of structures influencing each type of failure, relation of the characteristics to weight saving, secondary failures, experimental and analytical methods of studying buckling problems, comparison of different methods of analysis, the simple strut, column formulas, other stability problems, and possible methods of analysis of monocoque construction.

WHEN a structure is subjected to increasing loading of a type such that some part of it is compressed, there are two general ways in which "failure" can occur. The way most familiar to engineers is that in which at some point the material fails to stand up under the conditions of stress—combined perhaps with fatigue, extreme temperature, or other conditions—to which it is subjected. The other way in which failure may occur is that in which some part under compression reaches a state of instability, and buckling takes place.[2]

The first of these modes of failure is a failure of the material at some point or points. The mechanism of this failure takes place on a microscopic or perhaps even a molecular scale and is not well understood. Its laws are therefore studied almost entirely in a purely empirical manner. The second mode of failure is of a more structural character. Its mechanism is on a comparatively large scale, and its laws are quite well understood. It is therefore both practical and useful to study it theoretically as well as experimentally.

Preliminary Stress Calculations

Before we can determine whether, or when, failure of any type will occur at some point in a given structure we must first determine what the conditions are at all points, before it has failed. That is, we must determine how the loads or stresses are distributed throughout the structure, while it is still acting under the simple laws of elasticity. Sometimes the structure is so simple or familiar that this seems self-evident; sometimes the structure is so complex that this part of the problem involves complicated calculations or experiments. Engineers are likely to confuse this determination of the elastic stress distribution in the structure with study of the first type of failure, and to consider that it has nothing to do with buckling. This mistake arises chiefly from the fact that when we are studying the possibility of failure of the material, the determination of the stress distribution may be very difficult (as in some of the cases in the third part, AER-55-19c, of this paper), whereas after we know what the conditions are at each point the question whether failure will occur is usually simple or self-evident. On the other hand, the problem of determining whether buckling will occur or not under certain conditions of stress is in general much more difficult than the problem of determining the condition of stress. Practically all cases of buckling which have been studied theoretically up to the present have been cases in which the distribution of stress is very simple and familiar. But there are plenty of cases to be studied in which the stress distribution is far from obvious—as, for instance, a stressed-skin wing.

As the mechanism of failure of material is on a microscopic scale, this type of failure can start at any point in the structure when a certain stress is reached, even if on all sides of this point the stress is lower. Hence in studying this type of failure the maximum value of the stress is the thing to be found, and the stress distribution must be studied in great detail. On the other hand, buckling is more dependent on average conditions over considerable portions of the structure, so that it is not important to know the stress distribution in such detail. Nevertheless it should be emphasized that determination of stress distribution, theoretically or experimentally, is to be regarded as a preliminary survey of the situation to determine the conditions in all parts of the structure, preparatory to considering the possibilities of any type of failure.

Independence of Two Types of Failure

Having studied the structure as a purely elastic problem, we are ready to determine two things: the loading at which failure of material will start, and the loading at which buckling will start. We can consider these two questions entirely independently, and take the smaller of these two loadings as the answer to the problem. We need not worry about the possibility of a combination failure occurring at still lower loadings.[3] After one type of failure has started, then all conditions are changed, and subsequent events are quite likely to involve a combination with the other type of failure, but the conditions for the starting of each type can be considered to be independent.

Characteristics of Structure Influencing Each Type of Failure

The characteristics of a structure which influence one type of failure have little connection with the characteristics affecting the other type. As for the characteristics of the material used, failure of the first type depends on the strength of the material,

[1] Research Fellow in aeronautical structures, Guggenheim Aeronautical Laboratory, California Institute of Technology. Mem. A.S.M.E. L. H. Donnell was born in 1895 in Maine. He is a graduate in Mechanical Engineering, University of Michigan, 1915; Doctor's degree, University of Michigan, 1930. He worked in the engineering departments of automobile companies (Franklin, Packard, Dodge) for seven years, and taught engineering mechanics as Assistant Professor, University of Michigan, for seven years.

[2] It is conceivable, of course, that a state of instability may exist in which there is so nice a state of balance that buckling does not, at least immediately, occur. But this is of no practical importance, and it must always be assumed that buckling will take place as soon as a state of instability is reached. Thus a theoretical study of this subject usually consists and need only consist in a study of the conditions for instability—the conditions under which buckling *may* take place.

Part I of a Symposium, "Survey of Problems of Thin-Walled Structures," contributed by the Aeronautic Division and presented at the Pacific Coast Aeronautics Meeting, Berkeley, Calif., June 9 and 10, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] It may be argued that an exception to this may occur in such a case as an eccentrically loaded strut. However, the effect of one type of failure on another would not lower the failure load greatly even here. Also, true instability is impossible in this case, and the problem may be considered as a simple elastic problem up to the moment of failure of material. This question is considered in detail later for the case of struts.

while failure of the second type depends only on the stiffness of the material (that is, the modulus of elasticity, and to a slight extent Poisson's ratio) and is in no way influenced by its strength. The geometrical shape of the structure is of importance in connection with the first type of failure in so far as it determines the maximum stress. The influence of the shape on the second type of failure depends on quite different and more complex characteristics, having to do principally with the ratio between the smallest dimension perpendicular to a compression and other dimensions. Hence it is structures in which, due to weight considerations or other reasons, thin plates or rods are used to carry compressive stresses, that are likely to suffer buckling before failure of the material.

Relation of the Characteristics to Weight-Saving

One of the chief problems of the aeronautical engineer is to design a structure not only capable of resisting a certain loading condition, but having the minimum possible weight. As far as the first type of failure is concerned, this requires the choice of a material having a low weight-strength ratio, while for the second type of failure it favors a material with not only a low weight-stiffness ratio, but also with a low absolute density, so that thicknesses may be as large as possible. It happens that the weight-strength and weight-stiffness ratios for the three materials chiefly used for aeronautical structures, wood, duralumin, and high-strength steels, are not very widely different, so that the lighter materials, allowing greater thicknesses, are evidently more suitable for parts subjected to compression. However, other considerations seem to be favoring the heavier materials, and this makes the buckling problem more and more important.

For maximum weight saving, considering the first type of failure, the detailed design should be such that all parts of the structure reach failure of the material at the same loading. If at the same time the structure can be made in such a stable way that buckling failure does not occur before this same loading is reached, then we may consider that we have reached 100 per cent efficiency in weight saving for the materials and general design employed; to further increase the resistance to buckling does no harm, but also no good in general. This is the ideal, the goal to be aimed for; in some cases it can be attained easily, and in all cases it could theoretically be attained by a sufficient complication of the structure, although this might be quite impractical from economic, aerodynamic, or other points of view. If it is impossible to keep buckling from occurring before material failure, then there is no simple criterion for measuring the maximum of weight saving, but obviously the practical designer needs all the information possible on the laws of buckling.

Secondary Failures

In some cases, when failure once starts, it is so complete that we are no longer interested in the structure. In other cases, the first failure is of a partial or local character, and the loading may be increased until other partial or complete failures occur. The study of these later failures is likely to be very much more difficult than study of the first failure, as the structures are no longer in a simple elastic condition when they take place, but may be in a combination of elastic, plastic, and buckled states. Some problems of this type are considered in the second part of this paper. Of course if the first failure is sufficiently minor or local in character (as, for instance, the local yielding of ductile material around small holes, due to stress concentration), its effect may be neglected entirely in considering the next failure. Another generalization that can be made regarding secondary failures is that if a structure or part of a structure is subjected to compression and fails first by yielding of the material, then a buckling failure is certain to occur at very little increase of the load, no matter what the shape of the structure (unless it is of extremely stable shape). This very important generalization will be discussed in detail later, under struts.

Methods of Studying Buckling Problems, Experimental and Analytical

Let us consider now the general methods of studying buckling or instability. In a complicated structure there are usually many different types of buckling which may occur in different parts of the structure, or even different types which may occur in the same part. Each would occur, if nothing else happened first, at a certain loading of the structure. Our problem is to find this critical loading for each of these types of buckling failure and take the lowest loading as our answer. This is the loading at which the structure will first fail (what happens afterward is a new and more difficult problem, as discussed before). This multiplicity of the different possible types of buckling adds much difficulty to the subject. Not only does it add to the work to have to consider so many different things (although of course with experience many can be eliminated by inspection), but the question of whether we have considered all the possibilities, or have neglected some of them, is a major difficulty.

This makes experience with buckling problems in general and experiments on the particular type of problem in question of very great importance. A mathematical analysis which takes all possible modes of buckling into consideration and leads us inevitably to the correct solution is practicable only in simple cases. Hence in complex cases we often must rely upon experiments to indicate to us what modes of buckling must be analyzed. Even then the analysis is likely to be difficult and to necessitate simplifying assumptions such as the neglect of eccentricities and nonuniformity of material. Hence there is a strong temptation to neglect analysis and rely wholly upon experiments. However, it is obvious that experiments on each particular detailed design are expensive and tell us little about possibilities of improvement, while series of experiments, no matter how extensive, can obviously cover only a limited field, and applications of their results outside this field are dangerous. It would seem that, to have a knowledge of our buckling problems really useful for design purposes, we must have some kind of rational analyses (even if somewhat approximate), using experiments as a guide to and a check upon these analyses and to get an idea as to the variations to be expected in practice due to unknown factors such as eccentricities. In cases where we have not been able to make satisfactory analyses, we may be able to use the results of analyses of simpler but similar problems, or the results of very approximate analysis, as a basis for formulating the results of experiments; such formulations should be much more applicable outside the range of the experiments than completely empirical formulas.

Methods of Analysis, the Elastic-Line Method

There are two general methods for analyzing the conditions under which a structure or part of a structure will become unstable. The first method, which might be termed a "direct" method, consists in setting up a general expression for the lateral deflection (that is, deflection perpendicular to the compression[4]) of the body, in the same manner as deflections are calculated in any elasticity problem—that is, by assuming that there is deflection and applying the laws of equilibrium and Hooke's law to elements of the body. This gives an expression for the lateral deflection at any point of the body in the form of a differential equation involving the external loading (or the stresses produced by it) as a constant factor. Solutions of this differential equa-

[4] In some cases deflections in other directions also take place during buckling and must be considered. This is discussed later under the energy method.

tion represent possible deflected states in which the structure will be in equilibrium. If the problem is one in which instability is possible, it will be found that the only solutions satisfying the differential equation and the boundary conditions are as follows: One solution will be that in which the deflection is everywhere zero and the external loading may have any value; the physical meaning of this is obvious. In addition to this there will be other solutions, in each of which the external loading must have a certain definite value, and the deflections must vary in a certain way over the body, but may have any absolute magnitude;[5] each of these solutions represents a possible type of buckling, and the value which the external loading must have in it is the loading at which this buckling would take place if nothing else happened first. The smallest of these values of the loading is the loading at which buckling will first take place.

A variation of this method of analysis, perhaps more satisfying to practical minds, is obtained by assuming a small initial curvature (or eccentricity or bending moment), and then setting up an expression for the lateral deflection as before. Again, numerous solutions can be found, corresponding to the various possible types of buckling. The deflection given by one of these solutions for any point of the body is no longer zero up to the buckling loading and any value at this loading, as implied in the foregoing solutions, but is a definite function of the loading, of the approximate form:

$$d = \frac{e}{\frac{P_e}{P} - 1} \qquad [1]$$

where d is the lateral deflection at some point due to a loading P, e is a constant proportional to the initial curvature, and P_e is the critical buckling loading corresponding to the solution. Fig. 1 shows the deflection plotted against the load for various values of e. It will be seen that with smaller and smaller initial curvatures the law of the deflection approaches more and more nearly to that implied in the foregoing solution with no initial curvature.

A New Method

Another and less mathematical way of applying this principle of analysis, not previously published, is used later in discussing simple struts. In this an initial curvature is again assumed. Due to this initial curvature, the compressive load produces bending moments along the strut, which cause an additional curvature. This additional curvature produces additional bending moments, which cause another increase of curvature, and so on. This gives the final shape of the bar under any load as a superposition of an infinite series of deflections, starting with the initial deflection. If the loading is below the critical loading, this infinite series converges and gives a finite deflection. When the loading reaches the critical value, the series no longer converges. This method eliminates differential equations, and moreover leads directly to the correct shape of the buckling deflection, so that it is no longer necessary to choose between various possible types of buckling. If the assumed initial deflection happens to be of the same shape as the correct final buckling deflection, then all the increases in deflection will also be of this same shape, and the infinite series becomes a simple geometric series whose sum is well known. If the initial deflection does not happen to be of the same shape as the final buckling deflection, it is an interesting fact that the additional deflections, calculated from it and from each other, become of very nearly the final shape after a comparatively few steps. Hence, for any assumed shape of initial curvature, the first few steps may be calculated by elementary analytical or graphical methods, after which the remainder of the work is the mere summation of a geometric series. This method gives a graphical explanation of the otherwise very puzzling phenomenon of an initial curvature of one shape leading to a final buckling of a quite different shape. It is also very useful for studying the effects of various types of initial curvature and for obtaining simple ratios between the magnitudes of these various types which will produce the same final result. This method has not been applied to other cases than that of a simple strut, but other applications are quite possible.

The Energy Method

The other general method of analyzing the conditions for instability is the "energy" method. This begins with setting up an expression for the total energy change which takes place during a buckling deflection. (The direction or directions of this deflection will be discussed later.) This energy change is the algebraic sum of the work done by the external forces (or by the stresses produced by the external forces) during buckling, and the elastic energy stored up in the body in deflecting it (or the work done against the stresses produced by the deflection). If this total energy change is zero—that is, the work done by the external forces equals the elastic energy stored up—then the deflection can evidently take place spontaneously—that is, by buckling. Hence the equation obtained by setting the total energy equal to zero must be satisfied by the true values for the buckling deflections and loading. This equation is an integral equation for the deflections, involving the loading as a constant factor. It will be found that if we take *any* expression whatever for the deflections and substitute it into this equation, we can solve for a value of the loading which will make the equation satisfied. Obviously all such solutions cannot represent true buckling conditions, even if we limit ourselves to those which satisfy the boundary conditions. The correct solutions are those which represent states of deflection and loading under which the body can be in equilibrium. The only way that we could make it in equilibrium while bent in a wrong shape is by applying additional external forces to it. Hence we can consider wrong solutions as correct solutions for a similar structure which is subjected to additional constraints. Since additional constraints can only increase the stability and therefore the buckling loading, it is evident that the correct solution is that one which leads to the minimum value for the buckling loading.

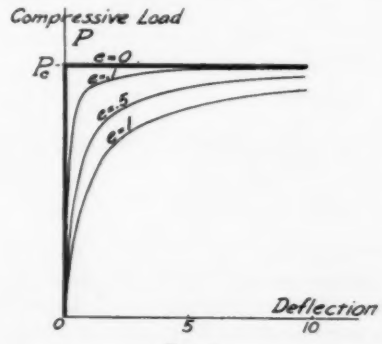

Fig. 1

The physical significance of this can best be understood by imagining that we could plot on paper a quantity describing shapes of the deflections against the value for the loading which we would obtain by substituting the deflection expressions into

[5] In setting up the differential equation, we assume that deflections are small and neglect quantities of a second order of smallness, as in other elasticity problems. If a more exact analysis is made, it is found that conditions change slightly when the deflections become very large. This is of no importance in most applications.

the energy equation. We would obtain a curve such as suggested in Fig. 2*a*. The point at which the curve is horizontal corresponds to the true shape of the deflection and the true buckling loading. Now the fact that the curve is horizontal at this point means that if we make a small error, such as *a*, in the shape of the deflection, we would only make a much smaller error *b* in the value for the loading. The practical significance of this is that if we take an expression for the deflections which satisfies the boundary conditions and is of the same general form as the true buckling deflections and substitute it into the foregoing energy equation, and solve for the value of the loading which makes the equation satisfied, we obtain in general a very good approximation to the true buckling load. Hence if we know in advance the general shape which the buckling deflections will take, we can readily obtain by this means an approximate value for the loading at which the buckling will start. Frequently this is sufficient for our purposes.

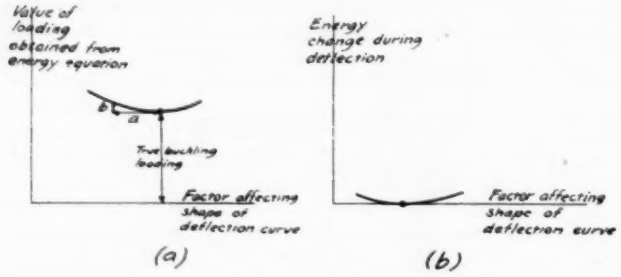

FIG. 2

More often, however, we must have some means of determining, more closely at least, what the correct shape of the deflection is. For this purpose we consider that this correct shape is produced by mixing various arbitrarily chosen shapes (each of which satisfies the boundary conditions) in the proper proportion. It is well known that if we take a sufficient number of curves, such as ordinary sine and cosine curves of various frequencies, and combine them in the proper proportion—that is, multiply each by the proper factor and superpose—we can duplicate any desired curve. Having chosen the curves to be combined, arbitrarily (but with an eye to suitability), all that remains to be determined is the values of the factors which give the proportion of each in the mixture. In our case we make use of the fact that the correct solution is the one which leads to the minimum value for the loading, and determine the factors so as to make this value a minimum. We do this in the usual mathematical manner by solving for the loading in the energy equation and equating to zero the derivatives of the resulting expression with respect to each of the factors. This gives us as many equations as factors, so that it is only a matter of algebra to solve for the factors, put them back in the expression for the loading, and solve for it, or to use an equivalent determinantal solution.

This is the way in which the energy method has commonly been used, but it has the serious disadvantage that the expression for the loading obtained from the energy equation is the quotient of two expressions, each of which contains many terms (in all but the simplest problems). This makes the work of differentiation, and the "mere matter of algebra" of solving the resulting equations simultaneously, very difficult. Now it can be shown that the derivative, with respect to each factor, of the expression for total energy change during deflection is also zero, as suggested by Fig. 2*b*. The physical meaning of this is that if we have a structure in a buckled condition (which means in a condition of equilibrium) and we change the deflection curve slightly by applying additional external forces, the work done by the external forces and the elastic work stored in the structure will both start to increase at the same rate, so that the total energy change remains zero at first. Whether this represents a minimum, a maximum, or a point of inflection for the energy change is of no importance to us. After substitution of the arbitrary expressions for the deflection, the expression for the total energy, in even the most complex problem, reduces to a summation of squares or products of the unknown factors, with constant coefficients (determined by the physical properties of the structure). The partial differentiation of this expression with respect to each factor is therefore easy, and the equations obtained by equating these derivatives to zero are simple linear equations in the factors.

COMPARISON OF DIFFERENT METHODS OF ANALYSIS

Simple problems in buckling can be studied by any of the foregoing methods, by one about as easily as by another.[6] But for very complicated problems the energy method seems to be the only one practical. In many problems, such as the buckling of curved sheets, not only lateral deflections but deflections in all three directions must be considered. To study such problems by the elastic-line method involves simultaneous solution of three differential equations. Moreover, if the structure has discontinuities, as a sheet with stiffeners, the number of differential equations to be solved simultaneously to obtain a complete solution would be still greater. If the energy method is used, on the other hand, such complications merely increase the number of terms in the expression for the energy and in general the number of factors to be solved for. No matter how complex the problem, the mathematical operations remain of the same simple character. However, in general, the work involved, particularly the work of solving the final system of linear simultaneous equations, increases enormously with the number of unknown factors. This is the only real limitation of the energy method; if some easy method of solving such simultaneous equations were available, the analysis of almost any problem would be practicable.

To keep the number of unknown factors, and therefore of simultaneous equations, as small as possible, we must choose the arbitrary deflection shapes so that as few of them as possible need be combined to get a good approximation to the true buckling shape. Buckling deflections are in general of a wave form, so that trigonometric series, sine or cosine, are usually most suitable for this purpose. As is well known, such series can express any shape whatever, and mathematical operations with them are generally simple. Often the actual buckling shape is sinusoidal, so that one term of the series gives an exact solution, and it is seldom necessary to use more than a few terms to get a satisfactory degree of accuracy—especially since, with the energy method, an approximation to the true deflection shape leads in general to a much better approximation for the buckling loading, as discussed before.

THE SIMPLE STRUT

The simplest problem in buckling is that of a simple uniform strut under longitudinal compression;[7] this case will be considered in some detail, as many important principles applying to buckling problems in general can be illustrated by it. This was the first buckling problem to be solved, the solution being given by Euler in 1744. Most engineers did not realize at that time

[6] Both the elastic line and the energy methods are exact statements of the same physical problem. Fundamentally, therefore, they must amount to the same thing, and one form could be changed into the other by the proper mathematical manipulation. The energy method is sometimes mistakenly called an "approximate" method. Actually, if carried out completely, it would lead to an exact solution; however, it lends itself conveniently to approximate solution of problems for which an exact solution is impracticable.

[7] See Wagner, N.A.C.A. Tech. Mem. No. 500.

that Euler's formula gave only the load at which buckling would start, if nothing else happened first. Structural materials at that time were chiefly wood and masonry, and the columns made from these were usually so thick in proportion to the length that failure of the material occurred before buckling. Naturally Euler's formula did not give the correct value for the failing load, and so it fell into disrepute among engineers. In more recent years materials of higher strength have come into use, cross-sections have been reduced accordingly, and buckling failure often occurs before material failure, so that Euler's formula is frequently applicable.

Suppose that a hinged end strut has an initial curvature in the form of a half sine wave, given by the expression $y = d_i \sin \frac{\pi x}{L}$, as shown in the first sketch of Fig. 3(a). Due to the compressive load P, there are bending moments along the strut with the magnitude $Pd_i \sin \frac{\pi x}{L}$, and it can be shown by the usual elementary means that these bending moments cause an additional curvature given by $y = \left(\frac{PL^2}{\pi^2 EI}\right) d_i \sin \frac{\pi x}{L}$, shown by the second sketch in Fig. 3(a). This additional curvature causes the additional bending moments $P\left(\frac{PL^2}{\pi^2 EI}\right) d_i \sin \frac{\pi x}{L}$, which produce the additional deflections $y = \left(\frac{PL^2}{\pi^2 EI}\right)^2 d_i \sin \frac{\pi x}{L}$, shown by the third sketch. Continuing this indefinitely, we see that the total

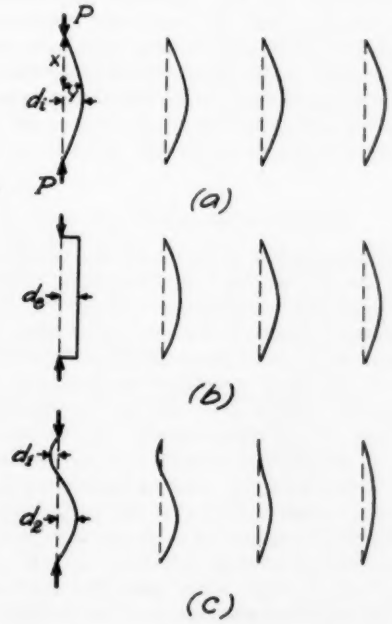

Fig. 3

movement of the center of the bar under the load P is given by the ordinary geometric series

$$d = \left(\frac{PL^2}{\pi^2 EI}\right) d_i + \left(\frac{PL^2}{\pi^2 EI}\right)^2 d_i + \left(\frac{PL^2}{\pi^2 EI}\right)^3 d_i \ldots\ldots$$

$$= \frac{d_i}{\frac{\pi^2 EI}{PL^2} - 1} \ldots\ldots [2]$$

If the load P is zero, this gives the initial deflection; the deflection becomes greater as P is increased, and finally becomes infinite when

$$P = P_e = \frac{\pi^2 EI}{L^2}$$

which is therefore the value of the critical buckling load P_e.

Substituting this in [2], we obtain Equation [1], e being equal to d_i in this case. In plotting this equation in Fig. 1, elastic conditions were assumed. Actually, even if the stress is well below the yield point when buckling begins, the combination of direct and bending stress, as the strut deflects, will eventually reach the yield point. The material on the concave side of the deflected strut will then yield and the stiffness of the strut will fall off rapidly, as indicated in Fig. 4(a). The load which an initially curved strut will take before complete failure, P'_e, will therefore be slightly less than the critical load, P_e, for straight

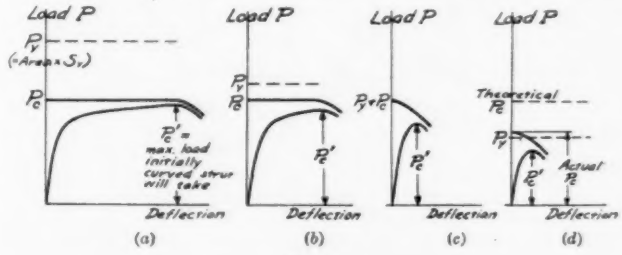

Fig. 4

struts. If the strut is nearly at the yield point when buckling begins, then obviously yielding on the concave side will come at a much smaller deflection, as indicated in Fig. 4(b), and the failing load for the initially curved strut will be still less. Fig. 4(c) and (d) show the conditions when the load at which the material yields is equal to and smaller than the critical load. It is assumed that the material has a sharp yield point; if the yield point is not sharp, analysis is much more difficult, but the general character of the results will be similar.

In the case just considered the initial curvature was the same as the final buckling curvature. If we start with a hinged end strut having the load eccentrically applied at the two ends, as shown in the first sketch of Fig. 3(b), then, due to this eccentricity, the load will cause uniform bending moments along the strut; these will produce a uniform curvature, as shown by the second sketch. This curvature to the arc of a circle is already not far from a sinusoidal curvature, and if we calculate the next increment of curvature, we obtain a shape practically indistinguishable from a sine curve, so that this and all the following increments can be considered to be sinusoidal. Similar results are obtained if we start with other shapes of initial curvature such as shown in Fig. 3(c), the increments of deflection becoming practically sinusoidal in a very few steps. To be sure, if the initial curvature is such that the tendency to buckle one way is exactly as great as the tendency to buckle the other way—for example, if we had symmetry about the center in Fig. 3(c)—then theoretically this symmetry will be maintained in all later steps. However if, by error, we give the slightest preponderance to one side in drawing one of the steps, we will find that this preponderance is greatly magnified in the next step, and very quickly the increments of deflection are all on that side. This is exactly the way it would happen in practice if we should have a state of instability in which there is so fine a state of balance that buckling does not at first occur. The slightest outside disturbance tending in the direction of a true buckling deflection is immediately magnified, and soon this deflection is complete.

For any given initial curvature we can calculate the successive

increments of deflection by elementary methods, until these increments become of constant shape. Comparing these with results obtained with sinusoidal initial curvature, we can easily find an equivalent sinusoidal initial curvature which gives the same results as the given initial curvature, at least for all but the first few steps. Using this in [2], we obtain a formula for the total deflection under any load; this will not be very accurate for small loads, as for such loads the first few increments of deflection are a large part of the total, but it will be a very good approximation for loads near the critical. The case of a strut with initial eccentricity of loading d_e, Fig. 3(*b*), is found to be equivalent to that of a strut with sinusoidal initial curvature such that $d_i = 1.25\ d_e$; and for the case shown in Fig. 3(*c*), where the initial curvature consists of two geometrically similar sine curves, it is found that $d_i = d_2 - d_1$.

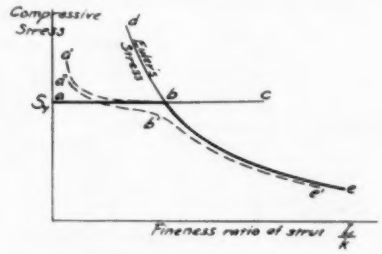

FIG. 5

By analogy or by repeating these methods we find that the critical compressive loads for struts with any end conditions are given by the general formula

$$P_c = \frac{n\pi^2 EI}{L^2}$$

or, dividing through by the area, the critical compressive stress is

$$S_c = n\pi^2 E \left(\frac{k}{L}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

where k is the smallest radius of gyration of the cross-section. The constant n depends on the end conditions, and has the values 1, 4, and $^1/_4$ for struts with both ends hinged, both ends fixed, and one end fixed and the other free, respectively. In practice, struts are usually fastened at both ends, with some frictional or elastic resistance to rotation. For such cases the value of n must evidently lie somewhere between the limits 1 and 4. It can be determined analytically if the end conditions are known, but is usually found experimentally.

Fig. 5 shows the compressive stress which produces failure, for a simple strut with given end conditions, plotted against the "fineness ratio" of the strut, L/k (the length divided by the smallest radius of gyration of the cross-section). The horizontal line *abc* shows the stress at which yielding of material would occur if nothing else happened first. The curve *dbe*, plotted from Euler's formula [3], shows the stress at which buckling would occur if nothing else happened first. Obviously, the heavy bent line *abe* gives the stress at which some kind of failure will first occur. As we increase the fineness of the strut, at first it will fail by yielding of the material (the line *ab*), then from a certain point on it will fail by buckling (the line *be*). If the material does not have a sharp yield point, but shows a rounding of the corner between the elastic and yield lines in its stress-strain curve, then there will be a corresponding rounding of the corner between the lines *ab* and *be*.

The line *a'be* shows the stresses at which complete or ultimate failure occurs, as determined by experiments and analysis.[8] It will be seen that it differs appreciably from the line *abe* only at very low values of the fineness ratio—that is, for extremely short, stocky columns. As we are not likely to find fineness ratios of this order in aeronautical structures, the simple law given by the line *abe* is sufficient for the aeronautical engineer. The physical meaning of this is that if a compressed strut fails first by yielding of the material, then complete failure (by buckling) will certainly occur at very slight increase of load. This principle applies also to other types of structures under compression, as discussed previously.

Column Formulas

Many attempts have been made to construct empirical formulas which would formulate experimental results on struts of various fineness ratios. From the foregoing discussion it is apparent that such a formula should represent the curve *abe* or *a'be*. As most of the formulas were made on the basis of incomplete experiments and without recognition of the exact problem involved, they are in general not very successful in this. Of course, actual struts always have a certain amount of initial curvature or eccentricity, and their behavior is as indicated by the line *a''b'e'*, all failing stresses being below those for corresponding straight struts by an amount depending on the ratio of the initial eccentricity to k.[9] Since this amount of initial curvature is likely to be small in well-made structures, and is in any case entirely undeterminable in advance, the most practical principle seems to be to let the factor of safety take care of this uncertainty (allowance for undeterminable and therefore unanalyzable factors being the legitimate use for a factor of safety) and to base design on the simple law represented by *abe*, which gives the limiting failure load for good construction. There would be no particular advantage in having a single formula to express this law. All the designer need do is to take the Euler stress or the yield point stress—whichever happens to be the smaller—as the failing stress.

Effect of Shear Deflection

Euler's formula was derived by considering the bending deflection of the strut due to the compressive load. The load also produces transverse shear in the strut, and, strictly, the deflection due to this should be added to the bending deflection in calculating the critical load. As in beam problems, if the struts are of rectangular or ordinary structural cross-sections, the shear stresses are small compared to the bending stresses, and the shear deflections are negligible compared to the bending deflections. But in aeronautical construction, to save weight, the parts of the strut taking the shear are commonly lightened up until they are stressed as highly as the parts taking bending stresses. The deflections due to shear will then be of the same order of magnitude as bending deflections, and the critical load for the strut will be much lower than that given by Euler's formula. This important question has been analyzed by Timoshenko and others for the case of a latticed column.[10]

Strut With Elastic Support

Practically all the more complex cases of buckling can be considered to be related to the case of a simple strut elastically supported along its length. This case is therefore worth brief consideration, although it is seldom found in simple form in practice. It was analyzed by Engesser and others for the case of uniformly

[8] See Engesser, V.D.I., 1898, p. 927; von Kármán, *Forschungsarbeiten*, 1910, no. 81.

[9] See Ros u. Brunner, Proc. Int. Cong. App. Mechanics, 1926; Westergaard and Osgood, Trans. A.S.M.E., 1928.

[10] See Timoshenko, "Strength of Materials," part II, p. 592.

distributed support, and by Zimmermann for the case of concentrated supports.[11] It is found that in general such a strut will buckle in a number of waves or half-waves. The resistance of such a strut to buckling is due partly to the stiffness of the strut and partly to the stiffness of the elastic support. Obviously the stiffness of the strut tends to keep the number of waves as small as possible, while the stiffness of the elastic support gives less resistance to buckling if the number of waves is large. The actual shape of buckling must be a compromise between these two tendencies, and the number of waves increases with the ratio between stiffness of the support and stiffness of the strut. As the number of half-waves is never fractional, the relation between the critical stress and the physical conditions is discontinuous as the number of half-waves changes from one number to the next. Fig. 6 shows the theoretical buckling stresses for struts of various lengths, the other physical properties and the elastic support per unit length remaining constant. Curve 1 shows the stress required to produce buckling in the form of one half-wave, curve 2 the stress required to produce buckling in the form of two half-waves, and so on. Obviously, the strut will fail first at the stresses given by the irregular heavy line. It will be noticed that as soon as the number of half-waves exceeds two, the buckling stress is practically independent of the length. This means that when the number of half-waves exceeds two, the buckling stress is also practically independent of the end conditions—that is, it makes no difference whether the ends are hinged or fixed—as a change in the end conditions can be considered as equivalent to a change in the effective length.

The photographs (see Fig. 9) show a model constructed to demonstrate the buckling of a strut with various degrees of elastic support. A vertical wire, representing the strut, is elastically supported by being attached to the ends of a number

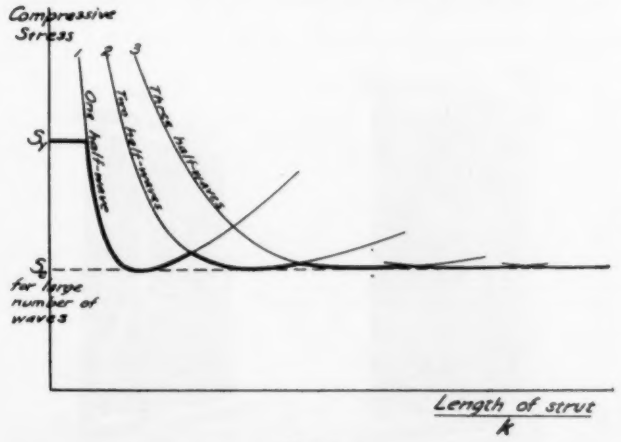

FIG. 6

of cantilever horizontal wires, as shown. By turning the knob at the top, the clamping point of the horizontal cantilevers can be moved, thereby changing their effective length and therefore their stiffness. If the strut is buckled, and the knob is then turned, the shape of the strut changes from one half-wave (as at A), to two, three, and four half-waves (as at B), and so on, the changes taking place quite suddenly.

FLAT PANELS

The stability of flat sheets of rectangular outline was analyzed by Bryan for the case of a plate hinged on all four sides and compressed on two sides, and by Timoshenko for other cases.[12] Plates compressed on two ends can be considered roughly as a series of struts side by side, with their lengths, L, in the direction of the compression. These struts are elastically supported by virtue of the fastening of the sheet along the sides, which causes buckling to be resisted by the stiffness of the sheet against lateral bending (with additional effect from resistance to twisting). The stiffness of this elastic support obviously varies inversely with the width perpendicular to the compression, w. A general formula for the uniformly distributed stress on the ends which will cause the plate to buckle is:

$$S_c = KE\left(\frac{t}{w}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

where t is the thickness of the sheet, and K depends on the ratio of length to width, L/w. Fig. 7 shows values of K for various

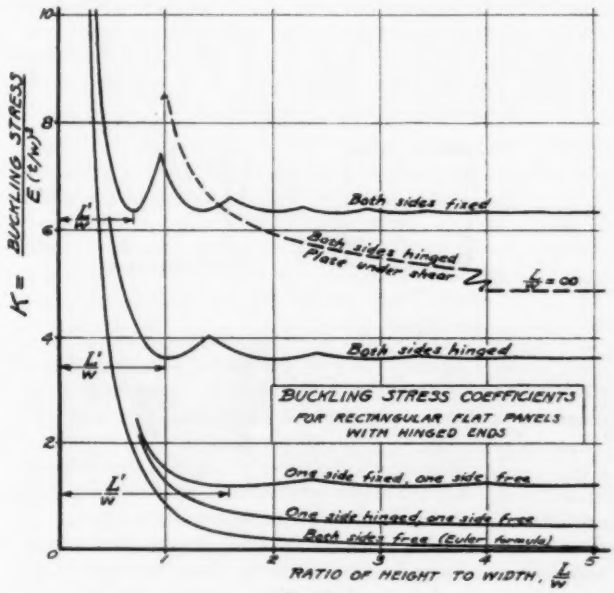

FIG. 7

edge conditions. It will be seen that in all cases, when L/w exceeds 2, K becomes practically constant, and has the following values for the cases given: ends hinged, sides hinged, 6.3; ends hinged, sides fixed, 3.6; ends hinged, one side fixed, one side free, 1.2; ends hinged, one side hinged, one side free, 0.4. (Poisson's ratio is taken as 0.3.) For the other extreme, when L/w is very small, the elastic support is also very small and the critical stress approaches that given by Euler's formula, with $k^2 = t^2/12\,(1 - \mu^2) = t^2/10.9$:

$$S_c = \frac{n\pi^2}{10.9} E\left(\frac{t}{L}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

The plate buckles in a half-wave or a quarter-wave in the w direction. In the direction of L it in general divides up into a number of half-waves. The lengths of these half-waves, L', will be approximately as given in Fig. 7, if the number of waves is large. It is evident that cross-stiffeners, running in the direction of w, would have to be spaced considerably closer than L' to do much good. If the spacing of such stiffeners is equal to or a multiple of L', they will be completely wasted, as the nodes of the buckling will be at the stiffeners. Longitudinal stiffeners will be much more effective; and if longitudinal stiffeners are

[11] See Timoshenko, Handbuch der Phys. u. Tech. Mechanik, vol. IV, pp. 106, 108; Klemperer, Trans. A.S.M.E., 1933.

[12] See Timoshenko, "Strength of Materials," part II, p. 604; Sezawa, Report of Aer. Res. Inst., Tokio Univ., no. 69; Mathar, N.A.C.A. Tech. Mem. No. 592.

used, the cross-stiffeners will be much more effective, through supplying additional elastic support to the longitudinals.

The critical stress for a flat rectangular plate acted on by uniformly distributed shear stresses on all four sides, and hinged on all edges, is also given by [4] and Fig. 7, S_c being taken as the shear stress. In this case buckling is caused by the compressive stress at 45 deg to the sides; the tensile stress at right angles to this helps to prevent buckling. The plate buckles in one half-wave in the direction of the shortest side, and usually in many waves in the direction of the longest side, the nodes being inclined.[13]

The foregoing are all theoretical results. Experiments indicate that they are accurate for very flat sheets; however, sheets thin enough to buckle before yielding are likely to have initial eccentricities of the same order of magnitude as the thickness, so that this factor usually plays a much more important part than it does in the case of struts. No actual figures can be given for the influence of eccentricity, as little work has been done on the subject; and in any case, as in all other types of buckling problems, the amount of eccentricity to be expected depends entirely on the carefulness of the construction.

FIG. 8

As in the case of struts, the edge conditions are in practice likely to be somewhere between the hinged and clamped conditions. However, there are many cases where pure hinging can be assumed, in spite of the lack of mechanical provision for it. Thus the four sides of a square box strut or the two sides of a compressed angle section will obviously buckle as shown in Fig. 8, in such a way that the angles between sides at the corners remain unchanged, and there will be no moments at the edges. However, if the adjoining sides are unequal, or any other condition makes them tend to buckle differently, then there will be interference between them, and the edge conditions will be between the hinged and the fixed.[14]

The general buckling of a sheet having different stiffnesses in the two directions, as a corrugated sheet or a sheet with many stiffeners, has been investigated by Reissner.[15] In such sheets the stiffness of the elemental struts into which we may consider the sheet to be divided are much greater than for a corresponding plain sheet, while the elastic support, due to transverse stiffness, is less. Hence the simple Euler's formula applies up to much greater values of L/w than for plain sheets.

CYLINDERS

The buckling of a cylinder under uniform axial compression can be considered equivalent to that of a group of struts running in the axial direction, under an elastic support due to the curvature. When a curved sheet buckles away from or toward the center of curvature, it must stretch or compress circumferentially. This produces circumferential stresses which resist the buckling like an elastic support. This problem was analyzed by Southwell and Timoshenko[16] by assuming that the buckling would be symmetrical about the center, with waves of definite length in the axial direction. This gives the critical stress as:

$$S_c = 0.6\, E\, \frac{t}{R} \qquad [6]$$

where R is the radius and Poisson's ratio is taken as 0.3. Experiments indicate that thin cylinders actually buckle in a definite number of waves about the circumference, at a stress much less than that given by [6]. The length of the waves in the circumferential direction is usually a small part of the circumference, which seems to indicate that where the stress varies along the circumference, as in cases of pure bending of a cylinder or combinations of axial compression and bending, buckling can start locally when the maximum compressive stress reaches about the value previously given for uniform compression. Numerous attempts have been made to obtain a theoretical explanation for the observed behavior of cylinders in compression and bending, but there seems to be still much to be explained.

Buckling of a cylinder under torsion is discussed by the author in a paper which will soon be published as a report of the N.A.C.A. A theoretical solution is given which is in reasonable agreement with experiments. Cylinders under torsion buckle in spiral waves. In the circumferential direction there are a number of waves, the number varying from a large number for very short cylinders to two for long cylinders. In the latter case the cross-section distorts to an ellipse.

The stiffness of flat panels is greatly improved by using corrugated sheet instead of flat sheet. Both theory and experiments indicate, however, that there is no such advantage in using corrugated sheet in making cylinders or curved panels. This is because the resistance to circumferential expansion or contraction is much lower with corrugated than with plain sheet construction.

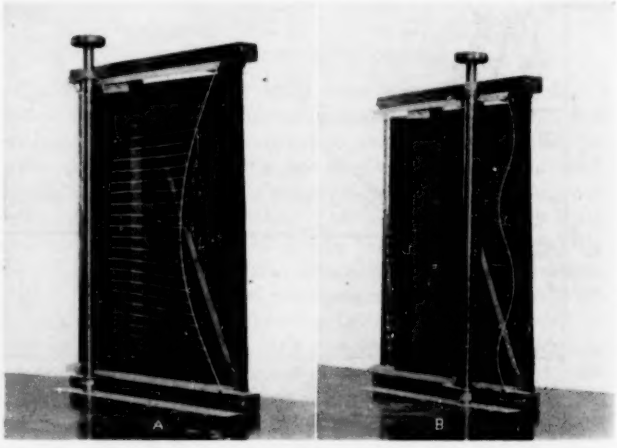

FIG. 9

The beneficial effect of curvature depends entirely on this circumferential resistance. With corrugated construction the decreased benefit from curvature just about balances the benefits from the increase in longitudinal stiffness. A construction composed of plain sheet with closely spaced stiffeners, on the other hand, has about the same resistance to circumferential contraction and expansion as plain sheet, and therefore gives the full benefit of the increase in longitudinal stiffness.

A practical advantage of corrugated construction, however,

especially when the curvature is not great, is that eccentricity is not nearly so much of a problem. Eccentricities of the order of the thickness of the sheet greatly affect the resistance of plain sheet, but have little effect with corrugated sheet, as they are small compared to the effective thickness. This applies also to flat panels. Eccentricities in general are of considerable importance in connection with the buckling of curved sheet, but probably not as much so as in the case of flat sheet, as the curving of the sheet tends to remove eccentricities.

Curved Panels

Curved panels, supported or fixed along the sides and compressed in the direction of straight elements, can be considered equivalent to a system of struts side by side, with an elastic support due partly to the curvature (that is, to resistance to circumferential tension and compression as in the case of complete cylinders), and partly to the support of the sheet along the sides (that is, to resistance to lateral bending and twisting). The effect of the side support is usually small compared to the effect of curvature, unless the angle subtended by the panel is small. Hence for most purposes the critical stress can be considered to be the same as for a complete cylinder; in any case this assumption will be on the safe side.

Other Stability Problems

Many other types of stability problems have been investigated, such as the lateral stability of beams and the stability of tubes and rings under external pressure,[17] but these are seldom of interest to the aeronautical engineer. The greatest need at present seems to be for more information on the subject of cylinders of round or other cross-section, particularly of stiffened construction.

Stiffened Construction

The obvious purpose of longitudinals and bulkheads, as far as resistance to buckling is concerned, is to increase the average stiffness of the shell in the longitudinal and circumferential directions. This stiffness could also be obtained by using thicker sheet, and this has the advantage that longitudinal and circumferential stiffness is supplied simultaneously by a single element, the sheet; whereas a system of stiffeners must be a double system, each part of which is useful for one direction only. However, the greater depth possible with stiffeners more than makes up for the disadvantage of this necessary duplication, and experience indicates that the necessary stiffness can usually be obtained with less weight with stiffeners than with sheet; where extreme lightness is necessary, the stressed sheet must be eliminated entirely, as in dirigible construction. An analytical study of this whole question would be of great value. Another great practical advantage of the use of stiffeners lies in the reduction of the importance of eccentricity, due to the greater effective depth of stiffened construction, as discussed before in connection with corrugated sheet.

Possible Methods of Analysis of Monocoque Construction

The resistance to general buckling of a stiffened shell can obviously be studied approximately by considering it to be equivalent to a homogeneous shell having the average stiffness in each direction produced by sheet and stiffeners together. One question which arises in applying this method of analysis is that of the influence of the sheet on the effective moment of inertia of the stiffener. This question must be answered by use of the methods described in the third part of this paper. If it is desired to similarly study the ultimate resistance of the shell after the sheet has buckled, then the influence of the sheet must be studied by the methods in the second part of this paper (AER-55-19b). Experimental work on the resistance of shells is being carried out in many places. At the California Institute both experimental and theoretical work is in progress. Two machines have been constructed, for small and for large specimens, capable of testing cylinders, or actual wing or fuselage sections, in uniform or varying bending, in torsion or compression, or in any combination of these loadings.

AER-55-19b

II—Strength of Thin Metal Structures Beyond the Stability Limit

By E. E. SECHLER,[1] PASADENA, CALIF.

When thin sheet metal was first used for aircraft, the design was in accordance with the usual laws of elasticity, and when buckling occurred in any part it was considered as failure. Frequently it was observed, however, that the buckling disappeared after the load was removed, without permanent deformation. This led to the study of thin sheet metal when used above the stability limit. The paper considers two methods of designing structures for thin sheet metal—one is to endeavor to make the buckling load correspond to a stress equal to the elastic limit of the material, and the other is to allow the structure to go into the buckled state at a stress below the elastic limit and then to determine the allowable load on the structure before permanent deformation would take place. It may be possible that a photoelastic study of buckled sheets would lead the way to a solution.

WHEN thin sheet metal was first used as an aircraft material, the structures to be made of this material were designed in accordance with the usual laws of elasticity, and the structure was considered as having failed when the buckling load had been reached in any part of the structure. It was noticed, however, that frequently after the buckling load had been reached, and even exceeded, on such a structure, the removal of the load caused the buckles to disappear, and no permanent deformation remained in the material. Further investigations showed that the load could be increased in some cases quite far beyond the stability limit before the material suffered any permanent deformation upon the removal of the load. This led to the study of thin sheet metal when used above the stability limit.

The foregoing discussion can be applied to any structure that has less resistance to one type of stress than to another. Take, for example, a fuselage or wing section made up of a number of light tubes or other strut members some of which are subjected to tension stresses and others to compressive stresses. If the tubes are of the same size, which may be necessary for design or construction reasons, those loaded in compression may fail by elastic buckling as columns before any failure occurs in the tension members. These buckled members will then cease to carry their proportion of any additional load, and this additional load must be taken up by either the tension members or by other compression members which are not stressed up to their critical value.

The aforementioned action, i.e., the elastic buckling of a part of the structure and the consequent redistribution of the load, may take place several times before any part of the structure is stressed beyond the elastic limit. If the structure is made up of a finite number of members, it is possible, although it may be laborious, to calculate with reasonable accuracy the loads at which the first buckling occurs and to determine the member undergoing this buckling. This is done by the usual methods of structural design, taking into consideration the critical column values of the members under compressive loads. The buckled member can then be replaced by a constant force, since a buckled strut offers very little additional resistance to further deflections, and the structure be recalculated for additional loading with the new distribution of stresses. This is continued until one of the members is stressed beyond the elastic limit or the structure becomes unstable due to members dropping out of action. This type of structural design follows the ordinary methods of determinant and indeterminant structures and will not be discussed further in this article. The limiting case of the foregoing problem is that of the thin sheet which has comparatively no resistance to bending and compressive stresses in relation to its resistance to tensile stresses, and it is this case which will be considered in more detail.

There are two possible methods of designing structures employing thin sheet material. The first is to endeavor to make the buckling load correspond to a stress equal to the elastic limit of the material. For this method of design the normal laws of buckling of thin sheets would be used, and buckling would be a true failure, since the deformations would not disappear upon removal of the load. The other method is to allow the structure to go into the buckled state at a stress below the elastic limit of the material and then to determine the allowable load on the structure before permanent deformation would take place.

An inspection of the first method shows that it may lead to sheet sizes and stiffener spacings which are not at all desirable from the standpoint of economical construction. For example, consider a sheet of 0.020-in. Dural, 9 in. long and 3 in. wide, supported on four sides and loaded with a uniform shear. The buckling stress is given by[2]

$$p_e = k \frac{\pi^2 E t^2}{12(1-\mu^2)b^2}$$

and for $a/b = 3$, $k = 6.1$, and for $E = 10^7$, $t = 0.020$, $b = 3$, and $\mu = 0.3$, $p_e = 2450$ lb per sq in., which is obviously much below the elastic limit of the material, and if the aircraft were to be designed using this method, the structure would be very heavy because the material would not be used to the best advantage.

On the other hand, if a reasonable value for the allowable stress in shear is taken, say, $p_s = 15{,}000$ lb per sq in., the value of b must be reduced to 1.2 in. to prevent buckling before this stress is reached. This gives a panel of 9 in. by 1.2 in., which means numerous stiffeners and expensive manufacture. However, if the original panel is allowed to buckle at the critical value, it can be loaded in the buckled state until the elastic limit of the material is reached in some point. This allows an economical construction and still permits an efficient utilization of the strength of the material.

The simplest illustration of the buckling of a thin sheet under load and the subsequent redistribution of the load to stresses of

another type is given in the case of a plain supported sheet under a shearing load (see Fig. 1). Considering an element in the sheet, we find that the shearing stress is resisted by two mutually perpendicular stresses, one tensile and one compressive, at an angle of 45 deg to the original shear. Since, for very thin sheets, the resistance to compressive stresses is practically zero, the sheet will buckle into waves running perpendicular to the compressive stress as soon as a very small shear load is applied. Additional load cannot then be carried in compression, but is all carried by the corrugated sheet in the form of tensile stresses parallel to the buckles (see Fig. 2). The magnitude of these tensile stresses is equal to twice the value of the shearing stress on the sheet,

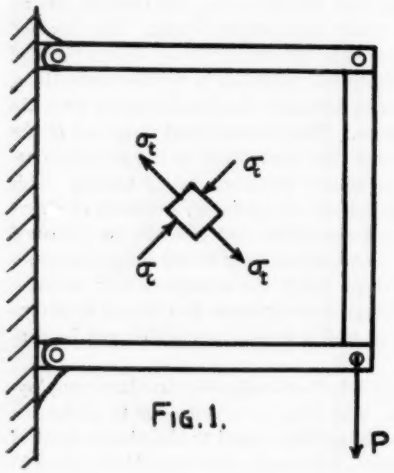

FIG. 1.

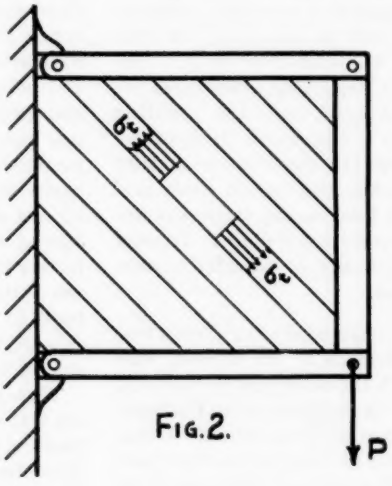

FIG. 2.

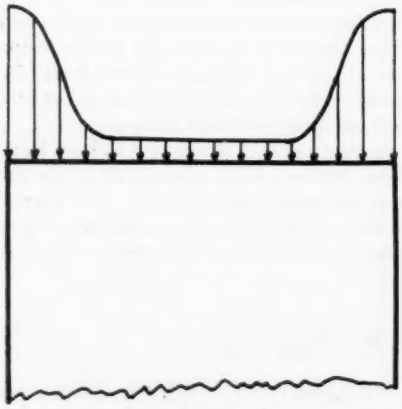

FIG. 3.

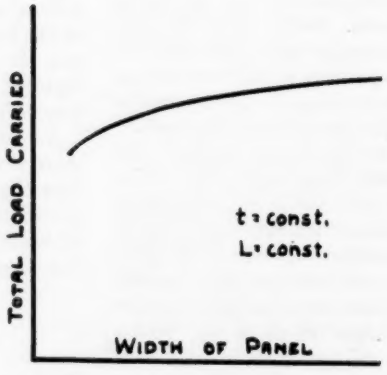

FIG. 4.

$S_t = 2S_s$, and, for a sheet supported by infinitely rigid members, the direction of the tensile stress is at 45 deg to the original shear.

The foregoing problem has been treated in great detail by Herbert Wagner, of Danzig, Germany, and his work is available to the designer in a number of translations in English.[3] In his work he first considers the case of a deep beam with a thin sheet web subjected to a shearing load, taking into account the stresses introduced in the uprights and the flanges by the diagonal tension field set up in the web. At very low values of the shearing stress the sheet goes into the buckled state, forming a tension field of stress in the web. The whole shear load is then transmitted as tension diagonally across the web of the beam. The first calculation is made assuming that this tension acts at 45 deg to the original shear load. These tensile stresses tend to produce bending in the beam flanges and to load the uprights between the flanges in compression. The deflection of these two members alters the distribution of stress in the tension field and the beam is then recalculated w th the altered distribution. This method can then be carried to any degree of accuracy desired. However, Wagner shows that by making certain approximations at the beginning of the analysis, the accuracy is usually sufficient after the first calculation.

The foregoing treatment is then expanded to the consideration of a beam with uprights which are not vertical, and it is found that for any beam there is an optimum angle at which the uprights should be placed to give the maximum strength-weight ratio. He also considers the effect of the compression loads on the uprights, taking into consideration their critical value as columns and the effect of the deflection of these uprights on the stress distribution as a whole. The case of a beam with taper is discussed, and the effect of this taper on the stress distribution in the web, uprights, and flanges. The whole discussion is very complete and is illustrated by examples which show the practical applications of the method. None of the formulas or results will be given here, as it would be impossible to give formulas without going into the assumptions and conditions under which they apply.

A few preliminary tests have been made on thin sheet subjected to shearing stresses, and the results of these tests were given in an article by Joseph S. Newell late in 1930.[4] The tests were made on both plane and stiffened sheet, and a comparison was made of the strength-weight ratios of the panel. It was found in these experiments that for the shear panel used, 24 in. by 36 in., the stiffened sheet gave a slightly higher strength-weight ratio for sheets of from 0.040 to 0.050 in. in thickness, but for other thicknesses the strength-weight ratio of the unstiffened sheet was better. This seemed true regardless of the number of stiffeners used. These experimental tests are being continued on thin sheet in shear, and more data may be available to the designer in the near future.

The investigation of curved panels under shear loads has not yet reached the stage where any reliable results are available to the designer. A few tests are mentioned by Wagner in Tech. Mem. No. 490, and in his article on flat sheets in shear he states that he will treat curved sheets in a later report.

The next problem to be considered is that of thin sheet used in compression. Obviously, if a thin sheet is unsupported and

[4] Joseph S. Newell, *Airway Age*, November and December, 1930.

loaded with a compression in its plane, the failure by buckling will come almost immediately. However, if the edges of the sheet are supported in some manner, then a different action takes place. The edges being restrained against motion in one or more directions has a tendency to delay the buckling phenomena and the sheet will support a load in compression. The value of this load can be determined by the well-known methods of Bryan and Timoshenko. This classical method assumes a uniform stress distribution up to the time the sheet buckles, and the solution is carried out using the boundary conditions corresponding to the edge restraint.

The values given by the foregoing method show that, except for extreme values of breadth to length of the sheet, the buckling takes place at a stress which is far below the elastic limit of the material. The question then arises if the sheet could not be used to sustain a load beyond the critical buckling load. This problem is being investigated at the present time by several different groups. Experimental work has been done at the National Advisory Committee, Stanford University, Massachusetts Institute of Technology, and the California Institute of Technology. Some of this work has been published, and more investigations by these groups are now under way. The N.A.C.A. has published its work in a late Technical Report,[5] and J. S. Newell has combined some of this work with that done at Stanford and M.I.T. in the two articles of *Airway Age*.[4] A preliminary semi-theoretical treatment of plane sheets loaded in compression suggested by Th. von Kármán at C.I.T. appeared recently,[6] and experimental work is now being carried out as a check on the theoretical values.

The important result of all of these experiments is that the strength of a supported sheet (in all of the foregoing cases simple support was used) is only slightly affected by variations in length and breadth of the sheet. For very narrow sheets the strength increases as the width increases, and the failure is due to the fact that the elastic limit of the material is reached before buckling takes place. For wider sheets, however, the sheet tends to buckle, and when this buckling takes place, a redistribution of the load occurs. The edges of the sheet being supported continue to carry additional load, but that part of the sheet at some distance from the supported edges buckles and carries little or no more additional load in its buckled state. The stress distribution would then be something like that indicated in Fig. 3.

In the work of the N.A.C.A. the experimental values of the allowable load on a series of sheets of different widths, thicknesses, and materials were taken and an empirical equation was given for the allowable load on any sheet. This equation was of the form

$$P = K_1 t^2 - K_2 t^3$$

where K_1 and K_2 are constants depending only upon the material used and not upon any dimension of the specimen. Deviations from this value were not great for sheets larger than 6 in. wide (all specimens considered were 24 in. long), while below this width the strength fell off rather rapidly. The experimental values obtained for the wider sheets were lower than would be normally expected, and this was explained by the fact that a comparatively light loading bar was used which had a tendency to deflect for the wider specimens.

The work at C.I.T. on plane unstiffened sheets was based primarily on an assumed stress distribution after buckling. The assumption was made that an "effective width" of the sheet near the stiffener was carrying the full load and that over this effective width the stress distribution was uniform. There were then two possible methods of considering this effective width. One was to consider it as a strip, supported on three sides, with the fourth side free, and the other was to consider that the tangent at the inside edge of this strip was horizontal, in which case the two strips could be considered together, disregarding all of the material in the center. It is obvious from an inspection of the buckling of such a panel that the correct answer must lie between these two methods. Both methods give, for the equation of allowable load, an equation of the form

$$P = C \sqrt{E\sigma_y}\, t^2$$

where E is the Young's modulus, σ_y the elastic limit, and t the thickness of the sheet; C is a function containing Poisson's ratio of the material, and the form of this function depends upon which of the aforementioned assumptions is used. This function is dimensionless, which leaves the equation dimensionally correct. It is believed that an experimental value of this constant C can be determined to be used as a design value.

The experimental work at C.I.T. has given results which are in the main similar to those obtained in other places. Great care was taken, however, to make the loading bar used in these tests rigid, and as a result the dropping off of the allowable load at the larger widths of sheet was not experienced. The curve of maximum load plotted against width of sheet seemed to indicate an asymptotic approach to a maximum, as would be expected from a stress distribution similar to Fig. 3. This curve is of the type shown in Fig. 4. It is hoped that a simple correction can be obtained from these curves to take account of the variation of P_{max} with the width of the sheet.

For plane panels with stiffeners, Newell suggests that the strength of the stiffeners tested as columns be added to the strength of the sheet, as given by the empirical formula:

$$P = K_1 t^2 - K_2 t^3$$

The comparison between this value and that found experimentally is given in the articles mentioned.

A slightly different line of attack is being followed at C.I.T., where the effective width of sheet is considered as acting in conjunction with the stiffener section to resist the compressive load. No experimental tests have as yet been made on stiffened sheet at C.I.T.

Mr. Newell's article also considers the case of curved sheet with and without stiffeners, and he gives a series of curves showing the relationship of curvature and number of stiffeners to the maximum allowable compression load. For stiffened, curved panels, the results seem to indicate that more research is necessary before anything of value can be given to the designer. Dr. Donnell, one of the present authors, is making a study of this problem for cylindrical sections, and tests will also be made on individual panels.

One problem which has not as yet been considered is that of thin sheet panels loaded in combined shear and compression. The experimental apparatus for this problem would be rather complicated, and it is also probable that with a complete solution of the two problems of pure shear and pure compression, these solutions could be combined in such a manner as to offer a solution to the problem of combined stress.

As the problem of thin sheet in the buckled state is essentially a problem of the stress distribution after buckling, it may be possible that a photoelastic study of buckled sheets would lead the way to a complete solution. Some photoelastic work has been done in the case of shear-stressed plates, and it may be possible to apply this method of study to the problem of the thin plate under compressive stresses. Some preliminary investigations of this method will probably be made soon at C.I.T.

III—Analysis of Some Typical Thin-Walled Structures

By TH. VON KÁRMÁN,[1] PASADENA, CALIF.

The structural skeleton of an airplane of the orthodox type can be considered as a truss, and the structural analysis uses, in general, the familiar methods. Also the structural analysis of the spar-rib type of wing system can be done by the theory of elastically supported continuous beams. The structural analysis of thin-walled structures is a much more complicated problem. There are different methods of attack. A survey of typical cases shows that there is a possibility of producing usable information. Experiments are being carried out on the stability and ultimate failure of cylinders in compression, bending, and torsion.

THE structural skeleton of an airplane of the orthodox type can be considered as a truss, and the structural analysis uses, in general, methods familiar in structural engineering. Also the structural analysis of a spar-rib type of wing system can be done by application of the theory of elastically supported continuous beams. The structural analysis of thin-walled structures is a much more complex problem, because the elastic behavior of the sheet as a structural element is more complicated than the behavior of the members of a truss. There are different ways to attack the problem:

(*a*) We can consider the elastic behavior of a flat or curved sheet under a given load system and consider the heavier elements as supports. This kind of analysis may be successful in the case that the stiffness of the supports is very large compared to the stiffness of the sheet, and so the elastic deformation of the supports, i.e., of the bulkheads or stiffeners, can be neglected in the calculation of the stress distribution or stability of the sheet. In these cases the stress analysis of the sheet gives valuable information on the local strength of the sheet itself and helps us to prevent local failure, but apparently we do not get information as to the resultant strength of the whole system.

(*b*) There is an academic possibility to consider the structure as an elastic system, composed by beams and plates, and to calculate stress distribution and stability, applying the equations of plates or shells to the sheets and the differential or partial differential equations of beams to the stiffness. Unfortunately, this kind of computation affords a very elaborate arsenal of mathematical methods and is handicapped by many uncertainties in the assumptions which have to be made as to the connections between the elements. Hence, except for some simple fundamental cases, this possibility will be of little value for the designing engineer.

(*c*) The third and most promising procedure is to consider some typical combinations of sheets and stiffness as "beams with compound sections" and to establish simplified methods of computation for these combinations—using some fundamental results of the elastic theory of plates and shells and completing them by experimental research for the cases which are too complex for the analysis. The structural skeleton of an airplane will be built up in this case chiefly by beams with thin and wide flanges or thin webs, and the main problem is to find out which portion of the load can be carried by the thin-walled parts of the section.

The simplest case of a combined section is that of a reinforced sheet, as shown in Fig. 1. Let us consider a bending load. The elementary theory of bending assumes normal stresses proportional to the distance from the neutral axis, the neutral axis being located at the center of gravity of the combined section. According to this elementary theory, the stress would be uniform along the whole width of the sheet. However, this can only be assumed, if the width of the sheet is small compared to its length. Two effects diminish the stresses in the outer parts of the wide flange; the first is due to the distortion of the sheet in its own plane and occurs whether the sheet is used in tension or in compression, and the second effect, due to the buckling of the sheet, occurs only in compression.

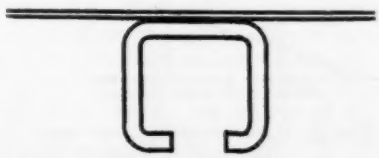

FIG. 1 TYPICAL COMBINED SECTION

In order to calculate the stress distribution in the first case (sheet in tension or in compression below the stability limit), we imagine the flange to be cut off along the section *a-b-c* in Fig. 2*a* before the beam is bent. The bending of the beam obviously changes the length of the line elements along *a-b*, so that in order to reattach the sheet, the latter must be stretched or compressed by shear forces applied on the cut section. We have to consider the problem of two-dimensional stress distribution in a strip subjected to shearing forces applied along one edge. The author has previously studied this problem by the use of Airy's method.[2] If the shearing forces or the bending moment can be developed in a Fourier series, Airy's method immediately gives the stress distribution along the width of the flange. The stress distribution is shown schematically in Fig. 2*a*, both in the main part of the beam and in the flanges. The stresses in the beam are composed of the linearly distributed bending stresses and uniformly distributed compression or tension stresses.

Dr.-Ing. von Kármán received his M.E. at Budapest in 1902 and Ph.D. at Göttingen in 1908; honorary degree of Doctor of Engineering, University of Berlin, 1929. He was Privat-Docent, Göttingen, 1910–1913; Professor of Mechanics and Aerodynamics, Director of the Aerodynamical Institute, University of Aachen, 1913; member of Gesellschaft der Wissenschaften zu Göttingen, 1925; foreign member of the Royal Academy of Sciences, Turin, 1928.

Part III of a Symposium, "Survey of Problems of Thin-Walled Structures," contributed by the Aeronautic Division and presented at the Pacific Coast Aeronautics Meeting, Berkeley, Calif., June 9 to 10, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Th. von Kármán, in Föppe, "Beiträge zur technischen Mechanik und technischen Physik, Springer, 1924. W. Metzer and A. B. Miller, *Luftfahrtforschung*, vol. 4, no. 1.

The resultant of the latter stresses is equal and opposite to the resultant of the stresses in the flanges. If the stress distribution in the flanges is known, an effective width can be calculated—i.e., the width of the sheet which, uniformly stressed by the maximum stress occurring in the adjacent part of the beam, gives the same resultant as the effective stresses.

We obtain the maximum of the effective width if we assume the sheet indefinitely extended. In this case the effective width depends chiefly on the rate of variation in the bending moment—i.e., on the span or on the distance between the zero points of the bending moment or on the length in the case of a column in compression. For a continuous beam under uniform load, we obtain the effective width w to be equal to:

$$w = 0.11s \quad \ldots\ldots [1]$$

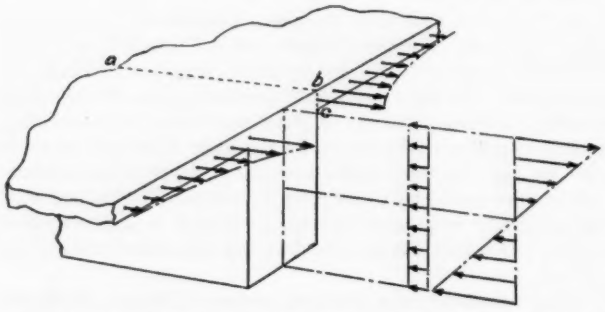

FIG. 2a STRESS DISTRIBUTION IN T-BEAM WITH WIDE FLANGES

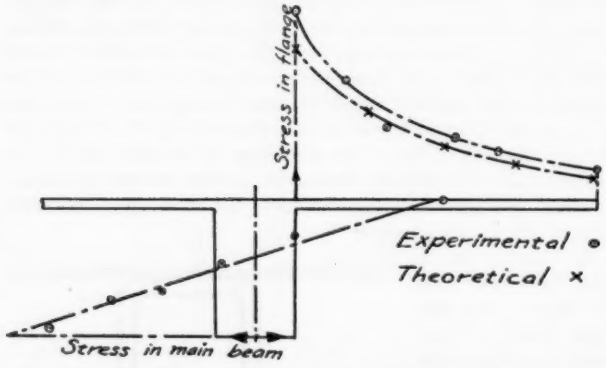

FIG. 2b COMPARISON OF COMPUTED AND MEASURED STRESS DISTRIBUTION IN T-BEAMS WITH WIDE FLANGES

where s = span, and for a beam on two supports with free ends:

$$w = 0.165s \quad \ldots\ldots [2]$$

In the general case the effective width is expressed by the Fourier coefficients of the bending moment considered as a function of the length coordinate of the beam. Fig. 2b shows the comparison between computed and measured stresses in the wide and thin flange of a T-beam.

If the sheet is used on the compression side, as is customary in aeronautical structures, the possibility of buckling must be considered. The stability limit can be calculated by equations deduced by G. T. Bryan, Th. Reissner, and S. Timoshenko. However, in most cases the sheet is used beyond the stability limit, the latter being very low in the case of thin sheets. The mechanism of stress distribution and the question of ultimate strength of thin sheets are discussed in the second part of this paper (AER-55-19b), and also the method suggested by the author to calculate approximately the ultimate strength is indicated.

Using this method, we obtain the following formula as an estimate for the effective width of the buckled sheet:

$$w = \frac{\pi}{\sqrt{12(1-\mu^2)}}\sqrt{\frac{E}{\sigma}}\,t \quad \ldots\ldots [3]$$

where t denotes the thickness of the sheet, E Young's modulus, μ Poisson's ratio, and σ the value $P/\delta w$, if P is the force carried by the sheet. It appears that the effective width depends on the load and decreases with increasing value of σ, until the latter reaches the yielding point σ_y. Putting $\sigma = \sigma_y$, the value of the effective width will be

$$w = \frac{\pi}{\sqrt{12(1-\mu^2)}}\sqrt{\frac{E}{\sigma_y}}\,t \quad \ldots\ldots [4]$$

Substituting for dural $E \cong 10.5 \times 10^6$ lb per sq in., $\sigma_y \cong 40{,}000$ lb per sq in., we obtain $w \cong 16t$. For steel we find $w \cong 22t$.

Shipbuilders are facing a similar problem, in the computation of the contribution of the hull to the effective section of bulkheads. They use practical rules suggesting an effective width equal to 20–25t.

In the cases just considered, it was assumed that the beam and the sheet were straight. Considering a cylindrical sheet with a circumferential stiffness, such as occurs in the case of a cylindrical monocoque fuselage reinforced by bulkheads and loaded in the plane of one of the bulkheads, a third effect diminishing the effective width has to be mentioned. It is obvious that the stress in the curved sheet produces a displacement in the radial direction (see Figs. 3a and 3b), and this displacement diminishes the circumferential strain and the circumferential stress, both in the case of tension (Fig. 3a) and in that of compression (Fig. 3b). The deformation of the sheet and the stress distribution resulting from this deformation can be calculated,[3] and we obtain for the maximum value of the effective width:

$$w = 0.54\sqrt{tR} \quad \ldots\ldots [5]$$

where R denotes the radius of curvature of the sheet.

A special problem related to that of the reinforced sheets is the stability and ultimate strength of sheets with isolated corrugations. The ordinary corrugated sheet can be considered as a homogeneous plate with increased flexural stiffness in the sections perpendicular to the corrugations. However, isolated corrugations are often used in order to increase the stiffness of a sheet; in these cases, the question of the average stiffness of the whole

FIG. 3a COMBINED SECTION IN BENDING, FLANGE IN TENSION

FIG. 3b COMBINED SECTION IN BENDING, FLANGE IN COMPRESSION

[3] An analogous problem occurs in the calculation of the flexural rigidity of curved pipes. Dr. Th. von Kármán, *Z.V.D.I.*, 1911, vol. 55. The present formula (5) has not been previously published. W. Hovgaard, *Journal of Math. and Physics of the M.I.T.*, also Proc. of the Third International Congress for Applied Mechanics, vol. 2, p. 331.

sheet is raised by the designer. This problem is obviously similar to that of the sheet reinforced by beams.

The curvature effect mentioned occurs also in the bending of straight reinforced sheets, but it is a second-order effect, because in this case the curvature $1/R$ is itself proportional to the bending moment M divided by the flexural rigidity yE, and so the variation on the stress distribution due to the curvature is of the order (M/yE).[2] Consequently, for slightly bent beams or in the case of buckling of columns this effect can be neglected.

The foregoing considerations show that the elastic behavior of a reinforced sheet is a rather complex problem, and systematic experimental research work is needed in order to determine the limits within which the theoretically deduced formulas can be applied and to determine the resultant influence of the different effects outlined.

Another use to which the flat sheet is often put is to serve as web of a deep beam (Fig. 4) on the side wall of a box. In this case also we have to distinguish between structures in which the stability limit is considered as an upper limit for the stresses and those in which the sheet is used as a "tension field" in the buckled state. In structures of the first kind the sheet usually has a considerable thickness and contains cutouts to reduce weight (Fig. 5). The strip with holes affords an interesting example of two-dimensional stress distribution. Using Airy's method, we are able to calculate the maximum stresses at the circumference of the holes and the influence of the holes on the rigidity of the whole construction. The infinite plate with a hole under uniform tension and shear has been calculated by many authors. The chief result is that the maximum stress at the circumference of the hole is twice the uniform stress applied to the sheet. This rule can be applied to strips of finite width, if the diameter of the hole is small in comparison to the width. At the author's suggestion, M. Hirota[4] recently calculated the stress distribution in the case that the diameter of the holes is from the same order as the width of the sheet. For the ratio 1:2 between diameter and width, he finds that the maximum stress is about eight times as high as

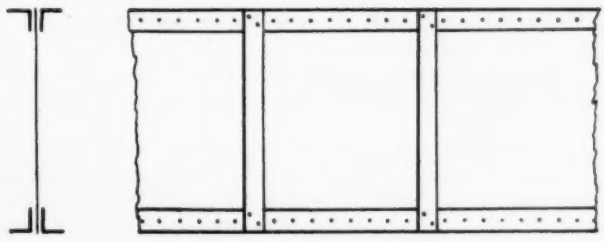

FIG. 4 TYPICAL THIN WEBBED BEAM

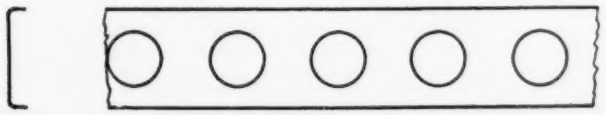

FIG. 5 WEB WITH HOLES

that which would occur without holes. It should also be mentioned that a beam whose web contains holes has considerably smaller flexural rigidity than would correspond to the average value of the inertia moment.

If the web or wall is enclosed between two rigid longitudinal elements and loaded by shearing forces, the stability limit is given by a simple formula, first given by Southwell and Skan; the influence of the "bracings" which generally are used in order to stiffen the plate both in the longitudinal and in the transversal direction has been worked out by H. Wagner and C. Schmieden.

[4] Thesis at the University of Aachen.

If the wall is used beyond the stability limit, we obtain "the tension-field type" of beam, i.e., the sheet can be replaced by a system of tension elements or strings, as shown in the second part of the paper. The most important progress in this field, due to Dr. Wagner's suggestions, is the fact that it is possible to develop structural elements lighter than trussed structures whose stress distribution and elastic behavior can be computed with nearly the same accuracy as is the case with simple trusses. Dr. J. Mathar, assistant professor at the Aachen University (Germany), made

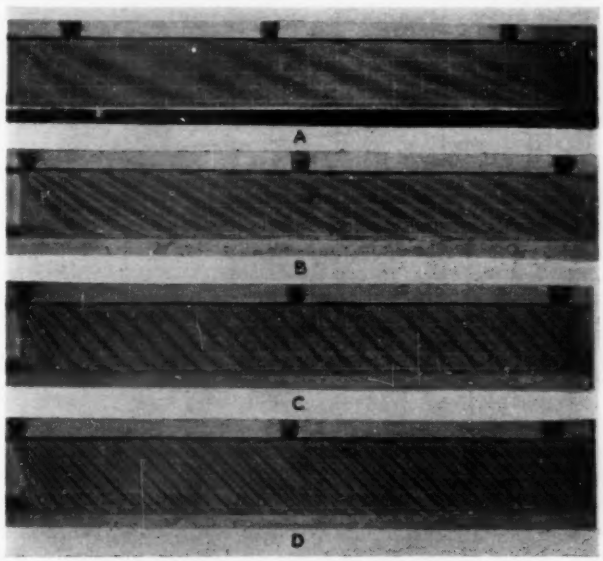

FIG. 6 ACTION OF WEB UNDER SHEAR
(A, p = 0.0025 kg per cm; B, p = 0.04 kg per cm; C, p = 0.01 kg per cm; D, p = 0.08 kg per cm; p denotes the shearing force per unit length.)

some experimental investigations on the elastic behavior of such high beams with tension field webs.[5] He made first some observations on a paper model, which show the development of the tension field, especially the rate of increase of the waves as a function of the shearing stress. Some of his photographic records are reproduced in Fig. 6. Then he constructed a model of a high beam, using dural sheet of 0.2 mm thickness as web between two longitudinal duralumin flanges of about 6 ft length. The sheet was stiffened by transverse braces; the number of the latter elements was varied from one to seven. If the beam is loaded by a concentrated force Q applied at the free end, the stresses in the longitudinal elements are found in first approximation to be equal to

$$\sigma = \frac{Qx}{h} \pm \frac{Q}{2} \cot \varphi \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

In this equation x represents the distance of the section considered from the load, h the height of the beam, and φ the inclination between the longitudinal elements and the direction of the tension elements or waves developed by the buckling of the sheet (approximately 40 deg). The tension stress in the sheet is:

$$\sigma = \frac{2Q}{th \sin 2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

in which t = thickness of the sheet.

The compression load in the upright elements (transversal bracings) is, according to this elementary theory:

[5] Jahrbuch der wissenschaftlichen Gesellschaft für Luftfahrt (W.G.L.), 1929, p. 205.

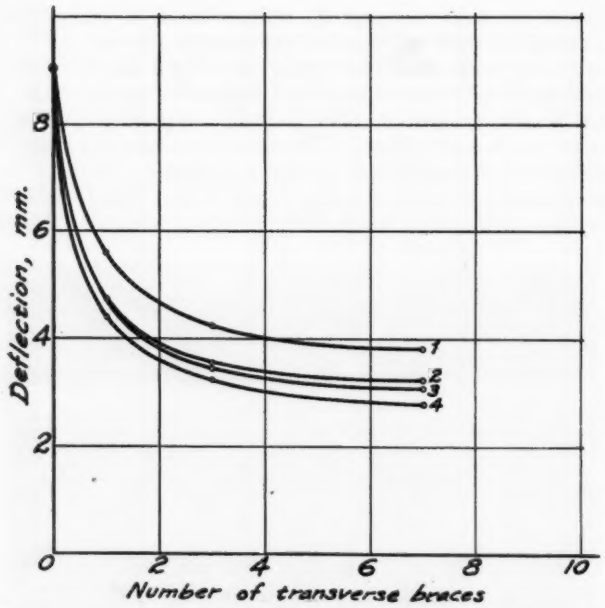

FIG. 7 INFLUENCE OF NUMBER OF TRANSVERSE BRACES ON THE STIFFNESS OF WEB IN SHEAR

$$P = \frac{Q}{Ch} \tan \varphi \quad \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

where C is the distance between the transverse braces. The stresses in all these elements have been measured by extensometer. Table 1 gives the comparison between computed and measured stresses in one of the panels (at a distance of about one-third of the length from the supported end of the beam). The load is equal to 60 kg.

Fig. 7 gives an interesting comparison between the values of the deflection at the free end of the beam as function of the number of the transverse braces, corresponding to four different types of connection between the flanges, the transverse braces, and the sheet:

Curve 1. Transverse braces pin-jointed to the flanges. No connection between sheet and transverse braces.

Curve 2. Rigid connection between flanges and transverse braces; sheet as in case 1.

Curve 3. Flanges and transverse braces, as in case 1; sheet fastened to the transverse braces.

Curve 4. Longitudinal and transverse braces, as in case 2; sheet as in case 3.

TABLE 1

Stress	Measured, kg per sq cm	Computed, kg per sq cm
In the upper flange	136	120
In the lower flange	147	156
Maximum tension in the sheet	172	180
In the transverse brace	18	22.5

J. Mathar also investigated the elastic behavior of a fuselage of rectangular section under different static and dynamic load conditions. An actual fuselage of the Dornier type was used for these experiments.[6] Mathar found that the effective rigidity of the fuselage in bending is fairly well approximated if the following elements are assumed to carry stresses: the walls and stiffness in tension, the stiffness alone in compression, and half of the side-walls.

This short survey of some typical cases shows that, in spite of some gaps in our present knowledge, the calculation of structural elements composed of beams and flat sheets can be attacked with some hope of obtaining usable information. The situation is worse as far as curved sheets and especially curved sheets in connection with stiffeners are concerned. A method similar to that sketched for calculation of the effective width of a flat sheet can probably be applied to curved sheets.

At the present time experimental investigations are being carried out at several places on the stability and ultimate failure of cylinders in compression, bending, and torsion and on the ultimate strength of reinforced curved sheets under different load conditions. It may be hoped that in the following few years the problem will be solved in sufficient generality to give a safe foundation for the design of monocoque structures.

AER-55-20

Possibilities of Cabin-Type Autogiros

By A. E. LARSEN,[1] PHILADELPHIA, PA.

The development of the Autogiro has virtually been made on the open-cockpit type, one to three place, weighing from 1000 to 3000 lb, and with an engine of 80 to 400 hp. The question has often arisen if it could be adapted to passenger transport. The author asserts that the cabin-type Autogiro is entirely possible. Three cabin Autogiros have been built, markedly different as to type, size, power, and general construction. The trial flights in this country suffered because of lack of mechanical starting units, not then available. Detail studies have been made of various sizes of cabin-type Autogiros, and the author gives an idea of the possibilities in this development.

THE progress of Autogiro development has virtually been made on the open-cockpit type. These machines have been one- to three-place and the weight from 1000 to 3000 lb with power plants from 80 to 400 hp. Questions often arise as to the possibilities of the cabin Autogiro and if it could be developed for transport work. This paper will definitely assert that the cabin-type Autogiro holds tremendously interesting possibilities, with promise of increased performance and still greater utility than has been displayed by the present Autogiro. Mention must be made of those cabin models of Autogiros that have been built:

1 The LePere cabin Autogiro, model C-18, made in France in 1929 by the Weyman LePere Company for the Cierva Autogiro Company, Ltd., of England, as an intended entrant in the Daniel Guggenheim Safe Aircraft Competition.

2 The Kellett convertible-cabin Autogiro K-3, now available in this country.

3 The Cierva Autogiro C-24, which received widespread publicity last Summer.

These three machines are markedly different as to type, size, power, and general construction.

The LePere combined the novel Autogiro features and metal construction. It was a four-place cabin type, with a geared seven-cylinder Wright J-6 engine; gross weight, 3060 lb; useful load, 1100 lb. The trial flights in this country were marked by experimental difficulties owing chiefly to lack of mechanical starting units not then available. Starting was effected by the deflector-tail principle, and though several rotors were fitted and numerous flights completed, the possibilities were not fully developed.

The Kellett Autogiro Company, of Philadelphia, devised a convertible cabin, capable of rapid fitting and removal on their side-by-side K-3. This arrangement follows the lines of the rather successful enclosures on a number of British sport planes and makes an admirable conversion without serious impairment of vision. The main characteristics: Gross weight, 2300 lb; useful load, 374 lb; rotor diameter, 40½ ft; 210-hp Kinner C-5 engine; maximum speed, 110 mph; cruising speed, 95 mph; initial rate of climb, 1000 fpm. It is doubtless a forerunner of a type that will find wide application among private owners.

England has given considerable thought to various sizes and types of cabin Autogiros, single-engine and multi-engine, pusher and tractor, and from numerous design projects the Cierva C-24 Autogiro was constructed along lines of maximum aerodynamic cleanliness. This little two-place machine, with a four-cylinder inverted aircooled D.H. Gypsy Mark III engine, developing 115 hp, attained 118 mph in trials. Its all-round performance compared favorably with the D.H. Puss Moth, considered a good example of modern English airplane design. This comparison, for practically equivalent weight and power, is as follows: Top speed, C-24, 118 mph; Puss Moth, 126 mph. Rate of climb, C-24, 900 fpm; Puss Moth, 900 fpm. The possibilities of cabin-type Autogiros are indicated most favorably. Following are comparisons of parasite drags of wind-tunnel models at 100 mph, with the fixed wing drag deducted: C-19 Mark III (the English type shown frequently in this country), biplane tail, 200 lb. C-19 Mark IV (the current production model in England), monoplane tail, 170 lb. C-24 (cabin), 100 lb.

Numerous studies have been made of the possibility of cabin-type Autogiros in this country, owing to the potential buying market developed by demonstrations in which particularly the PCA-2 three-place model was flown on numerous estates along the Eastern Central seaboard. Literally hundreds of estate owners will not lay out landing fields, but all would consider a fairly uniform type of Autogiro, of 300 to 400 hp, four- or five-place cabin, with provisions for luggage, and capable of two or three hour flights. The consistency of these specifications has resulted in the undertaking of such a project by one of the Autogiro licensees, Pitcairn Aircraft, Inc.

Other detail studies have been made, the computed specifications and performance of which follow. The first study, of a machine with gross weight of 7500 lb, had these specifications: Rotor diameter, 70 ft; chord, 24.6 in.; parasite drag, 425 lb at 100 mph; engine hp, 575 at 1950 rpm; propeller efficiency, 0.80; thrust hp, 460. The computed performances follow:

	Light	Loaded
Weight, lb	5,000	7,500
High speed, mph	137	128
Rate of climb, fpm	1,337	673
Ceiling, ft	23,700	13,300
Minimum speed, mph	24.0	35.4
Steepest angle of climb, deg	15.2	7.17
Speed of vertical descent, fps	16.6	19.8

A 15,000-lb three-engine Autogiro, with these specifications, was studied in comparison with a well-known 16-passenger tri-

[1] Chief Engineer, Autogiro Company of America. Agnew E. Larsen was born in Tacony, Philadelphia, Pa., on April 3, 1897. His primary and secondary school education was in York, Pa. An industrial and drafting apprenticeship was served in A. B. Farquhar Company, 1913 to 1916, York, Pa., followed by engineering studies at Ithaca, N. Y. In July, 1916, he attended the Atlantic Coast Aeronautical Station, Curtiss Flying School, Newport News, Va., and did experimental work for Mr. Pitcairn from September, 1916, to January, 1917. He was with the Thomas Morse Aircraft Corp. from March, 1917, to November, 1922, as chief draftsman and assistant engineer, and with Nordyke Marmon Company from November, 1922, to March, 1923, in the production department and as assistant to the efficiency engineer. In March, 1923, he went to Philadelphia to work for Mr. Pitcairn, and started the manufacturing organization of Pitcairn Aircraft, Inc., serving as chief engineer until January, 1930, and since then in his present position. He became vice-president on January 1, 1933.

Presented at the Sixth National Aeronautic Meeting, Buffalo, N. Y., June 6 to 8, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

motored transport plane: Rotor diameter, 100 ft; rotor chord, 47.6 in.; parasite drag, 650 lb at 100 mph; engine hp, 1300; propeller efficiency, 0.80; thrust hp, 1040. The computed performances follow:

	Light	Loaded
Weight, lb	10,000	15,000
High speed, mph	160	150
Rate of climb, fpm	1,510	820
Ceiling, ft	24,000	15,400
Minimum speed, mph	25.0	32.0
Steepest angle of climb, deg	16.0	7.25
Speed of vertical descent, fps	16.4	20.0

The third study was made on a 6500-lb machine, designed for nine passengers, for the sake of comparison with a well-known single-engine transport plane. The specifications are: Rotor diameter, 64 ft; rotor chord, 29 in.; parasite drag, 364.5 lb at 100 mph; engine hp, 575 to 1950 rpm; propeller efficiency, 78 at high speed loaded and 74 light; thrust hp, 448 at high speed loaded and 424 light. The computed performances follow:

	Light	Loaded
Weight, lb	4,000	6,500
High speed, mph	148	135.5
Rate of climb, fpm	1,600	820
Ceiling, ft	26,100	16,200
Minimum speed, mph	25.0	29.0
Steepest angle of climb, deg	18.0	8.5
Speed of vertical descent, fps	15.8	19.4

Following these studies, Autogiro cabin applications were considered in conjunction with a number of interesting types of planes, as for example the Stout Skycar, provided with 25 per cent increase in power.

The following study was undertaken to obtain an idea of the performance that might be expected from a twin-engined Autogiro of pilot-and-four-passenger capacity. With this data, the effect on performance of variation in parasite drag, the addition of controllable-pitch propellers whose low-pitch position would be at a design V/ND corresponding to the speed of maximum rate of climb, and of "boosted" or supercharged engines, both with and without controllable-pitch propellers, were investigated. It is believed the variation in performance due to the influence of these various items may be used to draw general conclusions as to their effect on any Autogiro.

The propellers referred to as "standard" are designed by the nomographic chart for propellers in the Air Corps "Handbook for Airplane Designers," 1925 edition. The design speeds in determining these diameters by this chart are taken as 10 per cent less than the actual "expected" high speeds found by Mr. Cierva as advisable in Autogiro propellers and corrected by a factor of 1.053, as it was found in propeller tests on the PAA-1 Autogiros that the best propeller was 5.3 per cent greater in diameter than one whose diameter was determined as above. However, the design V/ND for which the maximum efficiency was determined was at the high speed, for the large diameter, so all estimated propeller efficiencies are thereby conservative in this regard.

For the unsupercharged engines, the brake-horsepower corresponding to different engine rpm was obtained from power curves submitted by the engine manufacturer. The supercharged or "boosted" engine was considered as giving 50 per cent more than normal horsepower at the same rpm. Simply as a supercharged engine, this would correspond to one with a 10,000-ft rating. As it has been demonstrated as practical to run engines with both high compression and highly geared induction systems at full throttle for a minute to a minute and a half at sea level, it is considered reasonable to compute the performance with the power of the engine boosted 50 per cent as being a performance of which the machine is capable for take-off over obstructions or for short bursts of speed.

* Abbreviations: lp, low parasite; hp, high parasite; std., standard; cont., controllable; prop., propeller; eng., engine; sup., supercharged.

The power-available curves for different combinations, at different altitudes, were determined in the usual manner.

The performances of these machines were considered for the more efficient three-bladed rotor, based upon performance reports of the latest C-19 Mark III-A received from the Cierva Autogiro Company, Ltd. The parasite drag of this machine is 165 lb at 100 mph, and with the curve of power available furnished in this report, the rotor fixed-wing (L/D) ratio was computed from the climb and glide tests.

The climb tests give very optimistic results, showing a maximum fixed-wing rotor L/D of over 16. The glide data give more conservative results, a projection of the general curve showing a fixed-wing rotor (L/D) maximum of 13.6, which is considered reasonable and possibly on the conservative side. This latter set of data, in comparison with the characteristics of a four-blade rotor fixed-wing combination, is used in determining the rotor fixed-wing drag that is used in determining the "power required."

The parasite drags, corrected for slipstream velocity, are obtained for each modification of machine considered. The weight of each modification, fully loaded, the probable value of Ω/V at different speeds, the corresponding rotor fixed wing (L/D), and the rotor fixed-wing drag for each speed are found. The rotor wing drag and parasite drag are added, and the horsepower required determined from these total drags.

From these power curves the performance data are obtained, covering rate of climb, ceiling, speeds at altitude, engine rpm at altitude, and maximum path angle of climb. All performance figures are for the machine fully loaded, with pilot and four passengers, with four hours' gas, the specified amount of oil and 150 lb baggage. No attempt was made to estimate the rotor rpm exactly, the figures used in determining Ω/V corresponding to different speeds being obtained from analysis.

The main characteristics of each of the combinations, with their performances, are given in Table 1.

The conclusions from these performance estimates are as follows:

If the twin-engine machine can be made as clean aerodynamically as the "low parasite," it will have a very creditable performance. To obtain this, it is recommended that extensive wind-tunnel tests be carried out on the fixed-wing parasite parts assembly, that modifications be made during these tests, and that the final machine constructed be the best compromise of aerodynamic cleanness consistent with practical construction.

In the general case, aerodynamic cleanness plays a more important part in influencing performance than either weight or power, especially with the more efficient three-blade rotor. Consequently, all future designs of Autogiros, besides being made as light as possible with ample reserve power, should have all parasite drag reduced to a minimum. In this regard, anti-drag engine cowling, fillets at all intersecting surfaces, streamlining of all parasite parts, and elimination of gaps between surfaces should be considered in all design.

The addition of a controllable-pitch propeller to any design improves the take-off performance an average of 44 per cent in initial rate of climb, 96 per cent in maximum path angle of climb at sea level, and 6.8 per cent in absolute ceiling.

The addition of a 10,000-ft supercharger (which can be used full-on for short periods below 10,000 ft) to a machine with a sea-level propeller increases the initial rate of climb 76 per cent, the maximum path angle of climb at sea level by 79 per cent, and the absolute ceiling by 29.5 per cent.

The addition of a 10,000-ft supercharger, with a 10,000-ft propeller, increases the performance for an unsupercharged machine with standard sea-level propeller 82 per cent for initial rate, 71 per cent for maximum path angle of climb at sea level, 150 per cent for maximum path angle of climb at 10,000 ft, 30 per cent for high-speed at 10,000 ft, and 40 per cent for absolute ceiling.

Conversely, a 10,000-ft propeller on a machine, either unsupercharged or one with a supercharger not functioning, decreases the performance 22 per cent in initial rate, 7 per cent in high speed, 17 per cent in maximum path angle of climb at sea level, and 12 per cent in absolute ceiling.

It is believed the most satisfactory method of increasing engine performance would be a high-compression engine with a highly geared induction system, similar to that on the PCA-2 No. 5, which could be operated at full throttle for short periods below 5000 ft or 8000 ft, rather than an independent supercharger which would require one additional control and would take up more space in the engine compartment than the recommended arrangement.

The ideal combination would be a machine of low parasite drag, with high-compression engine and highly geared induction system, fitted with a controllable-pitch propeller.

The next phase of this design study investigated was that of the ability to overcome yawing moments at all speeds by the use of rudder alone, with one engine operating at full throttle. This investigation showed that it would be advisable to tilt the engines approximately 3 deg each, with the thrust lines converging aft in order to reduce the yawing moments due to the engines and to enable the slipstream to strike the vertical surfaces at a greater incidence. It was further shown that, in order to completely overcome the yawing moment due to one engine, it would be necessary to use a slotted-airfoil arrangement for the vertical surfaces, operating in conjunction with the rudder as a flap.

AER-55-21

Principle of Similitude as Applied to Research on Thin-Sheet Structures

By JOHN E. YOUNGER,[1] BERKELEY, CALIF.

Any program of research on airplane structures must give consideration to the design and stress-analysis requirements of the Army, the Navy, and the Aeronautics Branch of the Department of Commerce. The requirement that the breaking strength of the structure or of its component parts must be the basis of strength calculations places a difficult problem before research men. Hooke's law of proportionality of stress to strain forms the basis of the mathematical theory of elasticity, and above the proportional limit of the material (which for aircraft metals may be taken as the elastic limit), formulas based on this law do not apply. Formulas are derived from the standpoint of the mathematical theory of elasticity which fit the data quite accurately for stresses within the elastic limit. For stresses above the elastic limit an empirical formula will be necessary. In so far as the practical use of the data is concerned, since stresses above the proportional limit are involved, a derived formula may not be as desirable as the experimental curve. The value of the experimental curve depends very greatly upon the proper selection of the coordinates and the parameters.

IN ANY program of research on airplane structures, consideration must be given to the design and stress-analysis requirements of the Army, the Navy, and the Aeronautics Branch of the Department of Commerce. The requirement that the breaking strength of the structure or of its component parts must be the basis of strength calculations places a difficult problem before research men. Of course, Hooke's law of proportionality of stress to strain forms the basis of the mathematical theory of elasticity, and above the proportional limit of the material (which for aircraft metals may be taken as the elastic limit), formulas based upon this law do not apply.

The author wishes to avoid discussion of the desirability of discarding the ultimate-strength requirement as the basis of design for that of a lower stress requirement. Both sides of the question have excellent arguments in their favor. The fact is that the ultimate-strength requirement is the "law," and right or wrong, research men must take this into consideration if their results are to be of practical use.

Most theoretical formulas pertaining to the strength of a structure or the division of loads between members of the structure, as for example in the theory of least work, are based upon Hooke's law. Since we must determine, however, the breaking strength of the airplane or parts of the airplane, it is necessary to assume an extension of this law above the elastic limit or else use other means of developing our design criteria and formulas.

There are two principal ways in which design formulas for stresses above the elastic limit may be developed. The first is to assume the breaking strength to be below the proportional limit of the material, derive theoretical formulas by the application of the mathematical theory of elasticity, then assume the validity of these formulas above the elastic limit, or to assume that the basic terms in these theoretical formulas may be used in connection with experimental coefficients determined from model experiments. We incidentally note that very few engineering formulas are the direct result of theoretical calculations. They are nearly all tempered by experimental coefficients which have been very aptly called "coefficents of ignorance." An outstanding example of the application of a theoretical formula by means of experimental coefficients is the application of the so-called "precise three-moment equation," with the use of the chart of Fig. 13 in the Aeronautics Department of Commerce Handbook, Bulletin 7-A.

The second method of predicting the strength of a structure for stresses above the elastic limit is by the application of model testing through the principle of similitude. Coefficients from experimental results are obtained from model tests and applied to the full-scale condition through the use of empirically derived formulas. Model testing, in general, has formed the basis for strength calculations of airplanes, inasmuch as any experiment on the strength of a structure is a model test, whether the results be applied to the full-scale structure through the use of coefficients or through the use of empirically derived formulas.

In the application of the theory of dimensions in connection with the principle of similitude, it is necessary that we use good judgment in determining what physical conditions connected with our problem determine the strength of the structure. In other words, we cannot approach the problem blindly. We must assume the dimensions or other factors which may affect the result which we hope to obtain. Now, if we assume these incorrectly, then our result will obviously be incorrect. If we assume too few conditions, our results obviously may not be complete.

As a very simple case to introduce the subject, let us assume that we have been incapable of deriving the simple modulus-of-rupture formula,

$$f = \frac{Mc}{I} \qquad [1]$$

in which M is the bending moment, c is the distance from the neutral axis to the outermost fiber, and I is the moment of inertia of the cross-sectional area of the beam. As stated previously, let us assume that we know nothing of this equation, but that it is necessary for us, from an engineering standpoint, to know the

---

[1] Professor of Mechanical Engineering, University of California. John Elliott Younger was born in Canyon, Texas, on March 7, 1892. He attended High School and Junior College in Texas and the University of California, Berkeley, receiving his B.S. in 1923, M.S. in 1924, and Ph.D. in 1925, in Mechanical Engineering. Among the positions he has held are reserve military aviator, 1917–1919; second lieutenant, U. S. Army; faculty of University of California, 1925 to present time, with the exception of aeronautical engineer, Wright Field 1927–1929. Among his publications are "Dynamics of Airplanes and Airplane Structures" (with B. M. Woods), "Airplane Construction and Repair," and about 25 research papers.

Presented at the Pacific Coast Aeronautics Meeting, Berkeley, Calif., June 9 and 10, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

stress which will be introduced in a certain large beam before the beam is constructed. In order that we may apply our theory more readily, let us assume this beam to be rectangular in cross-section and of very large dimensions. For example, consider the length to be 1000 in., the depth 20 in., and the breadth 10 in. We are to apply a load of 1000 lb at the outer end. We must know the maximum fiber stress in the beam.

Under the assumption that we have no knowledge of the theory, we shall attempt to find this fiber stress by an experiment on a model of this beam. Let the scale of the model be one-tenth of the full-scale prototype. Let the scale = 10 = N; therefore we have the model 100 in. long, 2 in. deep, and 1 in. wide. We apply a load W to the model.

Now let us observe again the quantities we wish to find. We use the experiment on this model to find the stress from which we can determine the stress on the full-scale beam; hence we go from model to full scale. We first determine in so far as possible the dimensions and quantities which may influence the stress. Let us assume, then, that the fiber stress is a function of these dimensions or quantities. We of course know that the stress will be influenced by the moment of inertia, but we recall that the moment of inertia is a product of the derivation of the modulus-of-rupture formula; hence if we know nothing about that theory, as assumed, we would not be inclined to assume that the moment of inertia entered into the problem, and therefore we shall omit it in our first analysis. We note here that we assume that there is only one dimension, l, but if the model is geometrically similar to the full-scale prototype, then the one dimension expresses this relationship thoroughly. Let us first solve the problem on the basis of this assumption of geometrical similarity. We assume that the fiber stress depends upon the size of the beam and the weight W. Thus we write f as a function of l and W as

$$f = F(l, W) \quad [2]$$

We assume the form of the function to be

$$f = Kl^a W^b \quad [3]$$

which, it will be noted, is a function of a general form, since the value of a or b may be any quantity whatsoever. Writing this equation in dimensional form, we have

$$\frac{ML}{L^2T^2} = L^a \frac{M^b L^b}{T^{2b}} \quad [4]$$

Now equating the exponents of M, we have

$$1 = b \quad [5]$$

Equating the exponents of T, we find that $-2 = -2b$, $b = 1$, as previously noted. It is therefore possible to find only two unknowns, since two of our equations are identical. Equating the exponents of L, we have

$$-1 = a + b \quad [6]$$

or since $b = 1$, we have $a = -2$. Therefore, we have upon substitution in Equation [3]

$$f = Kl^{-2}W = K\frac{W}{l^2} \quad [7]$$

Therefore, we find that the fiber stress in each of the two beams is proportional to the ratio of applied load W and inversely proportional to the square of any dimension. We find therefore that (letting subscript f refer to full scale and m refer to the model)

$$\frac{f_m}{f_f} = \frac{K\left(\frac{W}{l^2}\right)_m}{K\left(\frac{W}{l^2}\right)_f} = \frac{W_m}{W_f}\left(\frac{l_f}{l_m}\right)^2 \quad [8]$$

Now we note that the ratio of the dimension f of the full-scale beam to the dimension of the model beam is the scale, which we designated as N. Therefore, we have, since $N = 10$

$$f_f = f_m \frac{W_f}{W_m}\left(\frac{1}{N}\right)^2 \quad [9]$$

It is not the formula here which is important, but the method of approaching the formula which is of primary value. Now let us apply this to the example. Let us assume that the weight applied to the model beam is 100 lb. Therefore, we have

$$f_f = f_m \frac{1000}{100}\left(\frac{1}{10}\right)^2$$

$$f_f = 0.1\, f_m \quad [10]$$

We note that f_m, the fiber stress in the model, is determined by experimental apparatus such as a strain gage. Having known this value, we can then determine what the fiber stress will be in the full-scale beam. Now let us assume that we have performed an experiment on the model and have obtained the desired result. We will, however, now revert back to our theoretically derived formula to determine f_m, and then let us determine f_f from the same formula, and see whether or not the relationship of Equation [10] actually holds. We find that

$$f_f = \frac{M_c}{I} = \frac{1000 \times 1000 \times 10}{\frac{10 \times (20)^3}{12}} = 1500 \text{ lb per sq in.}$$

Now from Equation [10] we find

$$f_f = 0.1\,\frac{100 \times 100 \times 1}{\frac{1 \times 2^3}{12}} = 1500 \text{ lb. per sq in.} \quad [11]$$

which checks the calculated result. Now it is to be noticed in this respect that whereas we use the simple cantilever beam for the derivation of our principle of similitude, the derived formula, Equation [10], will apply to more complicated types of beams. Yet for a model experiment in so far as the principle of similitude is concerned, it would be just as simple to determine the stress in this type of beam as it would be to determine the stress in a cantilever beam.

From Equation [7] we note, since the bending moment in the beam is $W \times l$, that

$$f = K\frac{M}{l^3} = K\frac{Ml}{l^4} \quad [12]$$

Since the moment of inertia may be expressed as a proportion of l^4 and c as a proportion of l, we may write Equation [12]

$$f = K'\frac{Mc}{I} \quad [13]$$

which is the modulus of rupture formula as we use it. Of course, we would not expect to derive a modulus of rupture formula from this standpoint. We are merely pointing out here that our derived formula gives a modulus of rupture in a form which is readily applicable.

As another example, let us consider the prediction of the

strength of a strut. The application of the mathematical theory of elasticity gives us, of course, Euler's formula,

$$\frac{P}{A} = \frac{C\pi^2 E}{\left(\frac{l}{\rho}\right)^2} \quad [14]$$

which states that the unit stress is proportional to $E\ (l/\rho)^{-2}$; that is,

$$\frac{P}{A} = KE\left(\frac{l}{\rho}\right)^{-2} \quad [15]$$

This formula of course applies only for stresses less than that of elastic limit, and accordingly has a very limited application. It does, however, indicate the coordinates for a graphical representation of the experimental data from which empirical formulas for stresses above the elastic limit may be determined, as, for example, Johnson's parabolic formula.

In attempting to represent experimental data graphically, for the purpose of determining an empirical formula, it is sometimes difficult to determine the coordinates to be used. In such cases, the principle of homogeneity of fundamental dimensions, length, mass, and time in an equation is of great assistance. It may be noted that most of the stress formulas applicable to the determination of the ultimate strength of aircraft structures may be arrived at by this simple process. For example, in considering the strength of struts, we assume that the strength is a function of the length, the modulus of elasticity, and the disposition of the cross-sectional area, which may be specified by the radius of gyration ρ, thus:

$$\frac{P}{A} = F(E, l, \rho) \quad [16]$$

Let us now assume a general form of this function, thus

$$\frac{P}{A} = KE^a l^b \rho^c \quad [17]$$

Writing the equation in the dimensional form, we have

$$\frac{ML}{L^2T^2} = \frac{M^aL^a}{L^{2a}T^{2a}} L^bL^c \quad [18]$$

Equation the exponents of M, we have $a = 1$. Equating the exponents of T, we find again that $a = 1$. Equating the exponents of L, we find $-1 = -a + b + c$, or $b = -c$. Thus Equation [17] becomes

$$\frac{P}{A} = KEl^b\rho^{-b} = KE\left(\frac{l}{\rho}\right)^b \quad [19]$$

Thus we find that P/A is a function of (l/ρ). This function may be determined from experimental data, in the form of an empirically derived formula.

Now for the purpose of studying the applications of the principle of similitude in determining the deflection of a structure, let us consider the simple example of bending of a cantilever beam. We are to find the deflection at the end of the beam. Let us assume that we have been unable to calculate this deflection from a theoretical standpoint. It becomes necessary, then, that we perform experiments on the model in order that we can determine the deflection of the full-scale structure. We apply the principle of similitude in order that we may determine the relationship between the quantities involved in the model and those same quantities which may affect this deflection. We assume that the deflection is a function of the variables as noted in Equation [20]:

$$y = F(l, E, W) \quad [20]$$

in which l is the length of the beam, E is the modulus of elasticity, and W is the applied load. We note that in Equation [20] we use one term involving the dimension of length; i.e., we do not incorporate the breadth and the thickness of the beam in the function, inasmuch as for geometrically similar structures these would be expressed as a proportion of l. Hence we are adding no new term in the function. We assume, therefore, that the equation may be written in the following form:

$$y = Kl^aE^bW^c \quad [21]$$

Writing the equation in the dimensional form, we have

$$L = L^a \frac{M^b}{L^bT^{2b}} \frac{M^cL^c}{T^{2c}} \quad [22]$$

Equating the exponents of the dimension L, we find that

$$1 = a - b + c \quad [23]$$

Equating the exponents of M, we find that

$$o = b + c \quad [24]$$

Equating the exponents of T, we find that

$$o = -2b - 2c \quad [25]$$

which is the same as Equation [24]. Let us assume that b and c are known quantities, since it is possible to evaluate only one of the unknown quantities a, b, or c. We therefore have

$$a = 1 + b - c = 1 - 2c \quad [26]$$

Thus we find in Equation [21] that

$$y = Kl^{1-x}E^{-c}W^c \quad [27]$$

Rewriting this equation, we have that

$$y = Kl\left(\frac{W}{El^2}\right)^c$$

which becomes

$$y = KlF\left(\frac{W}{El^2}\right) \quad [28]$$

Now writing the equation for the comparison of the deflection of the model to that of the full scale, we have

$$\frac{y_m}{y_f} = \frac{Kl_mF_m\left(\frac{W}{El^2}\right)}{Kl_fF_f\left(\frac{W}{El^2}\right)} \quad [29]$$

We note in Equation [29] that if $F_m = F_f$, then we can make a direct comparison of deflections. We note that the functions F_m and F_f must be equal because they are of an unknown form; that is, the comparison of the model to that of the full scale requires that these two functions be equal. They can be made equal provided

$$\frac{W_m}{E_ml_m^2} = \frac{W_f}{E_fl_f^2} \quad [30]$$

These terms can be made equal by selecting the proper experimental conditions. For example, the modulus of elasticity of

the model may be made the same as the modulus of elasticity of the full-scale prototype. In this case we find that

$$\frac{y_m}{y_f} = \frac{l_m}{l_f} = \frac{l_m}{Nl_m} = \frac{1}{N}$$

In other words, the deflection is proportional to the scale

$$y_f = y_m N \quad [31]$$

We should note that in general this relationship need not apply to the deflection of any structure. It is the application of the principle of similitude that we are attempting to illustrate. The derived formula has no particular value to us. A point which should be brought out is that for a particular problem we may apply the principle of similitude to determine the relationships which are desired.

A question has arisen as to what the effect would be of the comparison of the results obtained on the model to the full-scale prototype if, for example, the modulus of elasticity of the model is different from the modulus of elasticity of the full scale. If the moduli of elasticity are constant in both cases, a direct comparison can be made; for example, as noted in Equation [30]. However, if the modulus of elasticity of one material is not constant, but varies with the stress, this fact has to be taken into consideration in developing the dimensional equation.

Suppose that the stresses in the full-scale structure are to be above the elastic limit. In general, then, if the stresses in the model are not above the elastic limit, no direct application can be made. It appears in this case that the procedure to follow is to so determine the stresses in the model that the same ultimate strength is developed as is expected to be developed in the full-scale prototype. It would mean, then, that in general the elastic limit would be reached at approximately the same per cent of applied load on the model as on the full scale. In other words, it is clear that the experiment on the model should be similar to the experiment on the full-scale prototype in so far as approaching the elastic limit is concerned. In general, however, we note that unless the modulus of elasticity is involved it may not be necessary to give this case consideration. In all problems of deflection, however, this feature must be very carefully considered.

Let us consider another example of the application of the principle of similitude. The problem of vibration in aircraft structures is very important. However, it is quite often very difficult to determine the frequency of vibration in certain types of structures theoretically. We ask ourselves, then, the question as to whether it would not be desirable to construct a model from which we may determine the frequencies and other characteristics necessary. Then, if we find that the model has a certain frequency, we ask what would be the frequency of the full-scale prototype. Let us investigate this phase of the problem. Let us assume that we are considering the vibration of a cantilever wing structure, and to make it still more conventional, let us assume this cantilever wing structure to be uniform and homogeneous throughout its length. The quantities which may affect its vibration we write in Equation [32]:

$$f = F(l, \rho, E) \quad [32]$$

in which f is the frequency and ρ is the mass density per unit volume. We therefore write the equation:

$$f = Kl^a \rho^b E^c \quad [33]$$

Writing this equation in dimensional form, we have

$$\frac{1}{T} = L^a \frac{M^b}{L^{3b}} \frac{M^c}{L^c T^{2c}} \quad [34]$$

Equating the exponents of T, we find that

$$-1 = -2c, \quad c = \frac{1}{2} \quad [35]$$

Equating the exponents of M, we find that

$$0 = b + c, \quad b = -\frac{1}{2} \quad [36]$$

Equating the exponents of L, we find that

$$0 = a - 3b - c \quad [37]$$

Solving these equations, we find that

$$a = -1, \quad b = -\frac{1}{2}, \quad c = \frac{1}{2} \quad [38]$$

Thus we find that

$$f = Kl^{-1}\rho^{-\frac{1}{2}}E^{\frac{1}{2}} \quad [39]$$

or

$$f = \frac{K}{l}\sqrt{\frac{E}{\rho}} \quad [40]$$

Writing the equation of ratio of frequency of the model to that of the full-scale prototype, we find that

$$\frac{f_m}{f_f} = \frac{\frac{K}{l_m}\sqrt{\frac{E_m}{\rho_m}}}{\frac{K}{l_f}\sqrt{\frac{E_f}{\rho_f}}} \quad [41]$$

We note that if we make the modulus of elasticity and the density of the model the same as that of the full-scale prototype:

$$\frac{f_m}{f_f} = \frac{l_f}{l_m} = \frac{Nl_m}{l_m} = N \quad [42]$$

Thus

$$f_m = Nf_f \quad [43]$$

That is, the frequency is inversely proportional to the scale of the model. For example, if the model is $^1/_{10}$th scale, its frequency of vibration will be ten times the frequency of vibration of the full-scale prototype.

Let us apply the principle of similitude to beams subjected to combined transverse and axial loads, from the standpoint of determining the ultimate strength of the beams. This implies stress considerably above the elastic limit; hence our theory based upon Hooke's law does not apply.

We assume, in this case, that we are to compare the strength of, for example, steel or duralumin tubes. We are to perform a series of experiments and from these experiments we are to obtain data which may be applied to the design of tubes in aircraft structures. We assume that the axial stress is a function of the following terms:

$$\frac{P}{A} = F(l, r, t, M) \quad [44]$$

Assume l to be the length, r the radius of gyration, t the thickness of the wall of the tube, M the applied bending moment. Writing the equation in the general form, we have

$$\frac{P}{A} = Kl^a r^b t^c M^d \quad [45]$$

Writing the dimensional equation, we have

$$\frac{M}{LT^2} = L^a L^b L^b \frac{M^d L^{3d}}{T^{2d}} \quad [46]$$

Equating the exponents of M, we find that

$$d = 1 \quad [47]$$

Equating the exponents of T, we find again that $d = 1$. It is therefore apparent that we can find only two unknowns in this case. Equating the exponents of L, we find that

$$-1 = a + b + c + 2d \quad [48]$$

Let us assume that c and a are the known values. We have, therefore

$$b = -3 - (a + c) \quad [49]$$

We note, then, that

$$\frac{P}{A} = K l^a r^{-3-(a+c)} t^c M \quad [50]$$

Rewriting this equation, we find that

$$\frac{P}{A} = K \frac{M}{r^3} \left(\frac{l}{r}\right)^a \left(\frac{l}{r}\right)^c \quad [51]$$

It will be noticed that the arrangement of Equation [51] is not directly obvious. We must use our judgment, based upon past experience with structures, in this arrangement. We note, then, that in this equation the P/A of the material is proportional to the direct bending stress as specified by KM/r^3, and is a function of the ratio of the length to the radius of gyration or to the radius of the tube. Therefore, we find in plotting the data we may use P/A as the ordinate, as in Fig. 1, and the data will be applicable to the full-scale prototype, provided we use the same values of the ratio of length to radius of gyration and also provided that on the curve AB the values taken have a constant ratio of thickness to radius. We note, then, that the scheme of plotting the data as indicated in Fig. 1 is not accurate for tubes unless the ratio of the thickness to the radius is the same for the experiment as it is for the full-scale prototype. It may be noticed in this connection that the variation of the function t/r may be determined from a carefully planned set of experiments, and an empirical formula derived therefrom may be used in connection with the chart.

Let us take the same example and assume that P/A is also a function of additional quantities, such as, for example, the modulus of elasticity E, and the ultimate fiber stress in bending f_{ub}.

$$\frac{P}{A} = F(M, r, t, l, f_{ub}, E) \quad [52]$$

Let us apply the theory of dimensions and see what kind of a story it tells us this time. We find that

$$\frac{P}{A} = KM^a r^b t^c l^d f_{ub}{}^e E^f \quad [53]$$

We have, therefore, from the dimensional equation

$$\frac{M}{LT^2} = \frac{M^a L^{3a}}{T^{2a}} L^b L^c L^d \frac{M^e}{L^e T^{2e}} \frac{M^f}{L^f T^{2f}} \quad [54]$$

Equating the exponents of M, we find that

$$1 = a + e + f \quad [55]$$

Equating the exponents of T, we find that

$$-2 = -2a - 2e - 2f \quad [56]$$

which is the same as Equation [55]. Equating the exponents of L, we find that

$$-1 = 2a + b + c + a - e - f \quad [57]$$

From Equation [55] we find that

$$a = 1 - e - f \quad [58]$$

It is necessary to assume that e, f, and the other remaining exponents are known. We therefore have

$$\frac{P}{A} = KM^{1-e-f} r^{-1-2+2e+2f-c-d+e+f} t^c l^d f_{ub}{}^e E^f \quad [59]$$

Now, we have to use certain judgment in pairing off these terms. For example, we note that the ultimate bending stress will have some connection with bending moment. It is therefore reasonable that they should be paired together. It is apparent that the ratio of the length to the radius of gyration will influence the

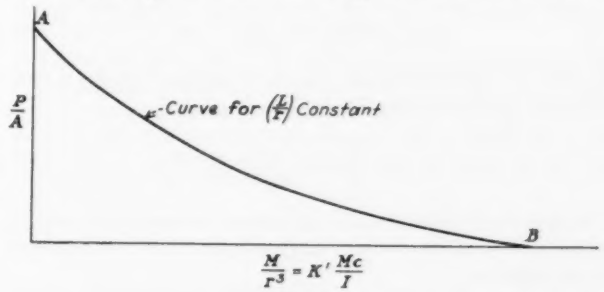

FIG. 1

structure, so it is logical to pair these terms; and in some manner possibly the modulus of elasticity may effect some other term, so that we could pair that with this other term. Therefore, we obtain

$$\frac{P}{A} = K \frac{M}{M^{(e+f)}} \frac{r^{3e} r^{3f}}{r^3 r^c r^d} t^c l^d f_{ub}{}^e E^f$$

$$= K \frac{M}{r^3} \left(\frac{t}{r}\right)^c \left(\frac{l}{r}\right)^d \left(\frac{f_{ub} r^3}{M}\right)^e \left(\frac{E r^3}{M}\right)^f$$

$$= \frac{M}{r^3} F\left(\frac{t}{r}, \frac{l}{r}, \frac{f_{ub} r^3}{M}, \frac{E r^3}{M}\right) \quad [60]$$

Let us consider some of the equations which we have previously derived, from the standpoint of differently assumed variables. For example, let us assume that the stress in bending is a function of

$$f = F(W, l, I) \quad [61]$$

We find from this that

$$f = \frac{W}{l^2} F\left(\frac{I}{l^4}\right) \quad [62]$$

Let us assume that the deformation of a structure is a function of the variables indicated in Equation [63].

$$y = F(P, l, E, I) \quad [63]$$

We find, then, from the theory of dimensions that

$$y = lF\left(\frac{P}{El^2}, \frac{I}{l^4}\right) \quad [64]$$

Let us now consider a torque equation. We assume

$$S = F(q, l, J) \quad [65]$$

in which q is the applied torque, l is the length of the loaded structure, S is the unit shear, and J is the moment of inertia of the cross-section. We find, therefore, that

$$S = \frac{q}{l^3} F\left(\frac{J}{l^4}\right) \quad [66]$$

The torsional deformation let us indicate as

$$\theta = F(q, l, J, E_s) \quad [67]$$

in which E_s is the modulus of elasticity in shear. We, therefore, have

$$\theta = lF\left(\frac{J}{l^4}, \frac{q}{E_s l^3}\right) \quad [68]$$

Now, if we consider the weights of the structure in a similar equation, we have to introduce the new terms, the density of the material and the gravity constant. We have, then,

$$f = F(P, l, I, \rho, g) \quad [69]$$

in which ρ is the density per unit of volume and g is the gravity constant. We find from this that

$$f = \frac{W}{l^3} F\left(\frac{I}{l^4}, \frac{P}{l^4 \rho g}\right) \quad [70]$$

This is the formula which would have to be used in suspension-bridge structural experiments inasmuch as it involves the weight of the structure.

Considering the deflection of the structure in terms of the additional dimensions ρ and g, we have that

$$y = Kl F\left(\frac{I}{l^4}, \frac{P}{El^2}, \frac{P}{l^3 \rho \rho}\right) \quad [71]$$

Writing similar equations for the conditions of torsion, we have

$$S = K \frac{q}{l^3} F\left(\frac{J}{l^4}, \frac{q}{l^4 \rho g}\right) \quad [72]$$

and

$$\theta = Kl F\left(\frac{J}{l^4}, \frac{q}{E_s l^3}, \frac{q}{l^4 \rho q}\right) \quad [73]$$

Likewise in determing the critical loading of a strut, we may add some additional terms, as in the following equations:

$$P = F(l, f_u, E, I, \rho, g) \quad [74]$$

in which P is the strength of the strut, L is the length, f_u is the ultimate strength in bending (the modulus of rupture), E is the modulus of elasticity, I is the moment of inertia in the cross-section, and g is the gravity constant. We find from the theory of dimensions that

$$P = K \frac{EI}{L^2} F\left(\frac{f_u}{E}, \frac{I}{l^4}, \frac{E}{l \rho g}\right) \quad [75]$$

We note in this last equation that the question which was previously mentioned has been answered. That question was as to how the apparent change in the modulus of elasticity at the elastic limit is going to affect the experimental results. We notice in this case that for direct comparison, at least for one term, the ratio of f_b to E of the model must be the same as this ratio for the full scale; that is

$$\left(\frac{f_u}{E}\right)_f = \left(\frac{f_u}{E}\right)_m \quad [76]$$

Again, if we have the two structures geometrically similar and in the same material, the terms I/l^4 and f_u/E will be constants and the factor $E/l\rho g$ may be expressed as the ratio $\frac{P}{l^3 \rho g} \Big/ \frac{P}{El^2}$. It follows that for this last quantity to be constant under the conditions just stated, the loading must be proportional to the weight of the structure and to the square of the scale ratio, since the modulus of elasticity is a constant for the given material. If all the terms within the parenthesis of Equation [75] are thus made constant, there remains

$$P = K \frac{EI}{l^2} \quad [77]$$

This term K is known as the critical load coefficient, and under these implied conditions reduces to the following:

$$K = \frac{Pl^2}{EI} \quad [78]$$

It is observed that in order to make the third term in the parenthesis of Equation [75] constant, it is necessary to make the loads proportional to the square of the dimensions as well as proportional to the weight of the structure. If the model is to be of the same material as the structure, as previously assumed, it must be loaded at certain intervals to bring the effective weight up to the required value. Unless this is done, another material must be chosen such that the terms f_u/E and $E/l\rho g$ both may be made the same in the model as in the structure. Likewise, most of our standard strength of materials formulas may be determined.

Structures of thin sheets of metal, namely, "monocoque" or "stressed skin," present many difficult problems in stress analysis, many of which, even for low stresses well within the range of Hooke's law and subject to mathematical analyses based upon the theory of elasticity, have not been solved. It appears that in this field of research work use may be made of the principle of similitude. Let us consider, for example, the strength of thin-walled tubes to resist torsion or bending. In these cases, we assume that the strength is a function of the modulus of elasticity, the radius of curvature of the metal sheets, and the thickness of the sheets, thus:

$$S = F(E, r, t) \quad [79]$$

Assuming

$$S = KE^a r^b t^c \quad [80]$$

Writing the dimensional equation, we have

$$\frac{M}{LT^2} = \frac{M_a}{L^a T^{2a}} L^b L^c \quad [81]$$

from which we find $a = 1$ and $c = -b$. Thus:

$$S = KE\left(\frac{r}{t}\right)^c = KEF\left(\frac{r}{t}\right) \quad [82]$$

We therefore represent the experimental data, torsion or bending, as allowable fiber stress as a function of r/t.

Among the research problems on thin-sheet-metal construction on which extensive data were obtained this year at the University of California were:

1 Allowable fiber stress in thin duralumin tubes subjected to bending, by F. F. Imperial and R. F. Bergstrom.

2 Allowable fiber stress in thin-walled duralumin tubes subjected to torsion, by A. E. Arslan and W. P. Berggren.

The tubes below 3 in. in diameter were taken from the stock of the Aluminum Company of America. The tubes 3 in. to 10 in. in diameter were from flat sheet and riveted sides of the tube; hence we may assume that the results are practically independent of the riveted joints. In all tests, wooden blocks were fitted in

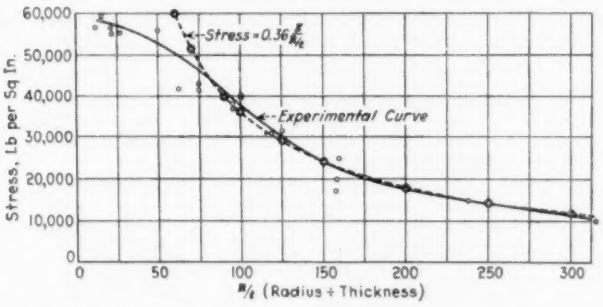

FIG. 2 BUCKLING STRESS OF THIN-WALLED DURALUMIN TUBES IN BENDING

the ends of the tubes, which were 36 in. in length, to which the loads were applied.

The results of the experiments are represented in Figs. 2 and 3. Mr. Bergstrom and Mr. Berggren succeeded in deriving formulas from the standpoint of the mathematical theory of

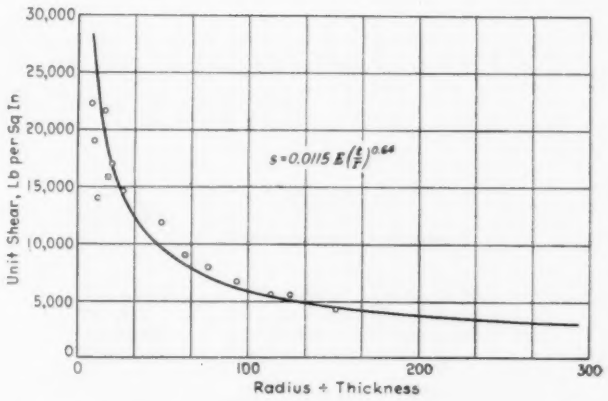

FIG. 3 BUCKLING STRESS IN TORSION OF DURALUMIN TUBES

elasticity which fit the data quite accurately for stresses within the elastic limit (see Figs. 2 and 3). For stresses above the elastic limit an empirical formula will be necessary. The derivation of formulas for Figs. 2 and 3 will be published in the near future by the authors of the experimental data.

We may note, in conclusion, that in so far as the practical use of the data is concerned, since stresses above the proportional limit are involved, a derived formula may not be as desirable as the experimental curve. The value of the experimental curve depends very greatly upon the proper selection of the coordinates and the parameters.

Progress in Applied Mechanics

Theory of Elasticity and Stress Analysis[1]

DURING the last year several problems in applied elasticity, having practical interest, have been discussed. Among the papers presented at the last two meetings of the Applied Mechanics Division of the A.S.M.E. was one by J. N. Goodier, on "Compression of Rectangular Blocks" (1).[2] This paper discussed local stresses produced by concentrated forces, and investigated also the accuracy of the ordinary bending theory when the forces applied at the ends do not follow a linear law. Other papers, by A. G. Solakian and G. B. Karelitz (2) and M. M. Frocht (3), dealt with the application of photoelasticity in the solution of design problems.

During the last National Meeting of the Applied Mechanics Division (New Haven, June, 1932) several papers on stress analysis were presented. One by Dr. A. M. Wahl (4) gave an approximate solution of the problem of the deflection of a semicircular plate under uniform load. The theory was checked by experiments on models, and found application in the calculation of the deflection of semicircular diaphragms in steam turbines.

A paper by Dr. M. A. Sadowsky (5) gave some interesting solutions of local stresses at the surface of contact between two bodies in compression.

A. N. Dinnik (6) presented a number of solutions of the problem of lateral buckling of columns of variable cross-section. Some of his results are of practical interest for airplane construction and for bridges.

A paper by H. Hencky (7) on the elastic behavior of vulcanized rubber gave a theory for materials with large deformations which is in good agreement with experiments.

A paper by Stewart Way (8) discussed the problem of the deflection of long rectangular plates uniformly loaded. It also gave some examples of the application of theoretical results to the design of ships.

J. N. Goodier (9) discussed the concentration of stresses around spherical and cylindrical inclusions and flaws. His paper may prove of interest in discussing some results of fatigue tests of weld metal having spherical cavities. Often fatigue cracks are originated at these cavities.

Papers by W. O. Richmond (10) and T. H. A. Brahtz (11) contained some new solutions of the two-dimensional problem in elasticity. Dr. P. A. Cushman (12) presented a paper dealing with some experimental results of the application of the soap-film method in studying stress distribution in bars submitted to the action of torsion and bending.

Papers by Dr. A. Nadai (13) and Dr. G. H. MacCullough (14) discussed several important problems on plastic flow of metals and set forth some new experimental results.

Last May, at the first International Congress for Bridge and Structural Engineering, which was held at Paris, a considerable number of papers dealing with applied elasticity were presented. Some of these dealt with problems of elastic stability, among them being one by Prof. L. Karner, in which the new developments in columns were discussed. A paper by F. Bleich was devoted to local buckling in the wall of a tubular compressed member; another, by Prof. M. Ros, discussed the problem of bending of eccentrically loaded columns; while a third, by the writer, dealt with the buckling of the webs of plate girders and on the design of stiffeners.

Several important papers on the theory of elasticity have appeared abroad during the last few years, of which four will be mentioned. One by O. Göhner (*Ingenieur-Archiv*, vol. 1, p. 619, and vol. 2, pp. 1 and 381) deals with stresses in helical springs. In the case of heavy helical springs, the diameter of the wire is not small in comparison with the diameter of the helix, and the usual elementary theory gives too low stresses. Some improvements in the theory have been made by V. Roever, and more recently by A. M. Wahl, the latter giving also an experimental proof of his formula. Göhner presents a complete theoretical solution of the problem, and the final results are in good agreement with Wahl's approximate formula. A paper by E. Melan (*Ingenieur-Archiv*, vol. 3, p. 123) deals with problems which are of practical interest in investigating stresses in welded structures. The author considers the case of a plate reinforced along a straight edge by a rib, and the stresses produced by a longitudinal force applied to the rib. A paper by H. Reissner (*Zeit. f. angew. Math. u. Mech.*, vol. 11, p. 1, 1931) gives the general theory of stress distribution produced in elastic bodies by non-uniform heating or by some permanent set. Another, by L. Föppl (*Zeit. f. angew. Math. u. Mech.*, vol. 11, p. 81, 1931), gives a new method of solving two-dimensional problems in the theory of elasticity, and applies it to the discussion of stresses around an elliptical hole.

During the last year two important books in the field of theory of elasticity have appeared. One, by E. G. Coker and L. N. G. Filon, on "Photoelasticity" (Cambridge University Press) deals at length with the technic of this kind of experimental study of stress distribution, but also presents a theory of the two-dimensional problem in elasticity and a description of the physical properties of materials used in experiments of this nature. It is the most complete treatise on photoelasticity that has yet appeared, and it will be of interest to all who are working in this field.

The second book, by Dr. A. Nadai, on "Plasticity" (McGraw-Hill) is an enlarged English edition of a work first published in German. It treats systematically various problems on plastic flow in metals, and will be of decided value to engineers working in the field of plastic deformation.

Rigid Dynamics[3]

In the field of dynamics two outstanding papers were presented at the New Haven meeting of the A.S.M.E. The first comprises an elegant analytical solution by F. M. Lewis (15) of the problem of the amplitude of a vibrating system which is accelerated or decelerated at a given rate through its critical speed. The other paper, by J. G. Baker (16), throws new light on the phenomenon of self-induced vibrations in engineering. It propounds the thesis that too much importance is usually attached to "resonance," because a large number of trouble cases are caused by "self-induction" rather than by "resonance."

At the Bigwin meeting in June, 1932, a symposium (17) was devoted to the subject of model experiments and dimensional theory.

In Germany a book on automobile shimmy was published by

---

Presented at the session of the Applied Mechanics Division, Tuesday morning, December 6, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

Personnel of the Executive Committee of the Applied Mechanics Division for 1932: Geo. B. Pegram, Chairman; J. M. Lessells, Secretary; J. A. Goff, F. M. Lewis, and E. G. Waters.

[3] Compiled by J. P. DenHartog.

Becker, Fromm, and Maruhn, giving a discussion of the underlying theory and elaborate of tests on this complicated subject.

It is well known that during the last decade or two great advances have been made in the applications of the gyroscope, with which the great name of Sperry is closely associated. During the past year a book entitled "Applied Gyrodynamics," by E. S. Ferry (18), has been published which describes this entire development in a logical and easily readable form. It will undoubtedly help to bring this fascinating subject within the understanding of a greater group than heretofore.

Mechanics of Materials[4]

The New International Association for Testing Materials held a congress at Zurich, Switzerland, September 6 to 12, 1931. Four groups were organized: A, Metals; B, Nonmetallic inorganic materials; C, Organic materials; and D, Questions of general importance. In group A, papers were presented by leading authorities on such subjects as testing of cast iron, strength of metals at high temperatures, fatigue, impact testing, properties of light alloys, and strength of welds. The papers presented at the congress are available in four volumes corresponding to the above groups (19).

Considerable interest is being shown in the properties of rubber as an engineering material. A Symposium on Rubber was held by the A.S.T.M. on March 9, 1932, in Cleveland. Seven papers were presented on various properties of rubber (20). A noteworthy paper on the elastic behavior of rubber (21) was presented at the New Haven meeting of the A.S.M.E. A rubber-litharge material, having the same specific gravity as concrete, but with a much lower modulus of elasticity, has been used in constructing a test model of an arch dam (22).

Several contributions have been made to our knowledge of creep of metals, both from the experimental (23) and theoretical (24) aspect. A book collecting much valuable information on the subject has been published in England (25).

In the fatigue-testing field more attention is being paid to elements of construction (26) and stress-concentration effects (27). The strengthening effect in fatigue of cold rolling a surface has been further demonstrated (27). In this connection it is of interest to find that an indentation made with the conical end of a center punch into the surface of a fatigue specimen did not lower the endurance limit (27); whereas a similar-sized countersunk hole (made with a conical end cutter) decreased the endurance limit considerably. In the former case, a cold-working effect is present. An interesting paper, showing the variation of damping with the number of cycles in the case of specimens tested at the endurance limit, has been published recently (28).

A means of testing models under the action of centrifugal force, simulating the action of gravitational force on large structures and geological strata, has been developed (29).

Several papers on the properties of zinc-coated steel were presented at the A.S.T.M. annual meeting at Atlantic City, June 23, 1932.

Other important contributions have been made concerning the strength of cast iron, effect of nitriding, strengthening of machine parts (screws) by cold working, etc.

It is impossible to cover the subject completely in a report of this kind, but it is hoped that at least the directions of progress have been indicated.

Hydrodynamics and Aerodynamics[5]

The problems of turbulence and of fluid resistance are still in the foreground of research work in hydrodynamics.

Turbulence. Considerable work has been done in investigating the mechanisms of turbulence (30). Experiments are being continued regarding the effect of a temperature gradient perpendicular to the direction of flow with respect to the rate of turbulence. By these investigations some light has been thrown on the complicated nature of the air movement within the atmosphere.

A new and very interesting experimental method for studying the internal movement of turbulent flow has been developed (31). By using an ultramicroscope, very interesting results have been obtained, particularly regarding the detail of the flow in the immediate neighborhood of a solid wall.

Fluid Resistance. Another step forward has been taken in the theoretical treatment of frictional resistance due to turbulent flow (32). The theory of fluid resistance developed by L. Prandtl and Th. von Kármán has been checked by extensive tests on turbulent flow through smooth and rough pipes (33).

The problem of fluid flow through bendings of pipes and the loss of pressure involved has been the subject of several papers.

Tests on wind pressure on buildings have been carried out at various laboratories (34).

Experimental work at laboratories handling shipbuilding problems has been focused on the mutual interference between ship and propeller. Several attempts have been made to obtain a more uniform velocity field at the propeller area by applying different types of guide vanes in front of the propeller. A large number of tests have been carried out to investigate the performance of seaplane hulls, particularly regarding the impact pressures due to waves when starting or landing the seaplane.

Cavitation. In connection with shipbuilding problems, considerable research work has been done on cavitation (35). The question of the influence of various shapes of propeller-blade sections on cavitation has been investigated. In addition, a study has been made to determine whether a certain time is necessary for developing cavitation and whether such a time effect may be of importance in engineering problems. Furthermore, an experimental investigation has been carried out to learn how far cavitation actually extends in special cases.

Fluid Flow. Extensive tests on the effect of drawing off parts of the boundary layer of airfoils by suction in order to increase their maxmum lift have been completed (36).

Several tests have been carried out with the purpose of influencing the flow around bodies or through diffusers of large diffuser angles by means of guide vanes in order to enforce potential flow lines. If this could be accomplished, a considerable energy loss due to eddying flow could be avoided.

In connection with wind-tunnel work an interesting paper has been published (37) on the noise produced by the air flowing with high speed through the open throat of a wind tunnel.

Considerable effort has been spent in investigating the influence of the compressibility of air in connection with the performance of thin airfoil sections having speeds near or beyond the acoustic velocity. This problem is of great importance due to the fact that the peripheral speed of a modern airplane propeller sometimes reaches, and even exceeds, the acoustic velocity.

The problem of the resistance of projectiles moving with supersonic velocities has been treated in a theoretical manner (38). The results obtained are in good agreement with experimental data.

Lubrication[6]

Continued interest has been demonstrated in this branch of applied mechanics throughout the past year.

Further work has been done in verifying the applicability of

[4] Compiled by R. E. Peterson.

the hydrodynamic theory of lubrication to actual bearings. The pressure distribution and journal location in the bearing have been measured, and additional evidence of the correspondence of the hydrodynamical theory with experimental observation has been thus collected (39). The effect of end sealing with pressure oil has been investigated experimentally (40). The friction in bearings with concentric and eccentric shafts has been measured. It has been demonstrated that with concentric journals the observed friction is close to the value computed on the basis of the hydrodynamic film, while a deviation was found when the journal ran eccentrically (41).

The analytical treatment of oil films has been furthered in a paper by A. Kingsbury (42), whose numerical tables and diagrams render the theoretical considerations regarding optimum conditions in bearings of assistance in bearing design.

Much attention has been paid to proper methods of testing oils and to the lubricating qualities of oils. A number of oil-testing machines have been proposed (43–45). A method of evaluating lubricating quality by means of the wetting ability of an oil has been proposed before the Lubrication Committee of the Oil Power Division. Lubrication of rolling-mill bearings has continued to attract attention (46, 47). In connection with these bearings, attempts have been made to apply new materials other than bronzes or lignum-vitae. Celoron (48) and micarta have been suggested as heavy-duty bearing materials. Observations on water-lubricated rubber bearings have been published, showing a very low coefficient of friction (49).

The question of wear of metals has brought forth several contributions giving results of experimental investigations (50, 51). Measuring the finish of metal surfaces has been also given attention, and instruments for the quantitative evaluation of finish are being developed and will be reported to the Committee in the near future.

Thermodynamics[7]

During the year just past, several important contributions to the knowledge of the thermal properties of steam have been made both in this country and abroad. Osborne and Stimson (52), reporting on the progress of research at the Bureau of Standards, have described the design, construction, and preliminary operation of a complete new saturated-steam calorimeter with which they are equipped to extend the range of direct measurements of the enthalpy of saturated steam and saturated water. Smith and Keyes (53) have submitted a body of new and more accurate pressure-volume-temperature data covering the range of volumes from 140 to 5 cu cm per gram, of pressures from about 14 to about 360 atm., and of temperatures up to 460 C. Koch (54) has published new measurements of the specific heat (at constant pressure) for superheated steam which have extended the range of pressures from 120 to 240 atm. with temperatures running from saturation to about 450 C. Later, Koch (55) has published an account of his investigations into the behavior of water in the critical region. His measurements of specific heat along the 240-atm. isobar flatly contradict the contention of Callendar that a discontinuity should exist to indicate a considerable value for the latent heat of vaporization at this pressure.

Hausen (56) has attacked the problem of formulating the properties of steam in a new and very interesting manner. Starting with a quantum-theory calculation of C_{p0}, the specific heat for zero pressure, based on optical measurements of the so-called characteristic frequencies for the water molecule, he forms the difference $C_p - C_{p0}$ from available specific-heat data and finds an empirical equation which represents the variation of this difference with temperature and pressure. Applying the well-known thermodynamic relations, he derives equations for the volume and the enthalpy to within certain unknown pressure functions, which are then evaluated from the available experimental measurements of these quantities. The very satisfactory agreement of the resulting formulation with the experimental data marks it as a distinct contribution to steam research.

Keyes and Smith (57), in their efforts to correlate various data on properties of saturated water and steam and from a consideration of various gas-thermometry investigations, have been led to suggest a revision of the accepted value for the absolute temperature of the ice point. Preliminary calculations indicate a value of 273.16 C instead of 273.1 C.

Jakob (58) has given a masterful survey of steam research in Europe and America in a series of four lectures before the University of London. The fourth lecture is of especial interest as it calls attention to the increasing importance of investigations into what Professor Jakob calls the "dynamical properties" of water and steam. These include viscosity, heat conductivity, and coefficient of radiation. E. Schmidt (59) has recently published measurements on the total radiation of steam for temperatures up to 1000 C.

Only briefest mention can be made of other important investigations in the field of thermodynamics. Factors governing the transfer of heat by fluids in motion are being studied with a view toward rationalizing the design of heat-transfer equipment. The actual mechanism of evaporation is being subjected to careful examination. Studies of the mixing process so important in the application of rectification to the separation of various mixtures into their constituents have been described. The measurement of fluid flow by means of orifices and nozzles has been so far advanced as to almost place it on a rational basis.

Of immediate interest to the turbine engineer are the experiments of Burghauser (60), which indicate that friction at the walls of blade passages can only account for a very small proportion of the loss of efficiency actually measured. Keenan (61) has called attention to a paper by Darrieus (62), and, on the basis of it, has recommended certain changes in the customary method of judging the performance of the steam turbine.

Self-Induced Vibrations

By J. G. BAKER,[1] EAST PITTSBURGH, PA.

A "self-induced" vibration is defined as a phenomenon in which the alternating forces furnishing the energy to the vibration are controlled by the motion, in contradistinction to a "forced" vibration, where the force depends on time only. The following are examples of self-induced vibrations: (1) All bowed string or blown musical instruments, (2) the vacuum-tube oscillator, (3) fluttering of valves in air or water lines, (4) nosing of locomotives and street cars, (5) airplane-wing flutter, (6) certain cases of hunting of generators, and (7) certain cases of vibration of transmission lines due to wind. In physics and electrical engineering self-induced vibrations are common and often very useful, whereas most mechanical or machinery vibrations do not fall in this classification, since unbalance forces and other alternating forces unaffected by the motion are very common. Kimball and Newkirk[2] were the first to call attention to and to explain self-induced vibration phenomena capable of causing serious mechanical difficulties. This paper discusses methods of studying self-induced vibrations and describes several representative cases that have been studied by the author and his colleagues in the last few years.

1 Introduction

A PHENOMENON in which a force causes a vibration and the vibration controls the force will be called herein a self-induced vibration. Before the time of modern machinery, this type of vibration was most important. Except for the piano and other instruments in which the vibrations are caused by suddenly applied or suddenly removed forces, practically all musical instruments produce sound by means of self-induced vibrations; for instance, the flute, organ, clarinet, and cornet.[3]

Many toys that have appeared on the market recently are excellent examples of this type of motion.[4] Nearly all pendulum and balance-wheel oscillations in clocks and other timing devices are self-induced vibrations. The doorbell, the automobile horn, the oscillating vacuum-tube circuit, and the power-driven tuning fork are apparatus that function on account of self-induced vibrations.

To the electrical engineer who has encountered the vacuum-tube oscillator and the d-c to a-c inverter, the phenomenon of self-induced vibration has been duly emphasized. To the mechanical engineer, on the other hand, the importance of this type of motion has been obscured somewhat by the great attention he has been required to give to resonance phenomena.

In the last few years several serious cases of self-induced vibration trouble have appeared in the field of mechanical engineering. It was therefore thought appropriate to review the subject with the point of view of the mechanical engineer, and to describe and attempt to explain some typical self-induced vibration phenomena.

2 General Relations

The solution of the problem in general consists in answering the following questions:

1 Given a system of masses, flexibilities, etc., will the system be capable of self-induced vibrations? And if so:
2 How will it vibrate—e.g., what will its mode of vibration be?
3 What frequency and what amplitude will it have?
4 To what extent may the vibration be affected? and
5 By what means?

The system in question may or may not be linear. Consider first that it is linear—viz., that each force in the system is proportional to the displacement or to the derivative of the displacement of some mass of the system. Let the masses be $m_1, m_2, m_3, \ldots . m_n$. Let the displacements of these masses be $x_1, x_2, x_3, \ldots . x_n$. With all displacements held permanently at zero except x_1, let the force on m_1 (due to the displacement x_1) be $-k_{11}x_1$. Let the force on m_2 (due to the displacement x_1) be $-k_{21}x_1$, etc. With all the displacements held at zero except x_1, and with x_1 zero but the first derivative dx_1/dt not zero, let the force on m_1 (due to the velocity dx_1/dt) be $-c_{11}(dx_1/dt)$ and the force on m_2 be $-c_{21}(dx_1/dt)$, etc. Finally, considering the inertia as a force, the inertia force of m_1 will be $-m_1(d^2x_1/dt^2)$. Due to the same acceleration, the force on m_2 will be $-m_{21}(d^2x_1/dt^2)$. Thus the first digit of the subscript indicates upon which mass the force acts, and the second digit indicates by which displacement the force is caused. For example, $-c_{nm}(dx_m/dt)$ would mean a force on mass m_n due to the velocity dx_m/dt of mass m_m. From the conditions of equilibrium we may write one equation for each mass, as follows:

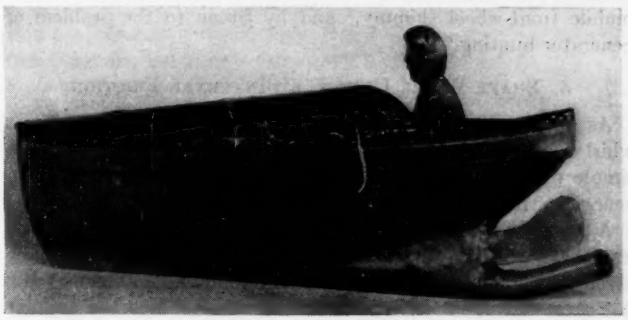

Fig. 1 Toy Boat

[3] A. B. Wood, "A Textbook on Sound," p. 175.

[4] They consist mostly of animals of various shapes having the legs freely pivoted to the body. When put on a floor and pulled forward by means of a string, the toy does not move forward uniformly, but walks in definite steps, accompanied by a sideways oscillation. Another interesting toy is the "put-put boat" shown in Fig. 1 and explained later in the paper.

Contributed by the Applied Mechanics Division of The American Society of Mechanical Engineers and presented at the Applied Mechanics Meeting, New Haven, Conn., June 23 to 25, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

$$\left.\begin{aligned} m_{11}\frac{d^2x_1}{dt^2} + c_{11}\frac{dx_1}{dt} + k_{11}x_1 + m_{12}\frac{d^2x_2}{dt^2} + c_{12}\frac{dx_2}{dt} + k_{12}x_2 \\ + m_{1n}\frac{d^2x_n}{dt^2} + c_{1n}\frac{dx_n}{dt} + k_{1n}x_n = 0 \\ m_{21}\frac{d^2x_1}{dt^2} + c_{21}\frac{dx_1}{dt} + k_{21}x_1 + m_{22}\frac{d^2x_2}{dt^2} + c_{22}\frac{dx_2}{dt} + k_{22}x_2 \\ + m_{2n}\frac{d^2x_n}{dt^2} + c_{2n}\frac{dx_n}{dt} + k_{2n}x_n = 0 \\ m_{n1}\frac{d^2x_1}{dt^2} + c_{n1}\frac{dx_1}{dt} + k_{n1}x_1 + m_{n2}\frac{d^2x_2}{dt^2} + c_{n2}\frac{dx_n}{dt} \\ + k_{n2}x_n + m_{nn}\frac{d^2x_n}{dt^2} + c_{nn}\frac{dx_n}{dt} + k_{nn}x_n = 0 \end{aligned}\right\} \quad \ldots [1]$$

Equations [1] are representative of any linear system. The complete solution of [1] for x_n in general will be the sum of a number of terms of the form:

$$At^m e^{at} \sin(\omega t + \theta) \quad \ldots [2]$$

in which A and θ are constants determined by the initial conditions of the system; t is time; m is 0, 1, 2, ... (usually zero), and ω and a are constants determined by the parameters of the system in question. If any term of this solution has a positive value of a, the system is evidently capable of self-induced vibrations.

The foregoing method of attack of the problem has been used extensively, among others by Lord Rayleigh in determining the stability of certain hydrodynamic flows, and by the electrical engineers in determining the conditions for oscillation of vacuum-tube circuits. Applications to mechanical problems have been made by Becker, Fromm, and Maruhn on the problem of automobile front-wheel shimmy,[5] and by Stone to the problem of generator hunting.[6]

3 Shaft Whirl Caused by Internal Friction

As an example of the foregoing treatment, the case of shaft whirl due to damping in a rotating shaft will be considered.[7] A simple explanation of the effect can be given by means of an energy consideration.

A perfectly balanced disk m (Fig. 2) is mounted on the weightless shaft S. The latter is straight without load. Let m be given a constant angular speed ω. The angular displacement of a dot d on m will be ωt, where t is the time. Since the angular acceleration of the rotor is zero and since the shaft is attached

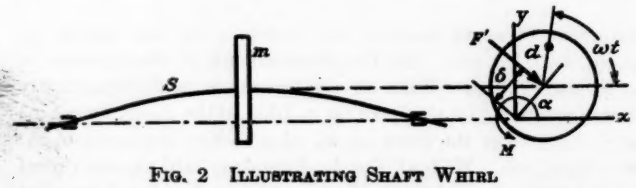

Fig. 2 Illustrating Shaft Whirl

at the center of mass of the rotor, neglecting air friction and assuming m to be mounted symmetrically between the bearings, the only reaction m can exert on S is a *force*. Let α be the angular displacement of the center of the disk m. The angular velocity of this point will then be $d\alpha/dt$. With a given radial displacement of the center of m, the material of S is undergoing alternating stresses at a frequency proportional to $\omega - (d\alpha/dt)$.

Kimball's experiments[7] indicate that the energy absorbed per cycle of alternating stress is independent of the frequency of stress alternation and is proportional to the square of the stress. Other experiments[8] are not in all cases in agreement with the latter of these conclusions; however, for the purpose at hand we shall assume both of Kimball's conclusions to be correct. Imagine that we are rotating at an angular velocity $d\alpha/dt$ and observing the shaft from the right end as represented in Fig. 3. We shall see the dot d rotating at an angular velocity $\omega - (d\alpha/dt)$. Each revolution we observe will represent one cycle of change in stress of any particle of the shaft material. The energy dissipated during this cycle will be proportional to the displacement squared, thus:

$$E = 2\pi D\delta^2 \quad \ldots [3]$$

where E is the energy dissipated per cycle and D is a constant of proportionality determined by integrating over the shaft. This energy must be supplied by an external moment M applied to S or m, if ω is to be kept constant.[9] From the conservation of energy in the shaft, we have:

$$M \cdot 2\pi = 2\pi D\delta^2 \quad \ldots [4]$$

But M must have a reaction. A reaction at the bearing would mean more energy dissipated and serve only to make M larger than represented in [4], We have also seen that m cannot exert a *moment*. It is concluded. then, that the reaction of M must be a force F' exerted by m on S perpendicular to the direction of the deflection δ; and the shaft exerts a force F on m equal and opposite to F'. So that, from [4]:

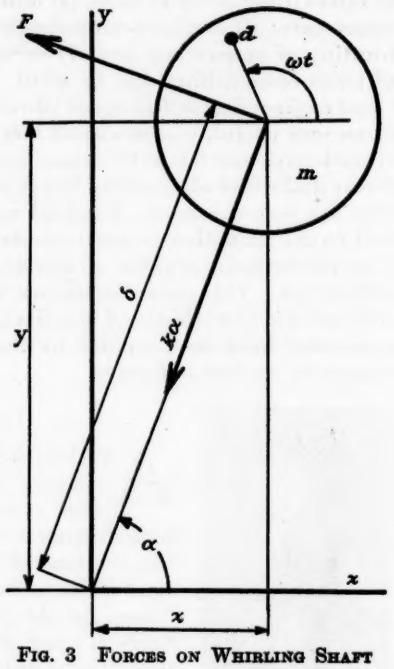

Fig. 3 Forces on Whirling Shaft

$$F\delta = D\delta^2$$

or

$$F = F'v = D\delta \quad \ldots [5]$$

If the shaft be rotated so that the frequency $\omega/2\pi$ is higher than the natural frequency of the rotor on the shaft, a free vibration of the center of M such that δ is constant and $d\alpha/dt$ is positive will result in F being in the direction of motion of the center of m. Thus F will maintain or increase this type of motion of m. On the other hand, if the rotational frequency $\omega/2\pi$ is lower than the natural frequency, it is impossible for F to act wholly or partly in the direction of motion. F therefore cannot maintain a vibration with $\omega/2\pi$ below the natural frequency.

The foregoing statements are better demonstrated by the

[9] The conclusions are not altered when the shaft is allowed to slow down freely.

following analysis, similar to that described under section 2. In Fig. 3 the rotor is shown isolated, while the effect of the shaft is represented by the elastic force $k\delta$ and the tangential force F. Let x and y be the coordinates of the rotor center. The equilibrium equations in the x and y directions give:[10]

$$\left.\begin{aligned} -F\sin\alpha - kx &= m\frac{d^2x}{dt^2} \\ F\cos\alpha - ky &= m\frac{d^2y}{dt^2} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [6]$$

where m indicates the mass of the rotor. From [5] and [6]:

$$\left.\begin{aligned} m\frac{d^2x}{dt^2} + kx + Dy &= 0 \\ m\frac{d^2y}{dt^2} + ky - Dx &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [7]$$

which are seen to fit the general scheme [1].

The solution of [7], derived in the Appendix, is:

$$\left.\begin{aligned} y &= e^{nt}[C_1\cos qt + C_2\sin qt] \\ &\quad + e^{-nt}[C_3\cos qt + C_4\sin qt] \\ x &= e^{nt}[C_1\sin qt - C_2\cos qt] \\ &\quad - e^{-nt}[C_3\sin qt - C_4\cos qt] \end{aligned}\right\} \quad \ldots\ldots [8]$$

C_1, C_2, C_3, and C_4 are constants of integration determined by the initial conditions, while n and q are given by:

$$n = \sqrt{\frac{-k + \sqrt{k^2 + D^2}}{2m}} \quad \ldots\ldots\ldots\ldots [9]$$

$$q = \sqrt{\frac{k + \sqrt{k^2 + D^2}}{2m}} \quad \ldots\ldots\ldots\ldots [10]$$

Usually D is small compared to k, in which case:

$$n = \frac{1}{2}\frac{D}{\sqrt{km}} \quad \ldots\ldots\ldots\ldots [9a]$$

$$q = \sqrt{k/m} \quad \ldots\ldots\ldots\ldots [10a]$$

so that the motion in any single direction is a vibration at the natural frequency $\frac{1}{2\pi}\sqrt{k/m}$ of the rotor on the shaft, which of course corresponds to the ordinary critical or whirling speed. The second terms of Equations [8] will disappear with increasing time, so that they can be neglected. The whirling amplitude $\delta = \sqrt{x^2 + y^2}$ can then be calculated with the help of [8]:

$$\delta = e^{nt}\sqrt{C_1^2 + C_2^2} = \text{const}\, e^{nt} \quad \ldots\ldots\ldots [11]$$

Thus the result [8] shows that the motion will be a rotation of the center of m at a radius δ, at a frequency $q/2\pi$ *in the same direction* as the rotation of the shaft material. It should be kept in mind that Equations [6] only apply if $\omega - (d\alpha/dt)$ or $\omega - q$ is positive—that is, for running speeds above the critical speed. For the case of a running speed below the critical speed, the phenomenon cannot be described by a single set of differential equations, because the direction of F will depend on the direction of whirl. A qualitative examination, however, will show that, below the critical speed, the shaft damping effect retards any vibratory movement that may be started.

[10] The deflection due to gravity introduces a complication in the analysis which would obscure somewhat our present purpose. Taking gravity into account, Equation [6] applies if the dynamic deflections are large compared to the gravity deflections. Practically, gravity helps in that the shaft will not vibrate due to elastic hysteresis until an initial disturbance occurs, producing deflections at least as large as the gravity deflection. Thus in passing through a critical speed with a horizontal shaft having appreciable internal damping, we may expect the shaft to continue to vibrate at its natural frequency even though the rotating speed of the machine is far above the speed corresponding to the natural frequency; but if in any way the vibration can be momentarily reduced to below the value of the static deflection, the vibration will be damped out.

4 Amplitudes of Vibration

It may be concluded from [2] that self-induced vibrations in linear systems can never be of constant amplitude except in the trivial case corresponding to $a = 0$ in [2]. The inverted statement is perhaps more important: namely, any vibrating system with self-induced vibrations of constant amplitude is not linear, with the same exception as before.

In the case of non-linear systems, the answers to the questions in a previous paragraph are more difficult. Some non-linear systems can, with very good accuracy, be treated as linear for small vibrations; in fact, this is perhaps the most common use of the linear treatment. For this type of system, the question, Will the system start to vibrate? may be answered.

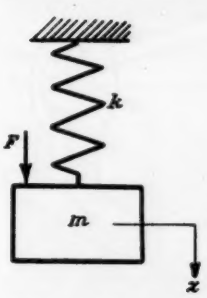

Fig. 4 Scheme of Pendulum Clock

The building up of self-induced vibrations in non-linear systems has been studied with non-linear differential equations for some cases by Van der Pol.[11]

5 Frequency of Vibration

Consider a mass m connected to a linear spring k, as shown in Fig. 4. Let this mass be kept in a state of steady oscillation by impulses F timed with its position. Under these conditions, the displacement x can be represented by:

$$x = S_1\sin\omega t + S_2\sin 2\omega t + R_2\cos 2\omega t + S_3\sin 3\omega t \ldots [12]$$

and the impulse force F can be written as:

$$F = A\sin\omega t + B\cos\omega t + A_2\sin 2\omega t + B_2\cos 2\omega t \ldots [13]$$

S_1, S_2, etc., A, B, etc., are constants. The ratio A/B depends on the timing of the impulses with respect to the motion; A_2, B_2, etc., will depend on A and B and on the nature of the impulses. S_1, S_2, R_2, etc., are found in terms of A, B, A_2, B_2, etc., by substitution of [12] and [13] in

$$m\frac{d^2x}{dt^2} + c\frac{dx}{dt} + kx - F = 0 \quad \ldots\ldots [14]$$

which expresses the equilibrium of the mass. From this substitution follows:

$$\left.\begin{aligned} A &= -mS_1\omega^2 + kS_1 \\ B &= cS_1\omega \end{aligned}\right\} \quad \ldots\ldots [15]$$

Dividing these by each other and solving for ω:

$$\omega = \frac{-\frac{A}{B}c \pm \sqrt{\left(\frac{A}{B}c\right)^2 + 4mk}}{2m} \quad \ldots\ldots [16]$$

Expressing the radical of [16] by means of the binomial

[11] B. Van der Pol, "On Relaxation Oscillations," *Phil. Mag.*, vol. 2 (1926), p. 978.

theorem and neglecting higher-order quantities, [16] reduces to:

$$\omega = \frac{-A}{B} \cdot \frac{c}{2m} + \sqrt{\frac{k}{m}} \quad \text{[17]}$$

In words, the frequency of the self-induced vibration is determined by the timing of the impulses and depends only on the phase between the *fundamental* component of the motion and the *fundamental* component of the impulse.

Equation [17] therefore expresses the deviation from the natural frequency caused by the impulses. In case $A = 0$ from [13], the impulse is proportional to $\cos \omega t$, which, comparing with [12], is seen to be in phase with the velocity dx/dt. In that case [17] shows that the mass vibrates at its natural frequency. In a real case the actual impulse has both A and B components; the A component doing work and not disturbing the frequency, while the B component does not perform work and only modifies the frequency.[12]

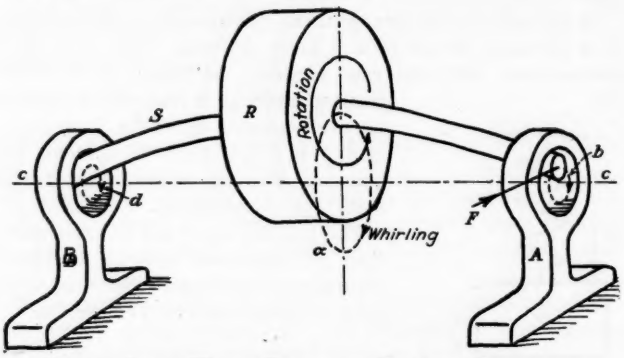

FIG. 5 SHAFT WHIRL CAUSED BY BEARING CLEARANCE

6 APPLICATION TO ACCURATE CLOCKS

The pendulum of a clock is an illustration of the foregoing case. The energy lost in friction is supplied by impulses timed with the position of the pendulum. The difference between the frequency of swing and the natural frequency of the pendulum is given by [17]. This difference is very small and can ordinarily be neglected unless great accuracy is desired. For extreme accuracy it is apparent that the quantity $-\frac{A}{B} \cdot \frac{c}{2m}$ must be kept constant as well as the natural frequency $\sqrt{\frac{k}{m}}$.

7 SHAFT VIBRATIONS DUE TO BEARING CONDITIONS

Kimball and Newkirk[2] have experimented with vibrations occurring at or near double the ordinary critical speed in shafts with generously lubricated bearings. In the phenomenon they describe, the forces furnishing the energy to the vibration come from oil pressures in the bearings. These oil pressures are dependent on the eccentricity of the journal with respect to the bearing. Although their explanation is based on the assumption that the shaft-center displacement in the bearing largely depends on the shaft speed, it is probably also somewhat dependent on the bearing load, and hence on the rotor displacement. If this is the case, the phenomenon is doubtless somewhat self-induced.

Stodola describes a shaft vibration with moderately lubricated bearings caused by a "periodical breaking down of the oil film."[13] A breaking down of the oil film is evidently affected by the load on the bearing, so that with the same reasoning as before, the phenomenon is probably classified correctly as a self-induced vibration.

With poorly lubricated bearings or bearings with considerable clearance, another type of self-induced vibration may be expected, which will now be discussed.

Fig. 5 represents a set-up with two rigid bearings A and B carrying the shaft S, on which is mounted the balanced rotor R. Without distortion, the axis of the shaft is the straight line c-c. With the shaft rotating counterclockwise, imagine the rotor center whirling in the circular path α clockwise. With only a small amount of oil or with large bearing clearances at any instant, the centers of the ends of the shaft will be displaced in the same direction as the center of the rotor, so that the shaft ends will move in the circles b and d, respectively, in a clockwise direction. Due to friction, the bearing will exert on the shaft a moment and a force F acting perpendicularly to the instantaneous displacement of the shaft center and in the direction of its movement. The motion imagined will then have work done upon it equal to $F = 2\pi b$ per cycle of whirling per bearing, where b

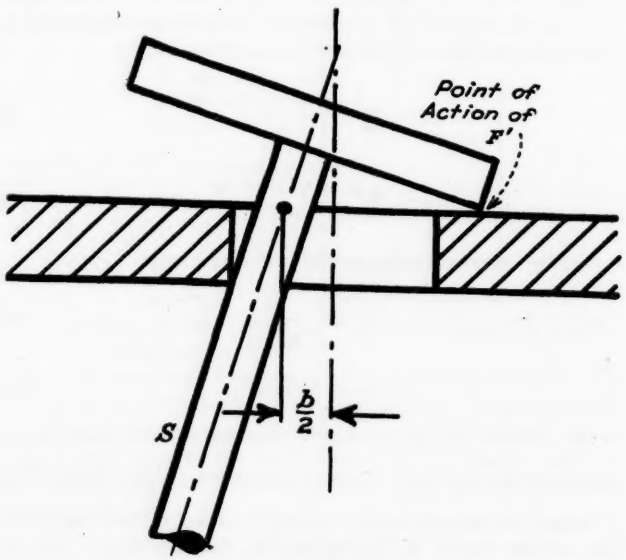

FIG. 6 THRUST BEARING

is the diameter of the circle b, which is approximately equal to the clearance between shaft and bearing. If this energy is sufficient to supply the damping involved in the whirling motion, the latter will usually be maintained. The whirling frequency will be independent of the rotational speed and will be at approximately the natural frequency of the set-up. The whirling may happen at any shaft rotational speed above a certain very low limit. This lower limit is apparently such that the direction of relative motion in the bearing at the contact point between shaft and bearing is zero, due to the whirling action and rotational action, in this respect, just canceling each other. This speed obviously bears the ratio δ/D to the speed corresponding to the natural frequency, which is the ordinary critical speed. δ is the diametral clearance and D is the bearing diameter.

Practically the same phenomenon can also occur in thrust

[12] The amplitude of the motion can be calculated from Equation [15]:

$$S_1 = -\frac{A}{m\omega^2 - k} = \frac{B}{c\omega}$$

or denoting by $F_1 = \sqrt{A^2 + B^2}$ the magnitude of the fundamental component of the impulse, this can be written as:

$$S_1 = \frac{F_1}{\sqrt{(m\omega^2 - k)^2 + c^2\omega^2}} \quad \text{[18]}$$

Expressions for the higher harmonics of the motion S_2, R_2, etc. can be found in a similar manner.

[13] "Steam and Gas Turbines," vol. 1, p. 491, New York, 1927.

bearings (Fig. 6). During the whirling motion, one point of the thrust-bearing runner will have greater pressure than other points, resulting in a greater tangential friction force at that point. If there is at the same time clearance in the journal bearing below, this tangential friction force can drive the shaft in its whirling motion and thus sustain the vibration.

8 Thrust-Bearing Model

The model shown in Figs. 7, 8, and 9 was constructed to study this effect. Dynamically the model was designed to simulate a vertical water-wheel generator installation, in which trouble of this sort was suspected. The rotor R is mounted in the center of the long shaft S (Fig. 7), and carried in the bearings A and B, which are supported by three radial coil springs each. The top coil springs P are held by the mass M, which simulates the inertia of the electric-generator frame. The lower springs Z are attached to the foundation. Both sets of springs serve to allow relative lateral motion between the shaft and the frame, corresponding to the clearance in the guide bearings. The springs U are attached to the bearing B and to a screw I, which can be moved up or down. This arrangement allows a variation in the thrust on the thrust bearing T. The mass M is held in position by three long vertical columns. These columns prevent M from rotation about any horizontal axis and from vertical motion, but offer little resistance to horizontal translation or rotation about a vertical axis. They are intended to simulate the flexibility of the generator frame. The model has two important modes of vibration: one in which the mass centers of M and R are practically stationary and the shaft moves in such a way that its center line describes a cone; and the other in which the rotor moves always in a direction opposite to that of the motion of the stator, both moving in circles (see Fig. 7). The vibration is usually purely in one mode or the other, depending on starting conditions. It can be changed from a given mode to the other by holding the shaft with the hand at an elevation which introduces damping in the existing mode, but not in the other. In any case, the whirling is at constant amplitude and frequency (the latter being a natural frequency), almost entirely independent of the speed of rotation of the shaft, except that the direction of the whirling motion is the same as that of the shaft rotation.

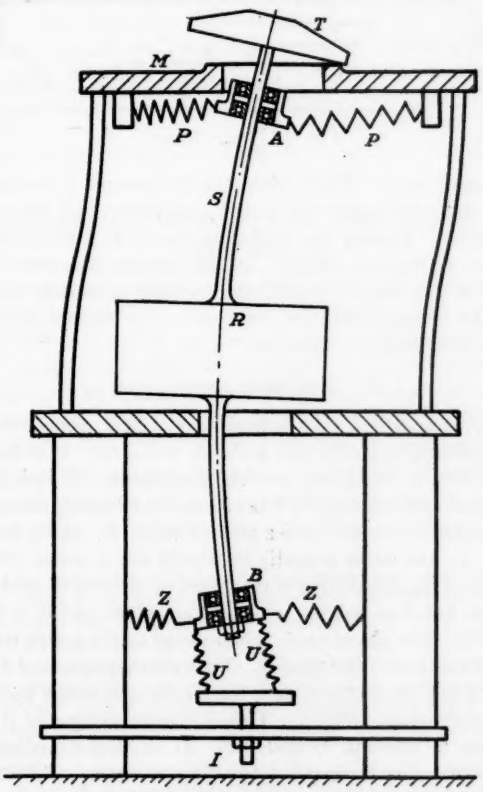

Fig. 7 Schematic View of Model

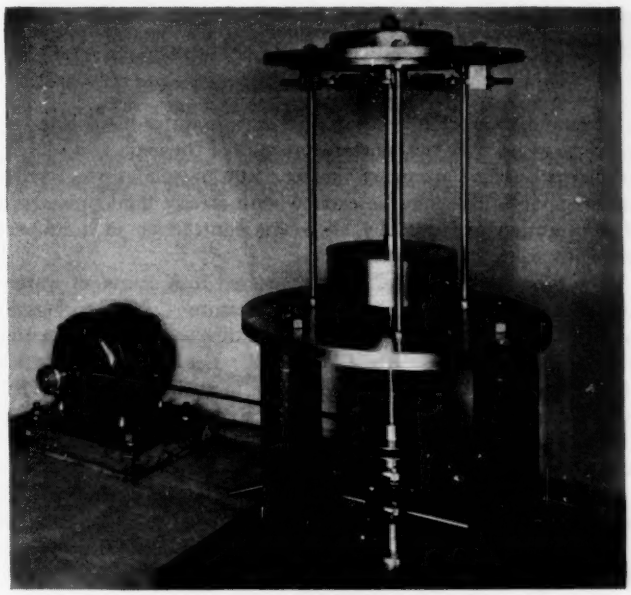

Fig. 8 Model for Demonstrating Vibration Caused by Thrust Bearing

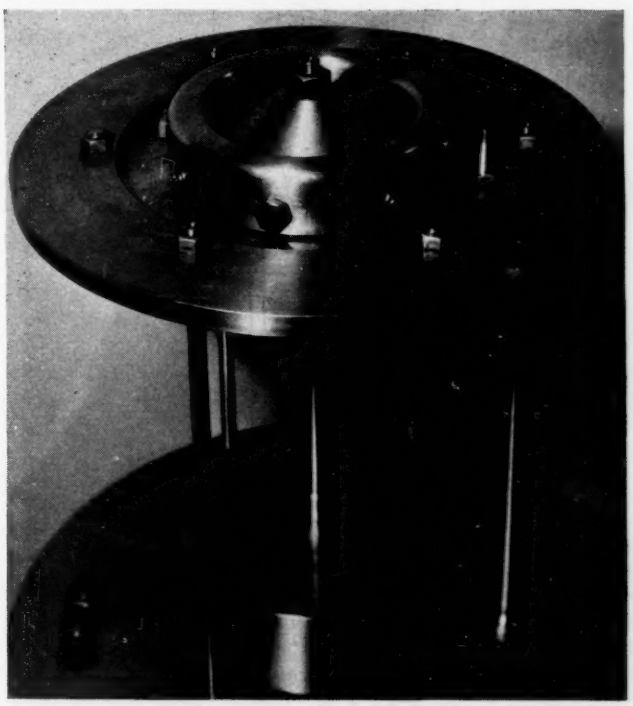

Fig. 9 Detail of Model

The whole phenomenon stops when the thrust on the bearing T is relieved. It was also impossible to make the model vibrate with thrust on the bearing T when it was arranged with an equalizer in such a way that relative angular motion about any horizontal axis between the thrust-bearing runner and stator was prevented. This latter arrangement is shown in Fig. 9. The

pins, of which one is removed, prevent the equalizer from functioning when in place.

9 Periodic Flow Phenomena

It is well known that violent vibrations in water mains can be produced with only the constant pressure of the main as a source of energy. There are many similar conditions under which self-induced vibrations may be excited with steady fluid pressures. The vibration produced by an elastic contraction in a rubber water tube is a good illustration.

The tube shown in Fig. 10 is connected to a source of water pressure p_1 and discharges at constant pressure p_3. The springs S and T force the cylinders A and B on the tube to furnish an elastic contraction that will be denoted by AB. Let d be the variable dimension of AB, and p_2 the pressure immediately below AB. The spring forces are so adjusted that with $d = 0$ and $p_2 = p_3$, there is a slight tendency for d to increase—i.e., for AB to open a small amount.

Assume p_1 is constant. This condition may be realized either by the use of a large container immediately above AB as a source of pressure, or if the elasticity of the tube above AB prevents pressure changes due to flow variation.

Taking as the starting condition $p_2 = p_3$, zero velocity of the water column below AB, and $d = 0$, d will of course immediately increase, making $p_1 = p_2$ and $p_2 > p_3$, with consequent further

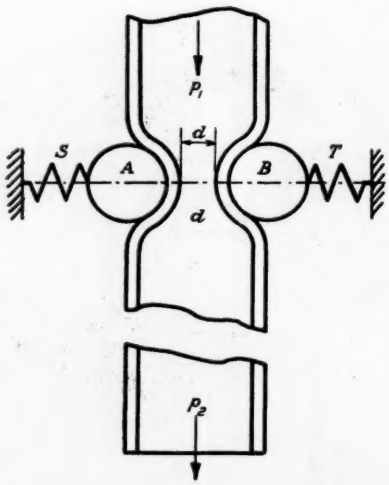

Fig. 10 Vibrating Water Column in Rubber Tube

increase of d and acceleration of the column of water below AB. When the velocity at the outlet increases to nearly that corresponding to p_1, the acceleration of the water column below AB disappears, and p_2 becomes less than p_3 on account of higher velocity at the contraction than at the outlet, so that the d immediately becomes zero. This causes deceleration of the water column below the contraction, which results in p_2 remaining less than p_3 and d remaining zero. The water flow now continues outward until sufficient time elapses for the difference $p_3 - p_2$ to stop the water column and reverse it. It has been found experimentally that p_2 easily becomes small enough to cause collapse of the tube walls. The reverse flow soon builds up the pressure p_2 to the value where $p_2 = p_3$, and the cycle repeats.

Evidently the time required to complete a cycle, as described, depends primarily on the time necessary to start and stop the column of water below AB. In view of this, the experimental fact that the period of such pulsations increases with increase in the water column length below AB is understood.

10 Air Horn

The operation of an air horn is another good illustration of self-induced vibrations of flow. An air pressure p_1 is applied to the pipe Q of the horn (Fig. 11). The air is throttled through the orifice A into the annular chamber C, where the pressure is p_2. The diaphragm D acts as a valve on the seat S. For simplicity of explanation assume that the pressure p_2 varies by an amount which is small compared to either $(p_1 - p_2)$ or $(p_2 - p_3)$, p_3 being atmospheric pressure. With this assumption, the flow through A is constant and the rate of flow into the horn from C depends only on the opening between D and its seat S. With D vibrating, the pressure p_2 will depend on the amount of air present in C. This amount at any instant depends on the history of the

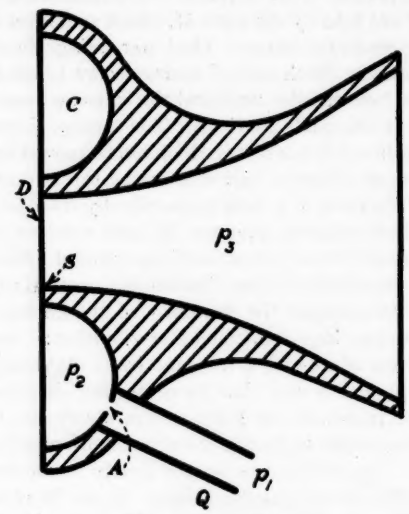

Fig. 11 Air Horn

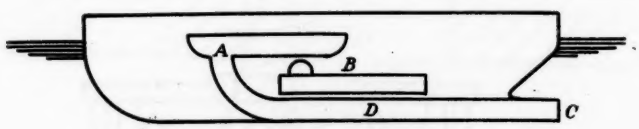

Fig. 12 Toy Boat

displacement of D. Thus while the diaphragm is moving outward, it just previously was closed completely, and the pressure in C is great. During the closing motion of D it previously was wide open, so that p_2 is small. In this manner it is seen that the pressure in C is greater during the opening operation of D than during the closing operation, so that a net amount of work is available to maintain a vibration.

11 Toy-Boat Propulsion

A year or so ago a very ingenious toy boat appeared in the stores, a photograph of which is shown in Fig. 1. It is described here because it furnishes another illustration of periodic-flow self-induced vibrations as well as of other interesting phenomena.

The source of energy is the alcohol lamp B, which heats the chamber A; the latter is partly or wholly full of water (Fig. 12). The top of A is a diaphragm constructed of bimetal in such a way that when hot it is bulging upward and when cold it is bulging downward. The chamber A is connected to the water astern of the boat by means of the tube D. With the diaphragm of A down, B heats A and its contents until the diaphragm snaps upward to its hot equilibrium position. This change in volume of A draws cold water in through D and cools A, so that the diaphragm snaps down again, forcing out the surplus water. With further heating, the cycle repeats several hundred times per minute.

During the time water is flowing *out*, it forms a "jet" issuing from C, which pushes the boat forward by its reaction. When the water is going *in*, however, the point C is a "sink;" the water is attracted to it from all sides, so that no retarding reaction is felt by the boat.[14] In total, therefore, there is a forward driving force during a full cycle. It is seen that the steady source of energy of the flame is inverted into the alternating flow, which in turn is rectified hydrodynamically into a unidirectional effect, driving the boat forward.

12 Transmission-Line Vibration Due to Wind and Sleet

There are two types of transmission-line vibrations of importance caused by a transverse wind: (1) Vibrations in moderate winds at rather high frequency due to "Kármán" vortices generated on the lee side of the wire. This phenomenon is to some extent self-induced in that the vibrating motion of the wire alters the flow in such a manner that vibrations may be sustained at frequencies considerably different from the Kármán frequency as determined without vibration. (2) Vibrations at very low frequency when the wires are loaded with sleet. This phenomenon, which is a typical self-induced vibration, has been explained by Den Hartog.[15] The explanation is briefly as follows: The resultant force of a wind on a round wire is always in the direction of the wind. On the other hand, when the cross-section of the wire is unsymmetrical, as may occur with sleet loads, the resultant force in general is not in the direction of the wind. For example, in Fig. 13, a rectangular section is shown. With a wind blowing in the direction a-a, the resultant wind force will be F_a. However, if the wind blows in the direction b-b, the resultant force will be F_b. If the wind is blowing in the direction a-a and the wire is given a velocity upward, the wind relative to the conductor will be in a direction b-b, and, as before, the resultant force will be F_d, which has an upward component. Thus, on account of the upward motion, an upward force is brought into play. Any vertical movement will be encouraged, so that self-induced vibrations will take place if the damping is not too great. Many sections do not have this characteristic; e.g., for a wind in the direction b-b the resultant force F_b might have a downward component, in which case vibration would be damped by the wind. Den Hartog gives a simple experimental means for testing this effect and an analysis whereby the stability of any cross-section can be determined from its aerodynamic drag and lift curves.

13 Self-Induced Vibrations From Fixed High-Frequency Disturbances

In all examples discussed so far, the source of energy maintaining the vibrations was invariably unidirectional or steady. There exists, however, another group of phenomena whereby a vibration approximately at a natural frequency may be self-sustained by an energy source which is alternating with a frequency mostly much higher than the frequency of the self-induced vibration. To be sure, this does not take place in purely linear systems; some pronounced non-linearity is necessary.

Typical examples of this type are shown in Fig. 14, (a) and (b). In Fig. 14(a), the magnet B is excited by a constant-frequency alternating current. The iron block A is mounted so that it may oscillate freely. If the motion of A is small compared to the total air gap, the force between A and B will be proportional to the square of the current in B and independent of the position of A. With a current frequency f, the frequency of the force would be $2f$. On the other hand, if the displacement of A is large with respect to the total air gap, the magnetic force depends a great deal on the position of A.

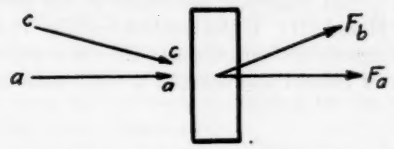

Fig. 13 Forces on Vibrating Transmission Line

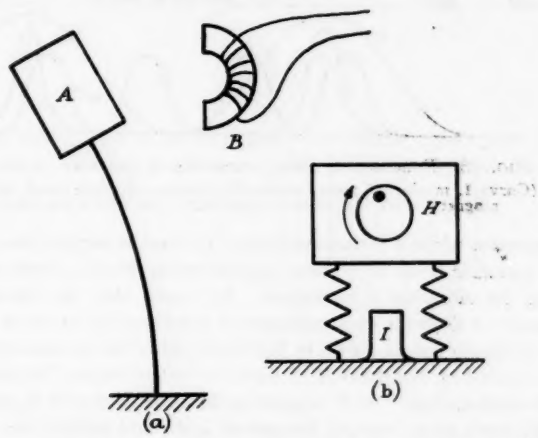

Fig. 14 Two Cases of Vibration Caused by High-Frequency Disturbance

Assume that the vibration of A is steady, represented by:

$$x = E \sin \omega t + F \cos \omega t + E_2 \sin 2\omega t + F_2 \cos 2\omega t \ldots E_n \sin n\omega t + F_n \cos nt$$

Let the periodic force on A due to the magnet B be $G \sin \gamma t$ when x is held constant. The magnetic force P at any instant will then be:

$$P = G \sin \gamma t \cdot f(x)$$

where $f(x)$ means a function of x. Since x is a periodic function, $f(x)$ will also be a periodic function, the lowest frequency component being the same as the frequency $\omega/2\pi$ of x. Therefore [19] may be written:

$$P = G \sin \gamma t[C_1 \sin \omega t + D_1 \cos \omega t + C_2 \sin 2\omega t + D_2 \cos 2\omega t \ldots + C_n \sin n\omega t + D_n \cos n\omega t] \quad \ldots\ldots\ldots [20]$$

G, C_1, D_1, $\ldots$ C_n, D_n, etc., are constants. Equation [20] can be changed algebraically to a sum of terms of the form $F \sin (\gamma \pm n\omega)t$.

In order to furnish the losses of the vibration, there must be an energy-supplying force on A of the same frequency as x; hence ω must be such that

$$(\gamma \pm n\omega) = \omega$$

or

$$\gamma = (1 \pm n)\omega \quad \ldots\ldots\ldots\ldots\ldots [21]$$

This indicates that γ cannot be less than and must be an even multiple of ω.

Satisfying [21] results in the magnetic force having the proper

[14] It is an experimental fact that the pressure of water issuing from a tube under water is the static pressure of the water at the level of the tube and that the pressure of water being sucked in under similar conditions is less than the static pressures by an amount corresponding to the velocity with which it is sucked in. This difference is well known to be the effect of the viscosity of the water at the surfaces of the tube. A brief study of the equilibrium of the water in the boat shows that the foregoing pressure cycle results in an average forward force on the boat hull.

[15] "Transmission-Line Vibration Due to Sleet," paper presented at the A.I.E.E. Summer Convention, Cleveland, June 20, 1932.

frequency to do work on the motion of A. This in itself, however, it not sufficient. The phase and stability requirements must be fulfilled if the motion is to be sustained. Physically the phenomenon can be understood by studying Fig. 15. Curve I indicates the motion of A; curve II is the magnetic force which this motion would cause if the magnet were excited by a constant current; curve III indicates the magnetic force variations due to the alternating current for a constant position x of A. Clearly the actual magnetic attraction is the product of the ordinates of II and III. If the condition of Fig. 15 is satisfied—i.e., if the magnetic-attraction curve III has a negative slope at the moment of nearest approach, it is clear that the attraction

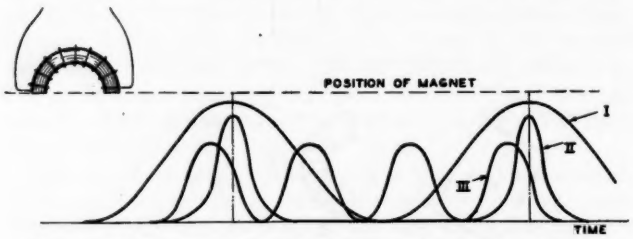

FIG. 15 FORCES AND DISPLACEMENTS IN SYSTEMS OF FIG. 14
(Curve I, motion of mass; curve II, force on moving mass with d-c magnet; curve III, force on stationary mass with a-c magnet.)

is greater while A is moving toward B than during the time that A is receding from B. Then, consequently, work is done upon A and its vibration is sustained. It is seen that the whole phenomenon depends on a pronounced non-linearity in curve II.

A similar case is shown in Fig. 14(b), where an unbalanced rotor is rotated on the mass H at high above the natural frequency of H on its springs. If H is given an impulse so that it moves back and forth at its natural frequency $\omega/2\pi$ and strikes the stud I, it will receive impulses that can be represented by [20], and hence the same conclusions can be drawn as before.[16] The details of the impact on the stud must be such that in the first half of it the force on H caused by the rotating unbalance tends to drive H into the stud, whereas during the other, receding, half of the impact, the unbalance force acts in the direction away from the stud. In this manner it is clear that energy is put into the slow vibration by means of the fast rotation.

This knocking phenomenon probably occurs often in high-speed machinery if there is any lost motion. In this way a vibration near a natural frequency may be maintained by a rotation far above this natural frequency.

14 CONCLUSIONS

1 Self-induced vibrations in linear systems cannot be of constant amplitude (except in trivial cases); for steady finite amplitudes some non-linearity in the system is required.

2 For linear as well as for non-linear systems, the possibility of self-induced vibration can be determined by calculation of the small vibrations of the system, the criterion being a positive exponent of the e-functions appearing in the solution. This is explained in section 2.

3 While most cases of self-induced vibration are caused by steady sources of energy, another type of self-sustained motion can occur which is kept up by an alternating-energy source of high frequency. Two cases of this type are discussed in section 13.

Appendix

SOLUTION OF EQUATIONS [7]

The equations in question are:

$$\left.\begin{aligned} m\frac{d^2x}{dt^2} + kx + Dy = 0 \\ m\frac{d^2y}{dt^2} + ky - Dx = 0 \end{aligned}\right\} \quad [7]$$

Eliminating x by differentiation, we obtain:

$$\frac{m^2}{D}\frac{d^4y}{dt^4} + \frac{2mk}{D}\frac{d^2y}{dt^2} + \left(\frac{k^2}{D} + D\right)y = 0 \quad [22]$$

Assuming $y = e^{rt}$ substituting in [22], and canceling out the exponentials:

$$r^4 + \frac{2k}{m}r^2 + \frac{k^2 + D^2}{m} = 0 \quad [23]$$

$$r = \pm\sqrt{\frac{-k \pm Di}{m}}$$

Assume:

$$+\sqrt{\frac{-k + Di}{m}} = n + qi \quad [24]$$

Squaring [24]:

$$-\frac{k}{m} + \frac{Di}{m} = n^2 + 2nqi - q^2$$

Equating real parts and imaginary parts:

$$\frac{k}{m} = q^2 - n^2$$

$$\frac{D}{m} = 2nq$$

Solving these for n and q and remembering that they are real:

$$\left.\begin{aligned} n &= +\sqrt{\frac{-k + \sqrt{k^2 + D^2}}{2m}} \\ q &= +\sqrt{\frac{k + \sqrt{k^2 + D^2}}{2m}} \end{aligned}\right\} \quad [25]$$

Similarly it may be shown that

$$\sqrt{\frac{-k - Di}{m}} = n - qi$$

The solution for y becomes:

$$y = Ae^{(n+qi)t} + Be^{-(n+qi)t} + Ce^{(n-qi)t} + De^{-(n-qi)t}$$

which may, if n and q are real, be written:

$$y = e^{nt}[C_1 \cos qt + C_2 \sin qt] + e^{-nt}[C_3 \cos qt + C_4 \sin qt] \quad [8a]$$

The solution for x, obtained by substitution of the expression [8a] for y in [7], is:

$$\alpha = e^{nt}[C_1 \sin qt - C_2 \cos qt] - e^{-nt}[C_3 \sin qt - C_4 \cos qt] \quad [8b]$$

Discussion

M. STONE.[17] The writing of a paper on self-induced vibration is a commendable undertaking, for it calls to the attention of engineers not steeped in the subject of vibration that there exists a large and important class of vibratory phenomena that cannot be treated under the simple category of motion stimulated by periodically varying forces, do not display what is ordinarily called resonance, and so forth. The writer has been interested in several of the cases discussed in detail by the author, such as shaft whirl caused by internal friction, shaft vibration due to bearing conditions, self-induced vibrations from fixed high-frequency disturbances, etc., for they have had to do with work falling under his jurisdiction, and he wishes to endorse the treatment that the author has given.

With reference to the general relation, under section 2 of the paper, the writer would like to add an important property of the set of Equations [1] that distinguishes them as possessing

[16] Curve II in Fig. 15 for this case represents the impact force, and naturally consists of sharp peaks even more pronounced than indicated in the figure.

[17] Engineer-in-charge of Development, Power Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

the property of self-induced vibration or not. In a paper[18] of the writer, it is shown that if $m_{nm} = m_{mn}$, $c_{nm} = c_{mn}$, and $k_{nm} = k_{mn}$, then the system is *not* capable of self-induced vibration. It is necessary that at least one or more of these quantities be unequal to have the system exhibit this property. This fact was elucidated in connection with the problem referred to by the author,[19] and is briefly described here as another case of self-induced vibration of a somewhat different type.

Consider the schematically sketched generator-governor system shown in Fig. 1. Consider the generator system for the moment; the differential equation of free oscillation is:

$$I\ddot{\theta} + c_s\dot{\theta} + k_s\theta = 0 \quad \ldots\ldots\ldots\ldots\ldots [26]$$

where:

I = total mass moment of inertia of the generator system—i.e., engine and flywheel and generator
θ = angular displacement from synchronous position
c_s = specific damping torque, as determined mainly by damper winding design
k_s = synchronizing torque of the generator, by virtue of its parallel operation with the network.

From a consideration of governor dynamics, it can be shown that it will vibrate freely according to:

$$m\ddot{x} + c_g\dot{x} + k_g x = 0 \quad \ldots\ldots\ldots\ldots\ldots [27]$$

where:

m = equivalent mass of governor, referred to translational motions of the sleeve
x = translational displacement of sleeve from equilibrium
c_g = damping constant in governor system, mainly provided by dashpot shown schematically
k_g = elastic restoring force/unit displacement of sleeve; this is a function of shaft speed.

Now by virtue of the way a governor and generator are interconnected for proper governing, Equations [26] and [27] are modified to give:

$$\left.\begin{aligned} I\ddot{\theta} + c_s\dot{\theta} + k_s\theta &= kx \\ m\ddot{x} + c_g\dot{x} + k_g x &= -c\dot{\theta} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [28]$$

as is shown in the paper referred to. It is seen here that $k = kg$ and $c_s = c$, referring to the remark made earlier concerning the necessity for the inequality of coefficients, and so the system is capable of self-induced vibration. The solution of [28] is carried out in the paper, the condition of instability being established by studying the sign of the exponent, as mentioned by the author.

In connection with this problem, it has been possible to disclose an exact analog between two coupled vacuum-tube circuits and the oscillatory generator-governor system,[18] thus providing an easy way of experimentally studying the effect of various magnitudes and the conditions of instability.

[19] "Parallel Operation of A-C Generators, Action of Governors and Damper Windings," M. Stone, before A.I.E.E.

A. L. KIMBALL.[20] This paper is of particular interest to the writer because it takes up the phenomenon of the self-induced whirling of a rotor when running above its critical speed caused by internal friction within the rotor or shaft. This phenomenon was first discussed by the writer before the American Physical Society at its Washington meeting in 1923, at which a small model was exhibited.

There are several publications on this subject not cited by the author to which attention should be called.[21]

Referring to the author's analysis in which he derives the outward logarithmic-spiral motion of the center of mass of the rotor, the same result is more directly obtained by the use of polar coordinates using the standard expressions for the vectorial and angular accelerations. These are:

$$a_r = \frac{d^2r}{dt^2} - r\left(\frac{d\theta}{dt}\right)^2$$

$$a\theta = r\frac{d^2\theta}{dt^2} + 2\frac{dr}{dt}\frac{d\theta}{dt}$$

Since the elastic force acts along the radius vector and the disturbing force transverse to it, the following pair of simultaneous differential equations are obtained:

$$m\frac{d^2r}{dt^2} - mr\left(\frac{d\theta}{dt}\right)^2 = -kr$$

$$mr\frac{d^2\theta}{dt^2} + 2m\frac{dr}{dt}\frac{d\theta}{dt} = Dr$$

Assuming the solution $r = r_0\varepsilon^{nt}$, there is obtained at once:

$$\frac{d\theta}{dt} = \sqrt{\left(\frac{mn^2 + k}{m}\right)} = \frac{D}{2mn}$$

from which $n = \sqrt{\left(\frac{-k + \sqrt{(k^2 + D^2)}}{2m}\right)}$, as obtained by the author.

The disturbing force responsible for this type of whirl can be pictured as a direct result of frictional stress components set up within the shaft along with the elastic stresses. This viewpoint is presented in the article in the *Philosophical Magazine*.[21]

The writer wishes to mention that the internal friction in an ordinary steel shaft is very small, and other frictional effects produced by cramp fits may be several times larger.

An experimental study of the relative amounts of these two types of friction has been made by the writer and is presented by him in an article entitled "Measurement of Internal Friction in a Revolving Reflected Shaft," *Genl. Elec. Rev.*, August, 1925.

The Fatigue of Metals—Its Nature and Significance

By H. F. MOORE,[1] URBANA, ILL.

The essential feature of "fatigue" failure in metals is a spreading crack. Studies of fatigue failure in single crystals of metal indicate that such cracks frequently start by slip along planes of atomic weakness. The study of fatigue failure of metals has shown certain limitations of the mathematical theory of elasticity when applied to actual non-homogeneous metals. The importance of the ability of a metal to resist occasional slight plastic action without starting a fatigue crack is emphasized. The relation between atomic strength and the strength of a multi-grained piece of metal is briefly discussed and a "crack-interference" hypothesis of fatigue failure suggested. The phenomenon of spreading cracks in metal under steady load at elevated temperatures is noted, and its significance discussed.

THE phenomenon of the failure of metallic structural and machine parts under repeated stress has been extensively studied for some three-quarters of a century, and has been studied with special intensity since the development of the automobile and the airplane. This phenomenon is commonly, but rather inaccurately, called the "fatigue" of metals. All recent studies indicate that the origin of this so-called "fatigue" is in a crack in the material which, under repeated stress, spreads and finally so weakens the machine or structural part that sudden fracture occurs. Just how such a crack originates, and under what conditions a minute crack develops into complete fracture of a member, are matters concerning which our present-day knowledge is far from satisfactory.

The study of the fatigue failure of single-crystal specimens of metals by Gough and others[2] indicates that for most metals, perhaps for all metals, a fatigue crack originates in a plane of atomic weakness along which "slip" (failure of elastic strength) has occurred, possibly by a wrinkling action along the plane of slip under the cycles of repeated stress. This wrinkling action tends to break atomic bonds at the "wrinkles." The first slip planes are along planes of atomic weakness rather than along planes of maximum stress or maximum strain, but after a crack once starts spreading to fracture, its course seems to be determined largely by the direction of maximum tensile strain. In single-crystal specimens of certain metals with close-packed hexagonal space-lattice[3] structure, observers have been unable to detect any slip before detecting a crack, while for several metals with body-centered or face-centered space-lattice structure considerable slip has been detected, although no fatigue fracture had occurred nor any crack been detected even under 100,000,000 cycles of reversed stress. "Just when and how does a fatigue crack start?" is still an unanswered question.

Mathematical Theory of Elasticity Statistically Rather Than Exactly True

One result of the study of fatigue phenomena in metals is the growing conviction that the whole mathematical theory of elasticity, on which all our computations of stress and strain are based, must be regarded as statistically true rather than exactly true when applied to the behavior of actual metals under stress. This theory is founded on certain postulates, among them the following: metals are (1) homogeneous, (2) isotropic, and (3) indefinitely divisible without change of elastic properties. One glance through a metallurgical microscope at a polished and etched piece of metal raises grave doubts as to the rigid truth of these assumptions, and the phenomena of fatigue failure strengthens this impression.

The formulas for computing the strength of materials were developed by and for structural engineers, and they have been most interested, not in spreading fatigue cracks, but in the failure of elastic strength or in fracture under a few repetitions of load. Moreover, localized failure in a few crystalline grains of metal does not, in general, mean any appreciable damage to beams, columns, and tie rods in a structure. So the formulas in common use, which may be regarded as "statistically true" for an aggregation of crystalline grains, serve the structural engineer very well indeed.

However, when machine parts are considered, the importance of localized failure, leading to a spreading crack under loads repeated hundreds of thousands of times, becomes vitally important, and the limitations of the mathematical theory, as applied to actual metals, become apparent. For example, the mathematical theory of elasticity indicates that the localized stress at a notch, a screw thread, or a small hole depends not at all on the material, but only on the shape of the piece. Actually metals differ widely in the ratio between the load which, if oft repeated, causes failure in a piece containing a notch or screw thread and the load which will cause failure in a similar piece of the same metal in which the notch has been smoothed out or the screw thread turned off. The abilities of various metals to adjust themselves to high localized stress without starting a fatigue crack differ widely, and the "crackless plasticity" which allows such adjustment is not a simple function, either of static strength, fatigue strength (of smooth specimens), ductility as indicated by elongation and reduction of area, or of the results of impact tests on notched specimens. This property is important in machine parts, but as yet no reliable method of measuring it has been devised.

---

[1] Research Professor of Engineering Materials, University of Illinois. Mem. A.S.M.E. Professor Moore was educated at the University of New Hampshire and Cornell University. He studied under Prof. Albert Kingsbury and Prof. John H. Barr. He has been connected with the Riehlé Brothers Testing Machine Company and the Materials Testing Laboratories of the University of Wisconsin and the University of Illinois. For the past twenty-five years he has been on the staff of the Engineering Experiment Station of the University of Illinois.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Dec. 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] Space lattice is the pattern of orderly arrangement of atoms in a crystalline grain of metal.

In all cases so far studied, although the mathematical theory of elasticity cannot be regarded as rigidly accurate when used to determine significant localized stresses in actual metals, it does give results *on the safe side*, and hence to the engineer it is still a vitally important theory. Probably the machine designer of the near future will have to become more familiar with its formulas than are the present-day designers, and, in addition, will find it of great advantage to become familiar with the theory of plasticity as developed by Nadai and others.[4]

Analogy Between Spread of a Fatigue Crack and Spread of Bacterial Infection

Analogies in scientific discussions are sometimes illuminating and always dangerous. With this word of warning the author wishes to present what some may regard as a whimsical analogy between the spread of a fatigue crack in metal and the spread of bacterial infection. It is probable that all of us carry around in our bodies the germs of several deadly diseases; probably all metallic machine or structural parts have in them many incipient cracks and weak spots. Under stress of chill or overexertion the normal resistance of our bodies to the spread of bacterial infection may be so lowered that such spread may go on to the point of causing serious illness, or even death; under mechanical

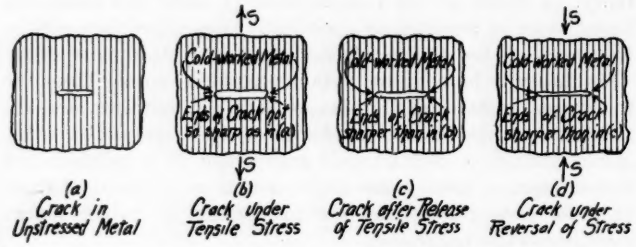

Fig. 1 Crack in Metal During Cycle of Stress

stress the resistance of a metal to the spread of an incipient crack may be so lowered that fatigue failure results. In the body the spread of bacterial infection calls up reserves of resistance which get into action to stop the spread of infection, frequently involving rise of body temperature, and sometimes involving overload on the heart or other organs; in most metals when a crack starts spreading there develop reserves of resistance in the shape of surrounding metal *strengthened* by slip (cold work), sometimes with rise of temperature, and sometimes with transfer of stress to adjacent parts of the metal. In both the human body and the metal there seems to be a conflict between beneficial and injurious influences with the result depending on the preponderance of one over the other.

Once again may the author call attention to the fact that the foregoing is an analogy, not a piece of rigid reasoning.

What is the relation between atomic cohesion and the fracture of a specimen or a machine part? Theoretical considerations, based on latent-heat values, indicate that the force necessary to actually break atomic bonds corresponds to a tensile strength 10 to 20 times that developed in static tension tests and 20 to 40 times that developed under cycles of reversed stress. On the other hand, tests of single-crystal specimens give an extremely low value of strength under repeated stress. Mechanical fracture seems to start either in minute areas of extremely high localized stress or to originate from the repeated sliding displacement of layers of atoms, with the resultant development of cracks.

In the multi-grained metal of machine parts the random orientation of crystalline grains may well set up barriers to the spread of cracks from unfavorably oriented grains to favorably oriented ones. If in the metal there are two or more kinds of grain, differing in strength, this barrier action may well be even more marked. A "crack-interference" theory of fatigue failure, similar in its general lines to the well-known "slip-interference" theory of Jeffries and Archer, seems worthy of consideration.

Why a Crack Spreads Under Repeated Cycles of Stress and Not Under a Steady Load

But why does a crack spread under repeated cycles of stress and not under a steady load? In the first place, it may be well to note that there is evidence that, under certain conditions of temperature, spreading cracks which differ markedly from fatigue cracks may sometimes occur under long-continued steady load. These cracks will be discussed in a succeeding paragraph.

Under a steady load, if an incipient crack is present in the metal, the crack probably spreads somewhat, and opens up with a rounding off of the ends. This is illustrated in Fig. 1 at (*a*) and (*b*). The spreading of the crack weakens the metal, but the rounding off of the ends lowers the stress concentration, and also cold-works and strengthens the metal. Thus there are both destructive and beneficial actions present, and, unless the load per square inch is very great, so great as to cause a rather general plastic flow of the metal, equilibrium is reached before complete fracture occurs. Even a very small amount of generally distributed plastic flow might well serve to prevent the spreading of a crack to complete fracture.

Now if the load is removed, the crack closes up and its ends become somewhat sharper than under load, as illustrated at (*c*), Fig. 1. Then if load is again applied the stress concentration at the ends of the crack is greater than it was when first under load, and may be either greater or smaller than it was at the ends of the incipient crack in the virgin metal. Moreover, at the ends of the crack, where the metal is strengthened by the cold-working it has received, its "crackless plasticity" is lowered, and it is less able to make crackless-plastic adjustments under succeeding cycles of stress. We do not believe that metal "crystallizes" under repeated stress, but it changes its properties, and then metal after many cycles of repeated stress may be either improved or damaged according as the beneficial or the injurious effects of the stress predominate. At the intensity of computed stress which we denote the endurance limit, the two influences just balance.

If the metal is subjected to cycles of *reversed* loading, the flattening of the crack and the sharpening of the ends are magnified, and with this action the stress intensification at the ends of the cracks is increased, so that the balance between beneficial and destructive effects takes place at a lower computed stress. This is illustrated at (*d*), Fig. 1.

Ductile Metal Does Not Resist Repeated Stress Better Than Brittle Metal

It is a very natural idea that a ductile metal will resist repeated stress better than a brittle metal, but the actual facts do not bear out this simple assumption. Probably some slight plastic action is involved whenever a machine part is subjected to repeated stress, especially if there are notches, screw threads, holes, or other "stress raisers" in it, but even the metals rated as brittle—cast iron, for example—can withstand some slight plastic action without starting a fatigue crack. For metal parts rarely subjected to severe plastic action—springs, for example—strength seems far more important than ductility. However, for many machine and structural parts, such as railway equipment, pressure vessels, bolts, etc., occasional severe localized stress is frequently developed, and the ability to resist such occasional plastic action without starting a destructive spreading crack is of great importance.

[4] Nadai, A., "Plasticity," McGraw-Hill Book Company, New York, 1931.

General ductility under a few loads, and the ability to withstand a few thousand cycles of stress involving localized plastic action, seem to be quite different properties. Under one load, or a few dozen loads, the ductility of the metal *as a whole* is called into play, and any incipient cracks which may form have very little chance of spreading to fracture. Under thousands of cycles of stress, *local* exhaustion of ductility under repeated plastic action tends to cause a crack to spread, as has been discussed in a preceding paragraph. Metals may show a good degree of ductility under a static tension test—may show good elongation and reduction of area—and yet may crack readily under thousands of cycles of repeated stress.

Fig. 2 shows micrographs of fatigue cracks in structural steel and in heat-treated alloy steel. The structural steel gave 38.8 per cent elongation in 2 in. and 63.9 per cent reduction of area; the chrome-nickel steel gave 24.2 per cent elongation in 2 in. and 6.87 per cent reduction of area. In the micrograph of the structural steel is seen a distinct "disturbed area" adjacent to the fatigue crack. Slip lines are seen several grains away from the crack, and evidently considerable energy has been absorbed in causing this relatively widespread plastic action. On the other hand, in the micrograph of the heat-treated alloy steel no such "disturbed area" can be detected, the general ductility of the metal does not seem to have been called into play, and much more of the energy of the cycles of repeated stress is available for starting and spreading a fatigue crack.

Structural Steel (Magnification, 200 ×)

Chrome-Nickel Steel (Magnification, 650 ×)

FIG. 2 MICROGRAPHS OF STRUCTURE NEAR FATIGUE CRACKS
(Traced from photomicrographs made by S. W. Lyon in the Metallographic Laboratories, University of Illinois.)

The terms "body," "dynamic ductility," and "crackless plasticity" have been suggested to denote this ability to develop localized ductility under repeated stress, and it is the author's opinion that the development of a practical test for this quality is a field of research offering no small promise of usefulness. Comparative fatigue tests of notched and unnotched specimens, comparative impact tests of notched and unnotched specimens, and damping tests in which the rate of dying out of vibration is measured[5,6] have been suggested, but none of them have proved their useful reliability as yet.

ENDURANCE LIMIT AN IMPORTANT PHYSICAL PROPERTY OF A METAL

From the great mass of fatigue-test data which has accumulated during the past twelve years has come the conclusion that the endurance limit(or fatigue limit)—the limiting stress below which unnotched specimens will withstand an indefinitely large number of cycles of stress—is an important physical property of a metal, and that it is a good index of the ability of the metal to withstand millions of cycles of repeated working stress, if there are very few occasional cycles of stress involving appreciable localized plastic action. Fatigue testing is so time-consuming, and the cost of specimens is so high, that it has not found a place in practical acceptance tests. So far no reliable short-time test for fatigue limit has been developed, but research for such a test is still in progress.

Much work remains to be done to determine the fatigue strength of metals under various ranges of stress, under cycles of shearing stress, and under combinations of steady shearing and varying flexural stress. A discussion of this subject would extend beyond the limits of this paper, and reference may be made to the article by Prof. J. B. Kommers in the 1930 report of the American Society for Testing Materials Research Committee on Fatigue of Metals.

Similarly, the very important subject of "corrosion fatigue" cannot be discussed in any detail in this paper, and reference may be made to the 1932 report of the American Society for Testing Materials Research Committee on Fatigue of Metals, to the papers of Dr. D. J. McAdam published in the Proceedings of the American Society for Testing Materials from 1926 to 1931, inclusive, to the paper presented by him before the 1932 Congress of the International Congress for Testing Materials at Zurich, and to the 1932 autumn lecture by Dr. H. J. Gough, of the British National Physical Laboratory, before the British Institute of Metals.

The formation and spread of cracks under long-continued static load has been noticed by investigators of the behavior of metals at high temperatures,[7] and some evidence of such cracks in lead under long-continued static load at room temperatures has been observed in the Materials Testing Laboratory of the University of Illinois. In steel and in lead these cracks seem to be intercrystalline rather than transcrystalline, as is the case with ordinary fatigue cracks. The study of the occurrence of such cracks under static load is an almost unexplored field of investigation, and one which seems very promising.

Discussion

R. E. PETERSON.[8] Professor Moore has given us a most valuable bird's-eye view of the entire field of fatigue of metals—a view which should be kept in mind in incorporating the detailed phases of the subject into the general scheme of working stresses.

In connection with Professor Moore's remarks concerning the origin of fatigue failure and the detection of the first discernible cracking, it may be of interest to mention some experiments

made by Davidenkoff.[9] Fifteen identical notched fatigue specimens were made of 0.2 per cent C steel. All specimens were run at the same load (a load causing fatigue fracture at 725,000 cycles), but were stopped and removed from the fatigue machine after different durations of running, (i.e., 50,000, 100,000, 200,000, etc. cycles). The specimens were then broken in static bending while subjected to liquid air (to produce brittleness). The results are shown in Fig. 3. The first discernible crack occurred at about 300,000 cycles, corresponding to the knee of the curve. Thereafter the breaking load decreased rapidly due to crack penetration. However, a weakening is noted before 300,000 cycles, as shown by the initial slope of the curve. This would seem to indicate that some kind of damage occurs right from the start of the test. While the significance of these tests is not altogether clear, some further work along the same lines may be of value.

APM-55-4

The Present State of the Turbulence Problem

By WALTER TOLLMIEN,[1] PASADENA, CALIF.

In this survey the author first describes certain types of turbulent flow, following which he deals successively with the production of turbulent motion; the instability of the laminar motion; fully developed turbulence; momentum interchange and mixing lengths; and relations between the shearing stress at the wall and the mean velocity distributions. Finally he takes up the calculation of skin friction for simple cases of fully developed turbulence, especially for that of the flat plate. Although the methods outlined have often led to practically useful results, it is the author's belief that they should be considered only as advances toward the real goal of the turbulence theory. The derivation of turbulence phenomena from the hydrodynamical equations will, in his opinion, be possible only by the application of statistical methods.

THE turbulence problem is especially interesting for two reasons. First, most flows occurring in technical applications and in nature are turbulent. Thus the turbulence problem has a great practical importance for aeronautics, hydraulics, meteorology, and so on. Secondly, this curious form of flow offers the greatest difficulties when we attempt to introduce it into the system of our usual hydrodynamics. By studying this problem we can hope to gain quite new basic physical insights.

Of course, the author can only present a survey of this complicated subject. For a long time experiments have been made on turbulence. Although we are still far from a complete comprehension even of the simplest turbulent motion, recently certain ideas have been developed that enable us to classify the very extensive experimental material on hand, as well as to forecast the character of some turbulent flows to a certain extent. In the following the author will outline these methods and give some results, but especially will he point out the problems still unsolved.

I—Some Types of Turbulent Flow

Instead of giving a definition of turbulence, which is difficult, the author will describe briefly the oldest example of a turbulent flow. Consider water flowing under a pressure drop through a straight tube of circular cross-section. If the material of the pipe is glass, then the flow can be made visible by injecting several color bands into the fluid, as did Osborne Reynolds, the father of turbulence research (1).[2] At low speeds of the fluid there are then seen at sufficient distances from the inlet of the pipe quite straight color bands parallel to the axis of the pipe. This form of flow is called "laminar." If we increase the speed of the fluid by increasing the pressure drop, at the so-called 'critical speed" the regular motion indicated by the color bands breaks down. We then see at first a quite irregular fluctuation of the color bands, and later only a colored cloud in the pipe, which means that the fluid is mixed to a high degree. The fluid now shows the so-called "turbulent" motion. Both facts, the irregularity of the motion and the mixing effect, are quite typical for turbulent flows.

In considering circular pipes with different diameters, and other fluids, e.g., air instead of water, we have to refer the observations to the non-dimensional Reynolds number, defined in this case as the mean velocity through the cross-section of the pipe times the radius r of the pipe divided by the kinematic viscosity ν. Neglecting the compressibility of the fluids, the transition between the laminar and turbulent motion is then determined by the "critical" Reynolds number.

Other fluid motions along rigid walls show similar behavior. Mention may be made of the change in the character of flow in the boundary layer[3] around a sphere causing the well-known sudden drop of the drag at the critical Reynolds number. In addition to this "wall-bound turbulence," essentially determined by the proximity of rigid walls, there exists also "free turbulence," i.e., turbulent flow far from the influence of walls. In this class may be mentioned the spreading out of an air jet in the still air or of a wake behind a body. We can say that "free turbulence" occurs when two fluid layers with a finite velocity difference come together. In this case the transition to turbulence seems to be more gradual, for there exists already at low Reynolds numbers a periodical motion (e.g., a von Kármán "vortex street") which is replaced at higher Reynolds numbers by the faster and more irregularly fluctuating turbulent flow.

The transition from simple regular motion to turbulent motion presents the first great problem.

II—Production of Turbulent Motion and Instability of the Laminar Régime

To illustrate the ideas we shall consider again the simple example of the flow through a pipe. A second reason for the choice of this flow is that almost innumerable experiments have been carried out for this case. We know that at a sufficient distance from the entrance of the pipe the laminar velocity distribution plotted against the radial distance from the axis forms a parabola. Why does not this simple solution hold beyond a certain value of the Reynolds number? The first answer that suggests itself is that this velocity distribution is only a solution of the hydrodynamical equations in a finite region of Reynolds numbers. We can convince ourselves at once that this conjecture is not correct. The flow in question satisfies the hydrodynamical equations of Navier-Stokes for all Reynolds numbers, and this holds generally. Considering the flows through arbitrary channels or past bodies of whatever kind, laminar solutions of the hydrodynamical equations for all Reynolds numbers always exist. Therefore turbulence can only originate because the laminar motion becomes unstable.

What do the experiments on this problem show? First, let us refer again to the flow through a tube of circular cross-section. The first finding of the experiments is that the critical Reynolds number is not a constant. Of course, the critical Reynolds number depends largely on the form of the mouth

---

[1] California Institute of Technology.

[2] Numbers in parentheses refer to items in bibliography at end of paper.

Presented at the Pacific Coast Aeronautic Meeting held at Berkeley, Calif., June 9 and 10, 1932, under the auspices of the San Francisco Section of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] The (laminar or turbulent) "boundary layer" is defined as the thin layer where the velocity increases rapidly from the velocity of the wall to a value which can be calculated from the pressure drop along the wall by using Bernoulli's equation. This last possibility indicates that at that place there is practically no energy dissipation. This means that the boundary layer is just the region of the action of viscosity or of turbulent fluctuations.

through which the fluid streams from the reservoir into the pipe. If the entrance is sharp-edged, a critical Reynolds number of about 2000 is obtained, while for a carefully rounded entrance (trumpet mouth) it is in the neighborhood of 5000. These differences are not astonishing, for the two cases are not completely geometrically similar. But even for the same entrance quite different critical numbers are obtained. By carefully avoiding vibrations of the apparatus and leaving the fluid in the reservoir at rest for several days, the critical Reynolds number can be considerably increased. In fact, Ekman (2) succeeded in obtaining a critical Reynolds number of 22,000! This means that the critical Reynolds number depends largely on the disturbances that take place.

Here must be stated the great lack of all these experiments: namely, the disturbances causing the observed instability of the laminar flow are not defined. Some first attempts have recently been made in applying definite disturbances (3, 4). Hitherto the most important observation on the mechanism of the instability of the laminar motion was that the inlet disturbances are most effective. Even a slight scratch in the trumpet mouth can lower the critical Reynolds number to one-

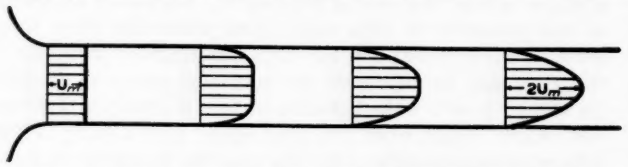

FIG. 1 FLOW IN THE LAMINAR INLET LENGTH OF A PIPE
(Inlet length about 0.15 $rU_m r/\nu$.)

half its previous value, while pronounced roughness of the walls far distant from the entrance has no influence at all. On the other hand, instability always begins in the "inlet length" of the pipe (Fig. 1). This length is defined as the region where the nearly constant velocity distribution at the entrance is gradually transformed into the final parabolic velocity distribution. The author does not know of any observation indicating that instability begins after the parabolic velocity distribution has been practically completely developed.

In other cases also experiments on the transition from laminar flow to turbulence have been made, although not to such an extent as for pipes. Mention may be made of investigations on the flow along a thin flat plate lying along the direction of motion, a case which will be treated later in detail. This transition is also observed in the boundary layers along the surface of airfoils or circular cylinders placed in an infinite stream. The boundary layer near the forward stagnation point is laminar; going downstream from this point along the surface of the body, however, the boundary layer sometimes becomes turbulent.

All these experiments refer to the so-called "upper critical Reynolds number," that is, their aim is to determine a limit for the stability of the laminar flow. The inverse problem is connected with the "lower critical Reynolds number." One then starts with a turbulent flow and finds, by gradually decreasing the Reynolds number, when the turbulent flow is no longer possible and is replaced by a laminar flow; i.e., the "lower critical Reynolds number" determines the limit of stability of the turbulence. In the experimental determination of this value the disturbances of the laminar flow are made "as great as possible," which is hardly in accordance with a proper formulation of the problem. According to L. Schiller (5), below a Reynolds number of about 1000, turbulence in pipes should be impossible.

To sum up, it may be said that the experiments that have been carried out show very little how turbulence is set up. What, now, can we learn from theory?

III—INSTABILITY OF THE LAMINAR MOTION: THEORY

The first method of attacking this problem is that proposed by Osborne Reynolds. A disturbance is superimposed upon the laminar flow, and the question is then asked whether the energy of the disturbance will increase or decrease. The disturbance assumed is to satisfy only the continuity and boundary conditions (e.g, all disturbance components vanishing at rigid boundaries), otherwise it is quite arbitrary. One part of the disturbance energy is dissipated by internal friction. Disturbances can increase their energy only by taking energy from the laminar basic flow. When this last amount of energy is greater than that dissipated, Reynolds assumes instability of the laminar flow (6). This conclusion is not justified because a momentary increase in the energy of the disturbance does not always mean instability of the laminar flow. Indeed, this method only shows whether some disturbance will in the next moment increase or decrease, and affords no information as to what will happen when the disturbance develops further according to the hydrodynamical equations. We obtain by this method only a limiting Reynolds number below which the laminar flow is certainly stable, since then every disturbance is decreasing in energy. However, the corresponding Reynolds numbers are so small that this limitation of the range of the critical ones is practically useless. Thus the Reynolds energy criterion fails completely with respect to the stability problem.

To describe the development of the disturbances according to the hydrodynamical equations, and thus to determine the actual instability of the laminar flow, the method of small oscillations is employed. Usually a two-dimensional laminar flow in the xy-plane is considered. For simplicity, this basic flow is assumed to have only a velocity component parallel to x and depending on y: $U(y)$. The disturbances are also taken as two-dimensional and can therefore be expressed by a stream function $\psi(x, y)$. Furthermore the disturbances are assumed to be small and all quadratic terms in ψ are neglected. Thus the following equation for ψ remains:

$$\frac{\partial \Delta\psi}{\partial t} + U\frac{\partial \Delta\psi}{\partial x} - \frac{d^2U}{dy^2}\frac{\partial \psi}{\partial x} = \nu \Delta\Delta\psi$$

Here $\Delta\psi$ is equal to $\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2}$, i.e., the curl or the vorticity of the disturbance, t the time, and ν the kinematic viscosity.

Now, according to the method of small oscillations, the disturbance is to build up from "partial oscillations," for since our disturbance equation is linear, such a superposition is permissible. ψ is composed of terms such as

$$\varphi(y)e^{i(\alpha x - \beta t)}$$

that is, of waves traveling in the x-direction. The concise complex notation is used; it is to be understood that, e.g., the real part of the expression above is to be taken. α is a real constant giving the spatial cycle, therefore the wave length of the partial oscillation is $2\pi/\alpha$. β can be complex $= \beta_r + i\beta_i$; the real part β_r gives the periodic cycle, and the imaginary part β_i the logarithmic decrement, which is positive for increasing and negative for damped oscillations. The real part c_r of the magnitude $c(= \beta/\alpha)$ is the wave velocity. By introducing this partial oscillation into the disturbance equation, we obtain

$$(U - c)(\varphi'' - \alpha^2\varphi) - U''\varphi = -\frac{i\nu}{\alpha}(\varphi'''' - 2\alpha^2\varphi'' + \alpha^4\varphi)$$

Taking into consideration the boundary conditions (vanishing of the disturbance components at rigid walls, etc.), we now have to find the relation between the three parameters of the

problem, namely, the Reynolds number R of the basic flow, and α and c, the parameters of the partial disturbance. For positive imaginary parts of $\beta = c\alpha$, instability will arise.

The first problem attacked by this method refers to the "simple shearing motion" or the "straight Couette flow" (Fig. 2). This flow is produced between two plates parallel to x which are moving with opposite constant velocities in the x-direction. The basic velocity U is then a linear function of y, which simplifies essentially the mathematical problem. The investigations of Orr (7), Hopf (8), and von Mises (9) show no instability of this

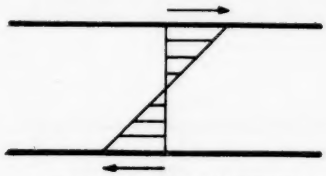

FIG. 2 STRAIGHT COUETTE FLOW

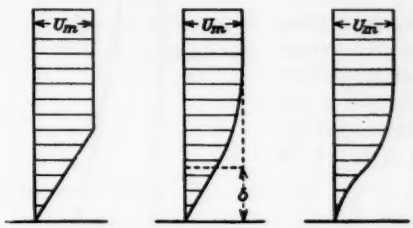

FIG. 3 VELOCITY PROFILES INVESTIGATED FOR STABILITY

flow, and accordingly it has been suggested that the proposed method fails in general for stability problems. This conclusion is not justified, because the straight Couette flow is too special an example.

Instability was first found by Prandtl (11) and Tietjens (12). But to avoid the mathematical difficulties involved by a persistent curvature (d^2U/dy^2) of the basic flow distributions, Prandtl replaced the gradually curved velocity distributions by polygonal profiles as first proposed by Rayleigh (10). He took into account the effect of a small viscosity, while Rayleigh had neglected the viscosity in the disturbance equation entirely. Now in certain cases this last effect causes an instability, e.g., in the first profile of Fig. 3, which shows a linear increase of the velocity from the wall over a certain distance, and further an indefinitely long continuation at constant velocity. But in the range of Reynolds numbers covered by the calculations some amplified oscillations always exist, while we should expect only damped oscillations below a certain Reynolds number. Of course this strange result of the calculations is due to the rough approximation of the profile by a broken line.

This explanation was corroborated by the author who investigated the case of smooth curved profiles (13). His discussion is carried out in detail for the laminar flow along a flat plate lying in the direction of the stream (Fig. 4). The corresponding velocity profile (second profile of Fig. 3) is characterized by starting with vanishing curvature (U'') at the wall and by reaching the maximum velocity U_m asymptotically. The form of the velocity distribution remains the same all along the plate, while the thickness of this laminar boundary increases slowly with the distance x from the leading edge [as $\sqrt{(\nu x/U_m)}$]. This small dependence on x can be neglected in the disturbance equation.

Figs. 5 and 6 show the results of the discussion for the case of neutral stability—where the transition from stability to instability occurs. The $\alpha\, c_r$ diagram gives the reciprocal wave lengths and the wave velocities of the corresponding partial oscillations, while the α-R diagram shows the corresponding Reynolds numbers. The Reynolds number is here defined as $R = U_m\delta^*/\nu$ where (cf. Fig. 3)

$$\delta^* = \int_0^\infty \frac{U_m - U}{U_m}\, dy$$

The usual definition of the boundary-layer thickness is rather arbitrary for the asymptotic transition of U into U_m, and is in this case $3.14\delta^*$. The inside of the curves gives the unstable region. The smallest Reynolds number where not all of the oscillations are damped is 420. The usual experimental value of the critical Reynolds number obtained by Burgers (14), van der Hegge Zijnen (15), and Hansen (16) is 950. By plotting this value in our α-R diagram fair agreement is shown, especially when we consider the strong influence of the special quality (wave length and wave velocity) of the disturbances. Disturbances of long wave length are those chiefly dangerous to the stability, and this is fairly well shown by certain photographic observations of the streamlines in the stage of incipient instability (11). In comparing theory with the experiments we should also not forget that the experimental critical Reynolds numbers correspond to an already considerable deviation of the flow from the laminar state instead of to the incipient instability in the theory.

This example is not so special as it would appear, since similar laminar profiles occur in the inlet length of a straight, deep channel with parallel walls, and generally in the laminar boundary layers along any bodies near a stagnation point.

On the other hand, certain modern investigations have confirmed a conjecture of Lord Rayleigh (17) that profiles with an inflection point (cf. third profile of Fig. 3) are highly unstable. We can realize that a low instability as found for the profile along the flat plate produces profiles with an inflection point, and that more violent breakdown of these profiles leads to turbulence.

Also the apparent contradiction between the theoretical

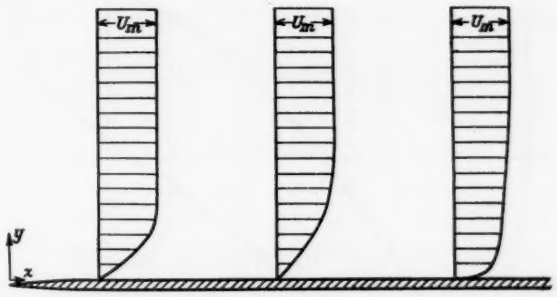

FIG. 4 TYPICAL TRANSITION BETWEEN LAMINAR AND TURBULENT FLOW ALONG A FLAT PLATE

[The first velocity profile is laminar, the second shows just a slight deviation from the laminar type, while the third is completely turbulent. The scale of y (normal to the wall) is about 50 times that of x (along the wall).]

stability of the straight Couette flow and the results of certain experiments has been recently cleared up. Indeed, the shearing motion between two straight parallel plates has never been observed, but the laminar motion between two concentric rotating cylinders (proper "Couette flow") shows a nearly linear velocity distribution over the radial distance between the walls if the difference of the radii of the two cylinders is small compared with the radii themselves. But observations when the outer cylinder was rotating and the inner one was at rest[4] showed the possibility of instability and turbulence. The reason is that at the starting of the whole system by the beginning

[4] The case when the inner cylinder is rotating is not available in this connection, because then, before the beginning of turbulence, the simple two-dimensional laminar motion is replaced by a regular three-dimensional periodical motion, as has been discussed by G. I. Taylor (18).

of the rotation of the outer cylinder, unstable profiles occur before the approximately linear profile has developed. This explanation is due to Prandtl (4) and has been checked by the calculations of H. Schlichting carried out according to the same method that was used by the author in the stability discussion of the profile along the flat plate. Of course, in the new problem the action of the centrifugal force has also been taken into account. The Reynolds number, defined as the circumferential velocity times the radius of the outer cylinder divided by the kinematic viscosity, has, according to certain observations, the critical value 70,000, while the theory places it at 66,000.

Although much detail work is still to be done along these lines, we can say that the instability of the laminar motion against small disturbances and the production of turbulence have been cleared up in principle. Of course, in reality the processes will often be more complicated than those assumed theoretically, because the disturbing oscillations will not be infinitesimal and often also three-dimensional.

IV—Fully Developed Turbulence: Momentum Interchange and Mixing Length

Proceeding to the second great problem of turbulence, the description of the fully developed turbulent flow itself, it must be stated at the beginning that we are still far away from an exact interpretation. But empirical rules and semi-empirical speculations provide useful material for technical application and future theory.

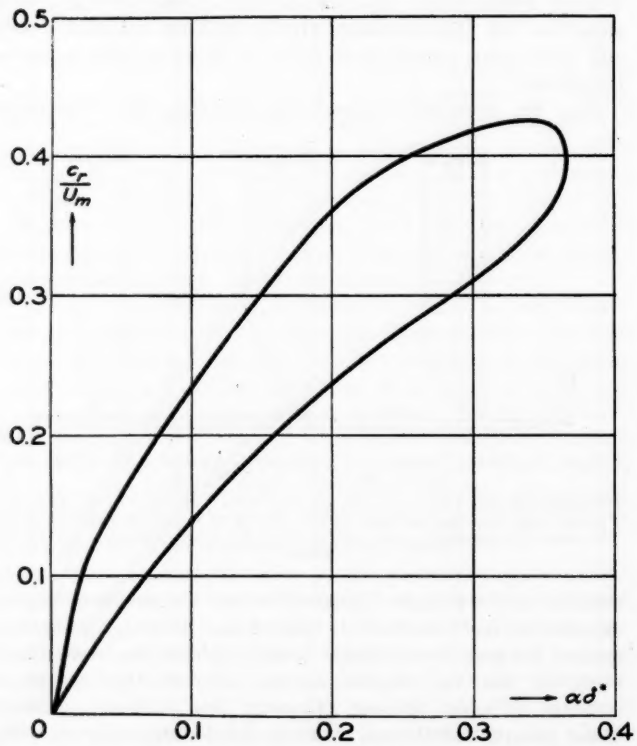

Fig. 5 Partial Oscillations in the Instability Region of the Laminar Flow Along a Flat Plate

Since fluid motion in the turbulent state is, according to all observations, so extremely irregular and complicated, we must at first confine ourselves to the consideration of mean values. Thus, according to Reynolds (6), we separate the actual velocity components u, v, w relative to the rectangular axes x, y, z and the pressure p into time averages $\bar{u}$, $\bar{v}$, $\bar{w}$, $\bar{p}$ at the point under consideration and the instantaneous deviations from the mean or the "fluctuations" u', v', w', p', so that, for instance,

$$u = \bar{u} + u' \qquad p = \bar{p} + p'$$

Now we can use the same form of equations of motion and continuity for the mean values as were used for the original values, if we but add a system of apparent stresses due to momentum interchange produced by the fluctuations.

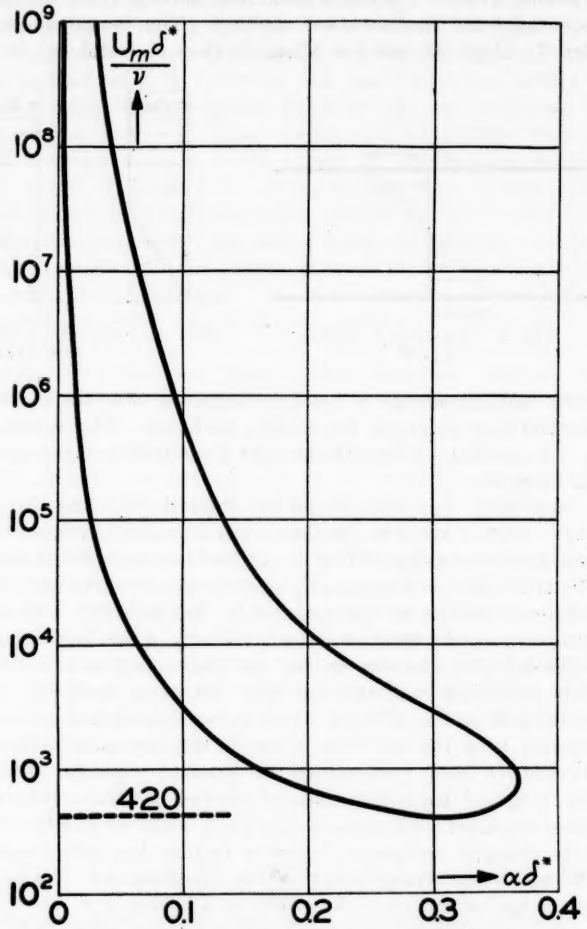

Fig. 6 Instability Region of the Laminar Flow Along a Flat Plate

For simplicity let us consider turbulent flows with a two-dimensional mean motion in the xy-plane. The fluctuations or the "relative motion" may be, and in general will be, three-dimensional. Furthermore, let us assume that the mean motion has its principal component $\bar{u}$ in the x-direction, in which case it will depend but slightly on x. In other words, we admit only a slight divergence or convergence or curvature of the streamlines of the mean motion. The following considerations are easily transferable to an axial symmetrical mean motion, y then being interpreted as the radial distance from the axis and v as the radial velocity component.

In the above-mentioned class of flows an apparent shearing stress like the effect of an apparent friction is of main importance in the additional stress system. Characterizing the apparent stresses by underscoring, we obtain this new shearing stress expressed by the mean momentum flux of the fluctuations:

$$\underline{\tau} = -\rho\overline{u'v'}$$

where ρ is the density of the fluid, and the overscoring again denotes mean values. In a deep channel with straight walls

parallel to x we can easily express the total shearing stress at large distances from the entrance where all mean values formed of velocities are already independent of x;

$$\tau = -\frac{d\bar{p}}{dx}(b - y)$$

y is taken from one wall of the channel, b is the half-breadth of the channel, the mean pressure drop is constant in the considered region, and τ is composed of the apparent stress $\underline{\tau}$ and the viscous stress $\mu d\bar{u}/dy$. Except for the immediate vicinity of the wall, this last stress produced by molecular or thermal motions is very small compared with the apparent stress. A quite similar relation exists in the case of the pipe.

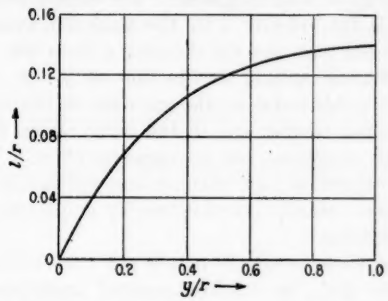

FIG. 7 THE MIXING LENGTH IN A PIPE

Statements of this kind, which all result from applying the formal process of forming mean values in the hydrodynamical equations, express the only exact relations which we know of at present between the apparent stresses and the mean velocities and pressure.

Yet Prandtl has put the apparent shearing stress into another form which at least facilitates further discussion in many cases (19). He introduces the "mixing length" l, a conception in some ways analogous to the idea of mean free path in the kinetic theory of gases. Let us consider the fluid particles that enter (by the turbulent fluctuations) a layer at a given y ($\bar{u}$ is essentially a function of y as mentioned before). Prandtl assumes that these fluid particles have a velocity u in the x-direction which corresponds approximately to the mean velocities $\bar{u}$ of layers at the positive or negative distances $\pm l$ from the given layer. In other words, the fluid particles travel the distance l without losing their individual properties, in this case the velocity u. Thus the mean value of the velocity fluctuation u' for the fluid particles coming from one side of the layer is $l d\bar{u}/dy$, and from the opposite side, $-l d\bar{u}/dy$. Prandtl further assumes that the velocity fluctuations v' in the y-direction are induced by the fluctuations u' in the x-direction when fluid globules with different velocities u meet or separate. The mean absolute value of v' can therefore be put proportional to $l\left|\frac{d\bar{u}}{dy}\right|$. Taking this proportionality factor together with l and also the correlation factor occurring when we average a product, we obtain Prandtl's final formula:

$$\underline{\tau} = \rho l^2 \left|\frac{d\bar{u}}{dy}\right| \frac{d\bar{u}}{dy}$$

Of course, it is assumed that l depends chiefly on the geometrical configuration of the flow considered, and to a lesser degree on the viscosity, etc., so that the shearing stress $\underline{\tau}$ is approximately proportional to the density and to the square of the velocities.

Now since we do not know the value of l, there seems little to be gained by using this formula. However, we can first calculate l from experimental values of $\underline{\tau}$, which latter is determined from the mean velocities and pressure as has been shown in an example. l is well suited to give an idea of the mixing process. For the present, consider a distribution of l in the turbulent flow through a pipe (Fig. 7). As would be expected, l increases linearly from the wall with good approximation over a considerable distance from the wall. This linear increase determines essential features of this turbulent flow, as will be seen later.

Secondly, in the cases of free turbulence a very simple assumption with respect to l gives good results. To illustrate, consider the mixing of a uniform stream with the still air along one side (Fig. 8). u_0 may be taken as the speed of the uniform stream, and x will be measured from the beginning of the mixing. Then the velocity profiles $\bar{u}(y)$ can be assumed to remain similar for all distances x. We now introduce this assumption into the equation of motion and take a shearing stress proportional to the density ρ and the square of the velocities by neglecting the effect of viscosity. Thus for $\bar{u}$ according to Prandtl, the form

$$\bar{u} = u_0 f\left(\frac{y}{x}\right)$$

is obtained where the boundary conditions are already considered. Thus the breadth of the mixing region is proportional to x. Now the mixing length l will be constant over every cross-section since no walls hinder the mixing, which means that l does not depend on y. On the other hand, for the form in which $\bar{u}$ is given above, l must be proportional to x, or

$$l = cx$$

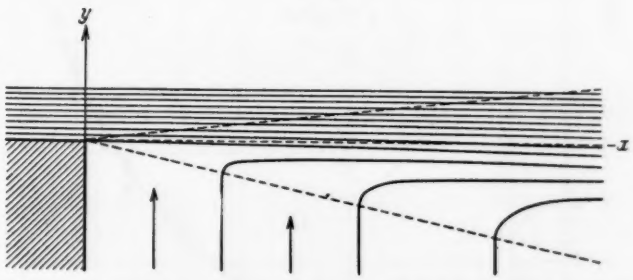

FIG. 8 STREAMLINES OF THE MEAN TURBULENT FLOW AT THE BOUNDARY BETWEEN A UNIFORM STREAM AND STILL AIR

c is the only experimental constant necessary for the calculations. The agreement of the velocity distribution calculated by the author (20) with experiment is very good. This case of turbulent mixing is of fairly great practical importance. It may be mentioned that the unavoidable part of the energy loss of an open-air wind tunnel is partially determined by this effect.

The spreading out of jets (20) and wakes (21, 22) has been treated in a similar manner. And in all cases this simple assumption that l is constant over every cross-section leads to a satisfactory agreement with observations.

Recently von Kármán has developed the mixing-length hypothesis from another standpoint (23). He assumes that the momentum transport of the turbulence is determined only by the field of flow in the immediate vicinity of the point considered, which means that the apparent shearing stress at *all* points in the fluid can be expressed in the same formal manner by the mean flow close to that point. This assumption will not seem so strange when we think of an analogous case: the laminar shearing stress produced by the thermal motion of the molecules obeys such a "local law," i.e., τ (laminar) $= \mu du/dy$. At any rate the assumption of a local law is the simplest possible. This

hypothesis leads to the further conclusion that the flow field of the fluctuations is *similar* about all points in the flow, on an average at least, only the time and length scales being changed. Introducing this assumption into the equation for the fluctuations where the quadratic terms are not neglected, von Kármán again obtains Prandtl's formula for the shearing stress, expressed by the mixing length, and in addition a formula for the mixing length itself:

$$l = \kappa \left| \frac{\frac{d\bar{u}}{dy}}{\frac{d^2\bar{u}}{dy^2}} \right|$$

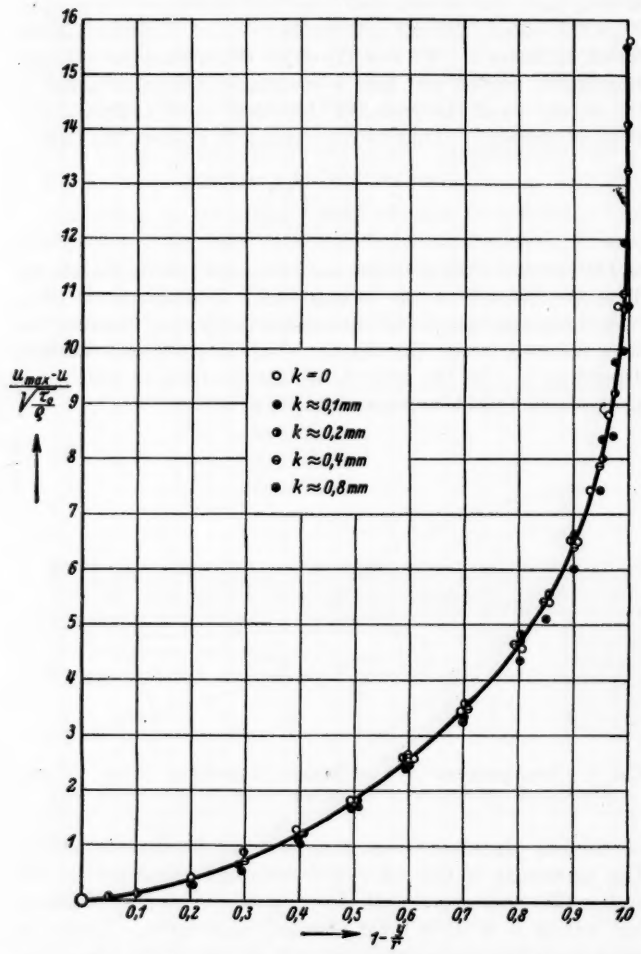

FIG. 9 DIAGRAM ACCORDING TO STANTON AND VON KARMAN OF MEAN VELOCITY DISTRIBUTIONS IN SMOOTH AND ROUGH PIPES AT A REYNOLDS NUMBER OF ABOUT 160,000

[In these experiments of Nikuradse (26) the walls had been roughened by gluing on grains of sand, the mean height of which over the wall was taken as the approximate length of roughness k.]

κ is a universal constant valid for all the types of flow considered where $\bar{u}$ is the principal component of the main flow. This constant κ, according to experiments, has a value of about 0.4. Although this formula breaks down in the region where the $\bar{u}(y)$-distribution has a maximum ($d\bar{u}/dy = 0$) or an inflection point ($d^2\bar{u}/dy^2 = 0$), we can eliminate in this way some of the previous rather arbitrary assumptions in regard to the mixing-length distribution. In particular this formula gives the linear increase of the mixing length near a wall ($l = \kappa y$) and its approximate independence of y in the cases of free turbulence.

V—FULLY DEVELOPED TURBULENCE: RELATIONS BETWEEN THE SHEARING STRESS AT THE WALL AND THE MEAN VELOCITY DISTRIBUTIONS

The second class of conceptions which make possible a much simplified description of the experimental facts, employs essentially certain empirical relations between the mean velocity distribution and the shearing stress at the wall which we shall call τ_0. Consider again the flow through a pipe. Then τ_0 is easily determined by the measured pressure drop, and the total-shearing-stress distribution is known as a linear function of the normal distance y from the wall as mentioned before.

Let us now compare measured velocity distributions in different cases, i.e., for different Reynolds numbers, and also for different degrees of wall roughness. For such a comparison we have to divide the velocity $\bar{u}$ by the maximum velocity $\bar{u}_{max}$ at the center of the pipe and the distance y from the wall by the radius r. Plotting $\bar{u}/\bar{u}_{max}$ as function of y/r we see that at increasing Reynolds numbers the gradient of the velocity near the wall becomes steeper and in the inner region flatter, since an increase in roughness has an opposite effect. Now it is a curious and important fact that we can essentially reduce the variety of these velocity distributions by employing a different method of plotting.

The first of these graphs is rather old (1911) and is due to T. E. Stanton (24), but its fundamental importance was first realized recently by Th. von Kármán at Aachen (25). Stanton makes the *difference* between the maximum velocity $\bar{u}_{max}$ and $\bar{u}$ non-dimensional by dividing by $\sqrt{(\tau_0/\rho)}$, and plots this quantity against the non-dimensional distance from the wall y/r. When we exclude the immediate vicinity of the wall and have sufficiently high Reynolds numbers (greater than about 50,000), this function g of y/r, or

$$\frac{\bar{u}_{max} - \bar{u}}{\sqrt{(\tau_0/\rho)}} = g\left(\frac{y}{r}\right)$$

is independent of the Reynolds number, that is, of the viscosity and the roughness of the walls (Fig. 9). Thus the viscosity and the wall roughness have no direct influence on the velocity distribution in the inner parts of the flow; they are of effect only through the medium of τ_0 and in the form of a kind of boundary condition, because the velocity distribution must of course have a continuous transition between the region close to the wall and the inner region of the flow.

The Stanton-von Kármán rule can be formulated in a very simple manner by making use of the mixing length, which procedure facilitates the physical conception. The complete equivalent of this rule is the statement that l has in all pipes the same distribution over the cross-section, or, as we can say, l/r is a function of y/r, given once for all (Fig. 7). This simple formulation again shows the advantage of introducing the mixing length and gives immediately a good idea of how the Stanton-von Kármán rule can be transferred to other conditions.

The counterpart of this rule is a relation between τ_0 and the velocity distribution near the wall and is due to L. Prandtl (27). But it is confined in its present state to smooth walls. Prandtl considers the flow near the wall, that is, in a region where the distance from the wall is small compared with the radius of the pipe. Then he assumes that $\bar{u}$ in this region depends only on the conditions in the neighboring surface, and is not affected by the flow conditions at a distance. This means that $\bar{u}$ shall only depend on y, τ_0, ρ, μ, but not on r and $\bar{u}_{max}$. We come to the most expressive formulation of this assumption by deriving from the five quantities $\bar{u}$, y, τ_0, ρ, μ a non-dimensional velocity and a non-dimensional distance from the wall:

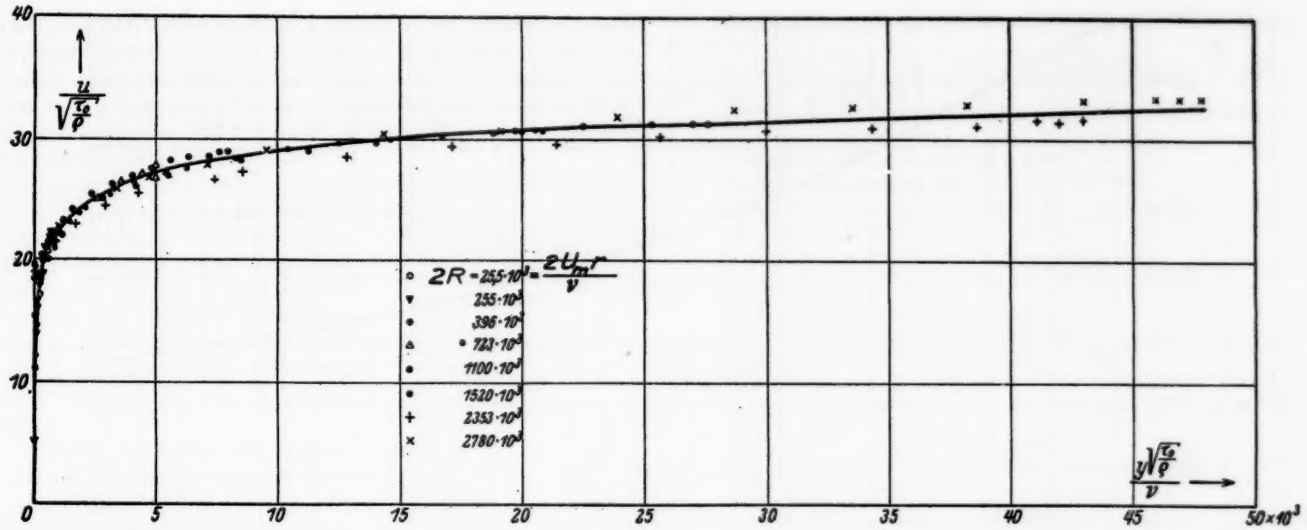

FIG. 10 UNIVERSAL u^* (y^*)-VELOCITY DISTRIBUTION CURVE NEAR SMOOTH WALLS ACCORDING TO MEASUREMENTS OF NIKURADSE (26) IN PIPES

$$u^* = \frac{\bar{u}}{} \sqrt{\frac{\rho}{\tau_0}}$$

$$y^* = \frac{y}{\nu} \sqrt{\frac{\tau_0}{\rho}}$$

Prandtl's assumption then means that u^* is only a function of y^* for values of y small against r. Plotting u^* against y^* we obtain a uniform curve in spite of the fact that for our diagram we used measured velocity distributions at quite different Reynolds numbers (Fig. 10). Of course, at lower Reynolds numbers smaller values of y^* are reached in the region near the wall than at higher Reynolds numbers; thus at a certain Reynolds number only a certain portion of the universal $u^*(y^*)$-curve beginning at $y^* = 0$ is realized. Fortunately this $u^*(y^*)$-curve can be represented by very simple formulas. The approximate formula

$$u^* = 8.7\, y^{*1/7}$$

which holds in a region of y^* between 20 and 1000, was found to have a great practical application. At higher values of y^* we can use the formula

$$u^* = \frac{1}{\kappa} \log y^* + \text{const}$$

in which the constant has a value of about 5.5.

Of course, these considerations can be immediately transferred from pipes to other flow conditions. We have to expect an analogous behavior near a smooth wall as long as the other boundaries have no great influence. Thus this rule checks experimentally very well in many other cases. Especially has the above-mentioned $^1/_7$-power formula often been found again, for instance, in flows through straight tubes with rectangular, triangular, and other cross-sections, in turbulent flow along a flat plate where the second logarithmic formula is also checked, and in accelerated and retarded flows as through convergent and divergent channels. On the other hand, this formula $u^* = 8.7y^{*1/7}$ has been used with great success for the calculation[5] of turbulent boundary layers and the distribution of τ_0, that is, the frictional forces at the surface of bodies. In this way von Kármán calculated the frictional resistance of a flat plate (28), to which case the author will return later, and the flow due to a rotating disk, and Clark B. Millikan (29) the frictional resistance of an airship. The agreement with the experiments is in all cases good. Only the calculated value of the frictional moment acting on both sides of the spinning disk will be given here: namely,

$$0.146\, \rho \frac{U^2}{2} r^3 \left(\frac{\nu}{Ur}\right)^{1/5}$$

where U is the circumferential velocity and r the radius of the disk.

VI—CALCULATION OF THE SKIN FRICTION FOR SIMPLE CASES OF FULLY DEVELOPED TURBULENCE, ESPECIALLY FOR THE FLAT PLATE

Furthermore, by a combination of these important conceptions, the mixing-length and the τ_0-rules, von Kármán succeeded in 1930 in formulating the law of the frictional resistance in pipes and along flat plates up to arbitrarily high Reynolds numbers (23, 30).

The last fact is extremely useful from the experimental point of view. Usually it is desired to make experiments with models of much smaller dimensions than those of the actual full-size objects. But, on the other hand, we have to extend our experiments to very high Reynolds numbers to be sure that we can transfer the results to practical cases. This last necessity generally involves much labor and great expense. For both problems this difficulty has now been eliminated, since we know the frictional resistance up to arbitrarily high Reynolds numbers.

The method will now be outlined. For the inner part of the flow, i.e., that not in the immediate vicinity of the wall, the viscosity can be neglected, as we have already seen, and the shearing stress calculated by means of the mixing length. According to the Stanton-von Kármán rule, l/r is always the same function of y/r. (For the plate we have of course to replace r by the thickness of the boundary layer.) Of this function only one

[5] For this purpose $u^* = 8.7y^{*1/7}$, which we can write in the original quantities as $\bar{u} = 8.7\ (\tau_0/\rho)^{4/7} \cdot (y/\nu)^{1/7}$ is extrapolated to the velocity at the outer end of the boundary layer. This last velocity is supposed to be known. Such extrapolation is generally risky, but causes no great errors in the following calculations. In the first $^1/_7$-power formula only the quantity τ_0 is still unknown, the distribution of which along the surface of the bodies is calculated by means of the momentum theorem.

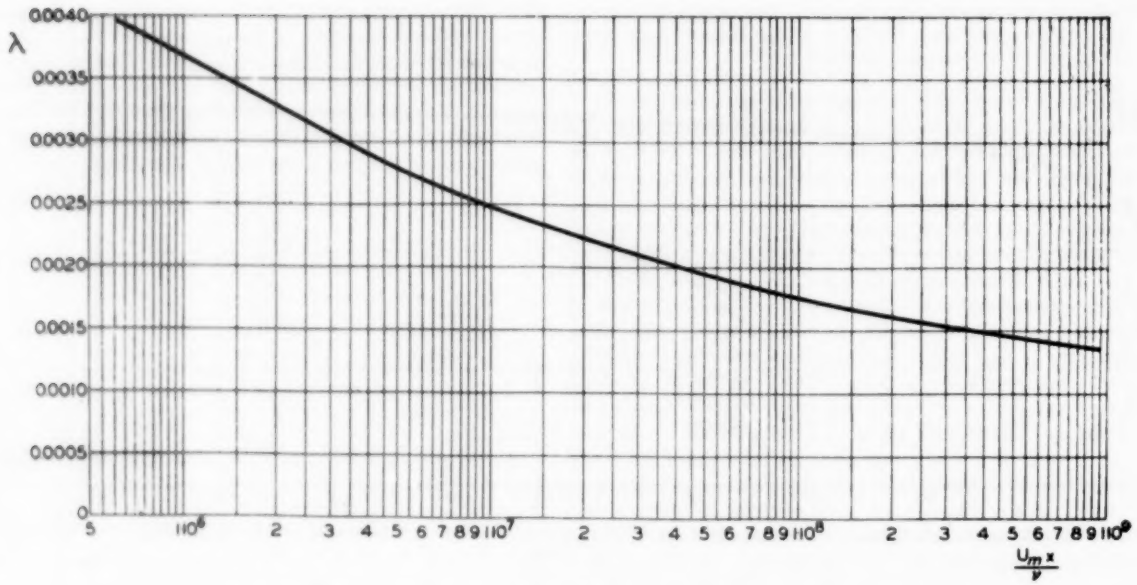

FIG. 11 SKIN FRICTION OF A TURBULENT FLOW ALONG A FLAT PLATE

property is used,[6] namely, that l/τ at first linearly increases with the distance from the wall, which means that $l/\tau = \kappa y/\tau$ or $l = \kappa y$. To connect this region of the flow with the region near the wall, Prandtl's consideration is used in the form that for a certain constant value of y^*, say, y_1^*, the corresponding value of u^* shall be a constant u_1^*. Both of these constants are supposed to be empirically known.[7]

The calculations of the frictional resistance based on these ideas check very well with experiment. In the case of the flat plate, let x be the distance from the leading edge of the plate, and U_m the velocity of the undisturbed flow far from the plate. Then in the diagram (Fig. 11) $\lambda = 2\tau_0/\rho U_m^2$ is plotted against $R_x = U_m x/\nu$. λ is a sort of local resistance coefficient just as R_x is something like a local Reynolds number. The total skin friction of a plate of certain length can easily be found by integrating τ_0 over the total surface of the plate. Of course, the boundary layer starts at the leading edge of the plate with a laminar portion, as has been frequently mentioned. For large values of $U_m x/\nu$ it is permissible to neglect this laminar portion and to begin at once with a turbulent motion as is done in the diagram and in the following approximative formula for large values of $U_m x/\nu$:

$$\kappa \sqrt{\frac{2}{\lambda}} = \log\left(\frac{U_m x}{\nu} \cdot \lambda\right) + \text{const}$$

the value of constant being about 1.01. It is well known that the case of a plate is often considered as a standard case of frictional resistance, and estimations are made therefrom for the skin friction of other bodies. The method outlined above can be employed to some extent in the case of rough walls (23).

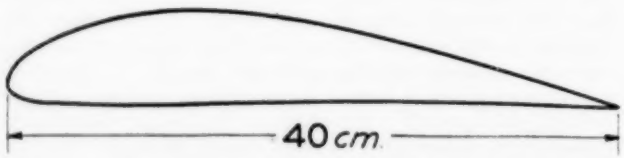

FIG. 12 AIRFOIL (GOETTINGEN PROFILE 387) USED BY GRUSCHWITZ (33) FOR MEASUREMENTS OF THE BOUNDARY LAYER ON THE UPPER SURFACE

VII—CONCLUSION

In concluding the present survey of modern investigations of turbulent phenomena, it must be admitted that in spite of recent surprising successes, only a small portion of the phenomena can be treated in such a systematic manner. Our considerations have all been limited to flows which have been mainly two-dimensional or axial-symmetrical. Moreover, the mean flow has been assumed to be essentially in one direction, x, with only slight curvature or divergence allowed.

Considering now only two-dimensional mean flow, the first outstanding problem is that of strongly accelerated or, in particular, strongly retarded flow. The last case is closely associated with the problem of investigating the conditions for the break away of flow from the upper surface of a body, i.e., the phenomenon of "burbling." This effect is very important in aeronautics because it determines the stalling of airplanes and therewith the limiting value of the maximum lift.

It has long been known that laminar flow has a greater tendency to break away than turbulent flow, but beyond this fact we know very little. Accurate measurements of retarded

---

[6] It can easily be proved that this empirical proportionality constant is the same as the earlier constant κ, the value of which is about 0.4.

[7] Wada (31), as early as 1927, made a proposal which seems at first glance very similar to the procedure outlined above. He assumes that the total shearing stress is composed of the laminar stress $\mu d\bar{u}/dy$ and the turbulent stress, given again in the simple form $\kappa^2 y^2 (d\bar{u}/dy)^2$. But he does not exclude from this consideration the region quite near to the wall as did von Kármán, who replaced it by a boundary condition (u^* at y_1^*). Wada's interesting proposal leads, for the region quite near to the wall (τ is approximately τ_0), to the conclusion

$$u^* = \frac{1}{\kappa} \log y^* + \frac{1}{\kappa} (\log 4\kappa - 1)$$

since the experiments give for the additive constant a value of about 5.5 instead of —1.32 as given by the above formula. This means that this simple superposition of viscous stress and turbulent stress entirely uninfluenced by the viscosity is not possible. Close to the wall the viscosity has a decided effect on the development of the turbulent stress.

turbulent flow have been made, especially by Nikuradse, with divergent (wedge-shaped) channels of great depth (32). Attempts have also been made several times to transfer these results to other cases of retarded flow—however, without great success. There is still very little known about the conditions for break away of turbulent flow.

Figs. 13 and 14 show the recent measurements of E. Gruschwitz (33) of velocity profiles on the upper surface of an airfoil (Fig. 12) in the region of increasing pressure. The differences between the laminar and turbulent profiles are clearly seen. At an angle of attack of 6 deg the flow holds to the surface, while at 12 deg it breaks away.

Another important and difficult problem is that of turbulent flow along highly curved surfaces. In spite of many attempts to analyze the problem, there is still little known further than the fact that for surfaces convex with respect to the flow the turbulent momentum interchange is decreased, while for concave surfaces it is increased. The explanation is that the fluid particles near the wall are slowed down due to the influence of wall friction, and are therefore subject to less centrifugal force than the faster-moving particles at a greater distance from the wall. This effect is technically quite important, but does not generally come into consideration in aircraft engineering since the boundary-layer thickness for the usual airfoils is small compared with the radius of curvature of the surface.

The author would conclude this brief review of some significant problems of turbulence with a general remark. Although the methods outlined in the present report have often led to practically useful results, they should be considered only as advances toward the real goal of the turbulence theory. The derivation of turbulence phenomena from the hydrodynamical equations will, in the author's opinion, be possible only by the application of statistical methods. Using conceptions of the theory of probabilities we may represent turbulent flow as composed of random fluctuations whose mean values obey certain definite laws. There have already been several interesting attempts along this line (34, 35). Similar attempts are being made on the experimental side to go beyond the usual measurements of mean values and investigate the structure of turbulent flow by observation of the turbulent fluctuations themselves.

APM-55-5

Analysis of Stresses in an Elliptic Ring

By MERIT P. WHITE,[1] PASADENA, CALIF.

Problems sometimes confront engineers the analytic solution of which requires quite a knowledge of mathematics. The author illustrates this with the calculations required in an investigation of a wind-tunnel problem. The method used is intricate and tedious. A simpler solution may be arrived at by use of the graphical method.

ENGINEERS are sometimes confronted with unusual problems whose analytic solution requires more knowledge of mathematics than most of them retain after completing their formal study of the subject.

Such a problem was encountered in connection with a recent investigation of a wind tunnel. This wind tunnel, Fig. 1, is made up of large circular pipes arranged to form a closed circuit and connected by stiff ring girders at the corners. These ring girders are of course elliptic in contour. The problem was to determine the stress at any point in the ring girder due to the dead weight of the structure.

In the case of ring a, Fig. 1, the horizontal pipe was considered cut just to the right of a, and a moment equivalent to the effect of the dead weight applied. An equal and opposite moment must exist within the vertical pipe. Each pipe is a beam with a stress at any point equal to My_c/I, where y_c is the perpendicular distance from the point to the neutral plane. This force is applied directly to the ring. The forces which one pipe exerts on the ring are shown in Fig. 2. The effect of the other pipe is exactly similar.

Let t be the thickness of the pipe; then in a distance ΔS_c (measured along a right section of the pipe) the total force acting in one pipe is:

$$P = \frac{My_c}{I}\ \Delta S_c t = \frac{My_c \Delta S_c}{\pi r^3}$$

which acts over a distance ΔS_e on the ellipse. Fig. 3 shows the relation between the elements of the ellipse and the pipe section. We have an equal force in the other pipe acting over the same portion of the ellipse. The effective force acting on the ellipse will be the resultant of these P's. Since the P's are at right angles, their resultant will be $P(\sqrt{2})$. This resultant will lie in the plane of the ellipse and will always be parallel to the major axis of the ellipse. This is evident from the fact that the plane of the ellipse is a plane of symmetry for both systems of forces, while, at any point, both forces and their resultant lie in a plane containing corresponding elements of both pipes, and therefore parallel to the major axis of the ellipse.

In a distance ΔS_e the force acting on the ellipse is

$$F = \frac{(\sqrt{2})My_c \Delta S_e}{\pi r^3}$$

We must first express $y_c \Delta S_c$ in terms of the elements of the ellipse. But $\Delta S_c = (r/y_c)\Delta x$. In a distance ΔS_e along the ellipse or in a horizontal distance Δx, the load on the ellipse equals $(\sqrt{2})M\,\Delta x/\pi r^2$. In other words, the horizontal distribution of the load is uniform.

Having completed the preliminaries, it only remains to apply enough equations of equilibrium (static and elastic) to determine the variation of thrust, shear, and moment along the ring.

The principal axes of the ellipse are axes of symmetry, so there can be no shear along these axes. Furthermore, as a result of this symmetry, we need consider only one quadrant of the ellipse.

Let the horizontal distribution of the load be K, where $K = M(\sqrt{2})/\pi r^3$. Then, considering the free-body diagram shown in Fig. 5:

$$\Sigma v = Kr - T_B = 0;\ T_B = Kr$$

$$\Sigma H = T_A = 0$$

$$\Sigma M \text{ about } B = M_A - M_B + (Kr^2/2) = 0$$

We need one equation from elasticity to determine M_A and M_B. This equation follows from the fact that the relative rotation of the tangents at A and B equals zero (from symmetry) or: The area of the M/EI diagram must be zero. E and I are constant. Therefore

$$\int_A^B M ds = 0$$

The major diameter of the ellipse is $(\sqrt{2})$ times the minor diameter. The equation of the ellipse is:

$$x^2 + \frac{y^2}{2} = r^2;\quad ds = \sqrt{\frac{r^2 + x^2}{r^2 - x^2}}\,dx$$

$$M = M_A - \frac{Kx^2}{2};\quad \int_0^r \left(M_A - \frac{Kx^2}{2}\right)\sqrt{\frac{r^2 + x^2}{r^2 - x^2}}\,dx = 0$$

Unfortunately, the latter expression is non-integrable. The substitution of $x = r\sin\theta$ gives a more simple form:

$$\int_0^{\pi/2}\left(M_A - \frac{Kr^2\sin^2\theta}{2}\right)\sqrt{1 + \sin^2\theta}\,d\theta = 0$$

This expression may be evaluated by expanding the radical in an infinite series, multiplying each term by the expression within the parentheses, and integrating. This gives a fairly satisfactory series. M_A can then be found as accurately as desired.

This method works, but is exceedingly tedious and requires a certain familiarity with mathematics. A simpler solution is desirable. For this reason, a graphical method was attempted.

We wish to determine the value of M_A which will make the area of the moment diagram equal to zero.

The first step is to lay out one quadrant of the ellipse (Fig. 6-*A*). Directly below this is drawn the moment diagram for the external forces, in this case a parabola (Fig. 6-*B*). Then,

[1] Assistant in Engineering, California Institute of Technology. Merit P. White was born October 25, 1908, at Wnately, Mass. In 1926 he was graduated from Northampton High School and entered Dartmouth College. While at Dartmouth he took courses preparatory to entering the Thayer School of Civil Engineering, which is connected with Dartmouth. He was graduated in 1930 from Dartmouth. In 1931 he received the degree of Civil Engineer from Thayer. The following year (academic) was spent at the California Institute of Technology, in Pasadena, as assistant in civil engineering (surveying instructor). He received the M.S. degree in June, 1932.

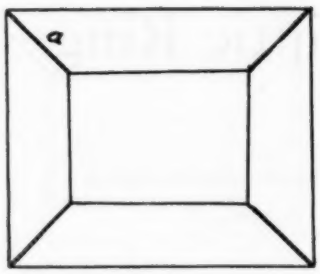

FIG. 1

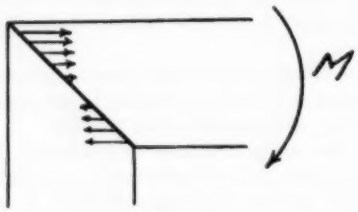

FIG. 2

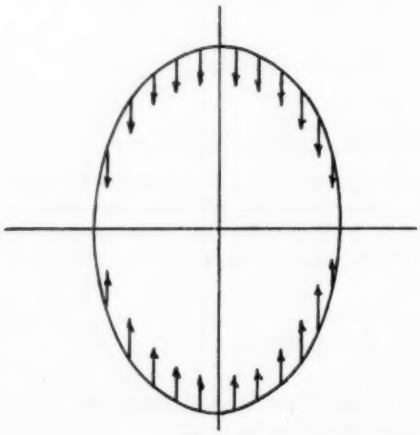

FIG. 4

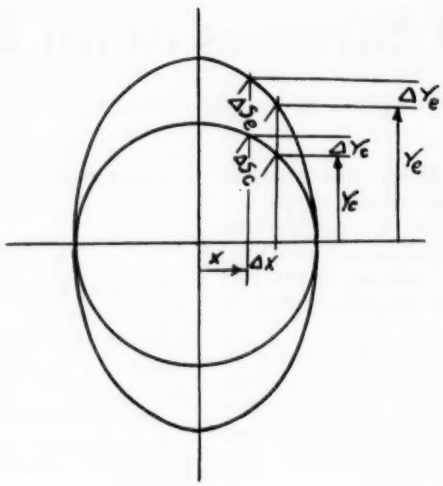

FIG. 3

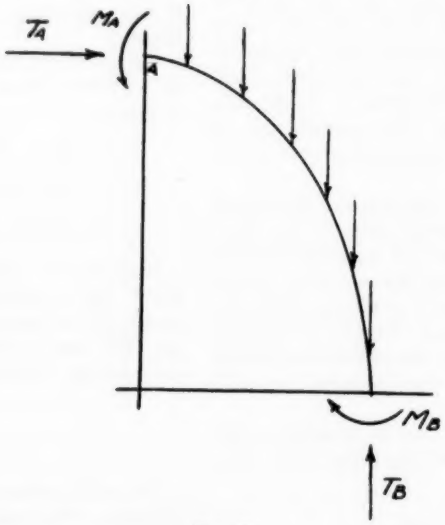

FIG. 5

on the developed length of the ellipse as an axis, there is constructed a new moment diagram (Fig. 6-*C*), whose ordinates are transferred directly from Fig. 6-*B*.

Then $M_A \times$ Developed Length = Area of Diagram, or M_A = average ordinate to moment diagram

Graphically, $M_A = 0.121M$
Analytically, $M_A = 0.1219M$

A series of concentrated loads or a change of cross-section (I) would not greatly complicate this process, but would make the analytic method almost impossible. For the simplest case, that of a uniform circular ring with continuous variation of load, the analytic method would be suitable.

If more than one equation from elasticity were needed—for example, if the moment of the moment diagram were also zero about some axis—this method could be extended. The moment diagram would be constructed as before and divided into areas with equal bases. Then the mid-ordinate of each area would be multiplied (algebraically) by its perpendicular distance to the axis about which moments are taken (obtained from Fig. 6-*A*). This would be done for the moment diagrams of M_A and V_A or H_A, expressed in terms of these unknowns. Finally, the algebraic sum of these moments would be set equal to zero, which would give another relation between the unknowns.

Stress Distribution in a Reentrant Corner

By J. H. A. BRAHTZ,[1] PASADENA, CALIF.

This paper deals with the stress distribution under plain strain in a corner of any angular magnitude, i.e., a plane with an angular incision or notch.

It begins with a brief statement of the method employed by Dr. Th. von Karman in his exact treatment of a beam in bending (Aachen Abhandlungen, Heft 7, 1927).

A generalization of this method is outlined which is applicable to the corner for any force distribution over the straight boundaries, and the solution is found for a concentrated load at any point of the boundary. The stresses are determined and shown to be infinite at the vertex of the corner.

The discussion points out the very interesting paradox that stresses may be finite for certain continuous loadings, but become infinite if a portion of the load is removed.

THE knowledge of two-dimensional stress distributions is useful for the solution of many problems in mechanical and civil engineering when the usual methods of strength of materials are not applicable or not sufficiently accurate. The stress distribution in the half-plane under the influence of a concentrated force acting on the straight boundary is of fundamental importance, and the solution of this problem is due to Boussinesq. Several extensions of his results have been made by Michell,[2] especially by means of the so-called method of inversion, the only conformal transformation of biharmonic solutions which leaves the boundary stresses undisturbed. By superposition of Boussinesq's solutions the stress distribution in the half-plane is easily obtained for an arbitrary load distribution along the straight boundary.

The stress distribution in a plane strip has been discussed by several authors, and special reference is made to a paper by Dr. Th. von Kármán[3] containing a general method for the determination of the stresses due to an arbitrary load along the boundaries. The paper is not yet available in the English language, therefore a brief description will be given of von Kármán's formulation of the problem.

A two-dimensional elastic system[4] is in equilibrium if the stresses σ_x, σ_y, and τ are the second partial derivatives of an arbitrary function $F(xy)$:

$$\sigma_x = \frac{\partial^2 F}{\partial y^2}; \quad \sigma_y = \frac{\partial^2 F}{\partial x^2}; \quad \tau_{xy} = -\frac{\partial^2 F}{\partial x \partial y} \ldots\ldots\ldots [1]$$

In order to be compatible with the stress-strain relations in accordance with Hooke's law, F must be a solution of the equation

$$\frac{\partial^4 F}{\partial x^4} + 2\frac{\partial^4 F}{\partial x^2 \partial y^2} + \frac{\partial^4 F}{\partial y^4} = 0 \ldots\ldots\ldots\ldots [2]$$

or in Gibbs's notation

$$\nabla^4 F = 0$$

F, known as Airy's function, and its first partial derivatives can be interpreted in terms of the quantities usually employed and defined in "strength of materials," namely, shear and moment of the external forces. By integrating [1] along the boundary between points A and B it is seen that the differences $(\partial F/\partial x)_B - (\partial F/\partial x)_A$ and $(\partial F/\partial y)_B - (\partial F/\partial y)_A$ represent, respectively, the resultant Y- and X-components of the load on the boundary between A and B, and, integrating once more, it is seen that the difference $(F)_B - (F)_A$ represents the increase in the bending moment in going from A to B.[5]

Hence, if all loads are assumed applied at the upper surface of the strip x-axis (see Fig. 1), the usual moment curve becomes identical with $F(x,0)$ for the strip in question and the problem of stress distribution becomes simply the determination of $F(x,y)$ for given boundary values.

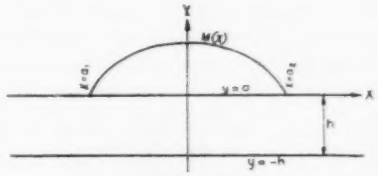

FIG. 1

It can easily be verified that the following functions are particular integrals of [2]:

$$A_1 \cos mx \cosh my,\ A_2 \cos mx \sinh my,\ A_3 \sin mx \cosh my,$$
$$A_4 \sin mx \sinh my,\ A_5 y \cos mx \cosh my,\ A_6 y \cos mx \sinh my,$$
$$A_7 y \sin mx \cosh my,\ A_8 y \sin mx \sinh my$$

and if we consider the coefficients A_1, etc. as functions of the parameter m, Airy's stress function can be written

$$F = \int_0^\infty \Big[(A_1 \cosh my + A_2 \sinh my + A_5 y \cosh my + A_6 y \sinh my) \cos mx + (A_3 \cosh my + A_4 \sinh my + A_7 y \cosh my + A_8 y \sinh my) \sin mx \Big] dm \ldots [3]$$

where A_1, etc. are to be determined by the boundary conditions.

The loads are assumed perpendicular to the upper surface of the strip or beam, and if the depth of the beam is h, the boundary conditions to be satisfied by F are:

$$\frac{\partial F}{\partial y} = 0, \quad F = M(x) \text{ at the upper boundary, } y = 0$$

---

[1] Research Fellow, California Institute of Technology. Dr. Brahtz received his M.S. at Royal Technical Institute, Copenhagen, Denmark, in 1914 and his Ph.D. at California Institute of Technology in 1932. He came to the United States in 1914 and served as district engineer on roads and bridges for the Minnesota State Highway Department for two years, and as special instructor in mathematics and mechanics at the University of Minnesota during the World War. He was consulting engineer to municipalities in St. Paul, Minn., from 1917 to 1928, and teaching fellow at California Institute of Technology from 1929 to 1932. Since then he has been research fellow in theoretical elasticity and photoelasticity in connection with the Pine Canyon Dam being built by the city of Pasadena.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[5] See Riemann-Weber, "Differentialgleichungen der Physik," vol. ii.

$$\frac{dF}{dy} = 0, \quad F = 0 \text{ at the lower boundary, } y = -h$$

As in Fig. 1, the moment $M(x)$ is assumed to be zero except in the region $x = a_1$ to $x = a_2$, and we now express $M(x)$ as a Fourier integral:[6]

$$M_x = \int_0^\infty (a \cos mx + b \sin mx)\, dm$$

where a and b are determined by

$$a = \frac{1}{\pi}\int_{a_1}^{a_2} M(\alpha)\cos m\alpha d\alpha$$

$$b = \frac{1}{\pi}\int_{a_1}^{a_2} M(\alpha)\sin m\alpha d\alpha$$

We now form the four boundary equations which must hold for all values of x. Hence, by equating to zero the coefficients of $\cos mx$ and $\sin mx$ we obtain eight other equations which determine the coefficients A_1, etc. (later in the paper this process is carried out in detail), and by the substitution of these in [3] we finally obtain the stress function F. The stresses are then found by employing [1].

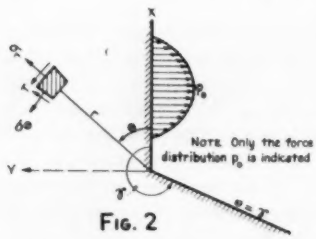

FIG. 2

In other words, if it is possible to represent the moment distribution $M(x)$ as a Fourier integral, the solution of the stress problem is immediately obtained.

Von Kármán and F. Seewald have applied this method to several important cases and obtained interesting results, among others the "corrected" relation between the bending moment and shear at a point of a beam and the curvature of the central line

$$K = \frac{M}{EI} + \left[\frac{6}{5G} - \frac{9\mu}{10E}\right]\frac{P}{A} \quad \ldots\ldots\ldots\ldots [4]$$

where K denotes the curvature; E and G, Young's modulus and the corresponding modulus in shear; μ, Poisson's ratio; A, area of cross-section; I, moment of inertia; and M and P, the bending moment and shear at the point in question. The second term corresponds to the influence of shear on the deflection.

A new and interesting conclusion of this theory is that the deflection of the central line of a long beam is wave shaped outside the loaded region.

Generalization. The method just described can be applied generally, not only to the half-plane, but to any angular portion (γ) of the plane with any distribution of normal and tangential forces over the straight boundaries.

Introducing polar coordinates the stress function must satisfy the equation

$$\nabla^4 F(r,\theta) = \left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{\partial^2}{r^2\partial\theta^2}\right)^2 F = 0 \quad \ldots\ldots [5]$$

with corresponding stresses

$$\sigma_r = \frac{\partial^2 F}{r^2\partial\theta^2} + \frac{1}{r}\frac{\partial F}{\partial r} \quad \ldots\ldots\ldots\ldots [6]$$

$$\sigma_\theta = \frac{\partial^2 F}{\partial r^2} \quad \ldots\ldots\ldots\ldots [7]$$

$$\tau = -\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial F}{\partial\theta}\right) \quad \ldots\ldots\ldots\ldots [8]$$

(See Fig. 2.)

The general solution of [5] is the real and/or imaginary parts of the complex function:

$$\varphi(z) = Af(z) + Bxg(z) + Cyh(z) \quad \ldots\ldots\ldots\ldots [9]$$

where $z = x + iy = r(\cos\theta + i\sin\theta) = re^{i\theta}$. A, B, and C are arbitrary complex constants; $f(z)$, $g(z)$, and $h(z)$ are arbitrary analytic functions.

For the present purpose the author will employ the functions obtained by taking real or imaginary parts of

$$\varphi_n = \frac{1}{2}A_n \begin{pmatrix} x \\ \text{and} \\ y \end{pmatrix} (z^{+im} \pm z^{-im}) \quad \ldots\ldots\ldots\ldots [10]$$

where m is a real and A_n an arbitrary constant to be determined by the boundary conditions.

Let $\xi = \log r$, and let $f(z)_r$ denote the real part of $f(z)$ or $Rf(z)$, and $f(z)_i$ the imaginary part of $f(z)$ or $If(z)$; then we obtain as particular solutions of $\nabla^4 F = 0$:

$$\left.\begin{aligned}
\varphi_1 &= \frac{1}{2}A_1 x(z^{im} + z^{-im})_r = +A_1 x\cos m\xi\cosh m\theta \\
\varphi_2 &= \frac{1}{2}A_2 x(z^{im} - z^{-im})_r = -A_2 x\cos m\xi\sinh m\theta \\
\varphi_3 &= \frac{1}{2}A_3 x(z^{im} + z^{-im})_i = -A_3 x\sin m\xi\sinh m\theta \\
\varphi_4 &= \frac{1}{2}A_4 x(z^{im} - z^{-im})_i = +A_4 x\sin m\xi\cosh m\theta \\
\varphi_5 &= \frac{1}{2}A_5 y(z^{im} + z^{-im})_r = +A_5 y\cos m\xi\cosh m\theta \\
\varphi_6 &= \frac{1}{2}A_6 y(z^{im} - z^{-im})_r = -A_6 y\cos m\xi\sinh m\theta \\
\varphi_7 &= \frac{1}{2}A_6 y(z^{im} + z^{-im})_i = -A_7 y\sin m\xi\sinh m\theta \\
\varphi_8 &= \frac{1}{2}A_8 y(z^{im} - z^{-im})_i = +A_8 y\sin m\xi\cosh m\theta
\end{aligned}\right\} \quad \ldots\ldots [11]$$

The coefficients A_n are now defined as functions of the parameter m. The stress function may then be expressed as

$$F = \sum_{n=1}^{n=8}\int_0^\infty \varphi_n dm = \int_0^\infty \left[\varphi_1 + \varphi_2 \ldots\ldots + \varphi_8\right] dm \quad \ldots\ldots [12]$$

from which the stresses are obtained by [6], etc.:

$$\sigma_r = \sum_{n=1}^{n=8}\int_0^\infty \left[\frac{\partial^2\varphi_n}{r^2\partial\theta^2} + \frac{1}{r}\frac{\partial\varphi_n}{\partial r}\right] dm \quad \ldots\ldots [13]$$

$$\sigma_\theta = \sum_{1}^{8}\int_0^\infty \frac{\partial^2\varphi_n}{\partial r^2}\, dm \quad \ldots\ldots\ldots\ldots [14]$$

[6] For explanation, see "Fourier Series," by W. E. Byerly.

$$\tau = -\sum_{1}^{8}\int_0^\infty \frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial \varphi_n}{\partial \theta}\right) dm \ldots\ldots\ldots [15]$$

Two typical cases of boundary loads must be considered:

(*a*) The load may be continuous (not necessarily uniform) over portions of the straight boundaries. Let it be assumed that the load is distributed over finite portions of the boundaries or, if the load extends to infinity, that the load per unit length becomes zero at infinity. Let the boundaries be the lines $\theta = 0$ and $\theta = \gamma$, and let the normal loads be, respectively, p_0 and p_γ and the tangential loads q_0 and q_γ. These quantities are functions of r, measured from the intersection of the boundaries, or functions of $\xi = \log r$. Using Fourier's double integrals we can write $p_0(\xi)$ in the following form:

$$p_0(\xi) = \frac{1}{\pi}\int_0^\infty \left[\cos m\xi \int_{\xi_1}^{\xi_2} p_0(\alpha)\cos m\alpha d\alpha + \sin m\xi \int_{\xi_1}^{\xi_2} p_0(\alpha)\sin m\alpha d\alpha\right] dm \ldots\ldots [16][7]$$

where the load $p_0(\xi)$ is assumed to exist only between the points ξ_1 and ξ_2. Similar expressions are obtained for p_γ, q_0, and q_γ.

Therefore the boundary conditions are

$$(\sigma_\theta)_{\theta=0} = p_0(\xi) \text{ expressed as in [16]} \ldots\ldots [17]$$

$$(\tau)_{\theta=0} = q_0 \ldots\ldots [18]$$

$$(\sigma_\theta)_{\theta=\gamma} = p_\gamma \ldots\ldots [19]$$

$$(\tau)_{\theta=\gamma} = q_\gamma \ldots\ldots [20]$$

where σ and τ are given by [14] and [15].

By now equating coefficients of $\cos m\xi$ and $\sin m\xi$ in the above equations, eight other equations are obtained which determine the eight functions $A(m)$ and consequently the stress function F by substituting $A(m)$ in [12].

(*b*) In the case of concentrated loads the boundary conditions are obtained in the following manner: It has already been shown that the differences $(\partial F/\partial x)_B - (\partial F/\partial x)_A$ and $(\partial F/\partial y)_B - (\partial F/\partial y)_A$ represent, respectively, the Y- and X-components of all the boundary forces between A and B. Therefore in the case of concentrated forces these differences become discontinuous (similar to the shear polygon for concentrated forces) and the jump in these values at a certain point is equal to the respective components of the concentrated force at that point. Consider for instance unit normal force acting at point $r = a$ of the boundary $\theta = 0$. Obviously

$$\left(\frac{\partial F}{\partial r}\right)_{a+\epsilon} - \left(\frac{\partial F}{\partial r}\right)_{a-\epsilon} = 1$$

where ϵ is a small positive quantity.

If there is no continuously distributed load on the boundary $\theta = 0$, then, by [17],

$$(\sigma_\theta)_{\theta=0} = \left(\frac{\partial^2 F}{\partial r^2}\right)_{\theta=0} = 0$$

Hence $\partial F/\partial r$ = constant on either side of $r = a$. These conditions can all be satisfied by writing

$$\frac{\partial F}{\partial r} = \frac{1}{\pi}\int_0^\infty \frac{\sin\left(m\log\frac{r}{a}\right)}{m} dm \ldots\ldots [21][8]$$

[7] See "Fourier Series," by W. E. Byerly.

[8] See Peirce, "Short Tables of Integrals," p. 484.

This integral has the value

$$-\frac{1}{2} \text{ for } \xi = \log(r/a) < 0 \quad \text{or} \quad r < a$$

$$+\frac{1}{2} \text{ for } \xi = \log(r/a) \gtrless 0 \quad \text{or} \quad r \gtrless a$$

The integral[9]

$$\frac{1}{\pi}\int_0^\infty \frac{n\cos m\xi - m\sin m\xi}{m^2+n^2} = \begin{cases} e^{n\xi} \text{ when } \xi < 0 \\ \frac{1}{2} \text{ when } \xi = 0 \\ 0 \text{ when } \xi > 0 \end{cases}$$

with its ramifications is often very useful in expressing boundary functions in Fourier integral form.

As an application of the foregoing, the stress function F corresponding to a unit normal traction at point $r = a$ of boundary $\theta = 0$ will be found for a reentrant right corner, i.e., $\gamma = 3\pi/2$. (See Fig. 3.)

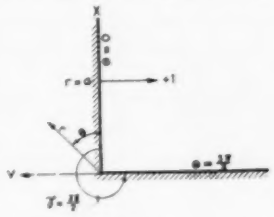

FIG. 3

The boundary conditions are:

$$\theta = 0 \begin{cases} \frac{\partial F}{\partial r} = 0 & \text{when } \xi = \log(r/a) < 0; \\ \frac{\partial F}{\partial r} = 1 & \text{when } \xi > 0, \\ \frac{\partial F}{\partial \theta} = 0 \end{cases} \qquad \theta = \gamma \begin{cases} \frac{\partial F}{\partial \theta} = 0 \\ F = 0 \end{cases}$$

Let $F = F_0 + F_1$. F_0 is determined by the boundary conditions

$$\left(\frac{\partial F_0}{\partial r}\right)_{\theta=0} = \begin{cases} -\frac{1}{2} \text{ for } \xi < 0 \\ +\frac{1}{2} \text{ for } \xi > 0 \end{cases}$$

Hence $\dfrac{\partial F_0}{\partial r} = \dfrac{1}{\pi}\displaystyle\int_0^\infty \frac{\sin m\xi}{m}\partial m$, by [21],

$$\left(\frac{\partial F_0}{\partial \theta}\right)_{\theta=0} = 0; \quad (F_0)_{\theta=\gamma} = 0; \quad \left(\frac{\partial F_0}{\partial \theta}\right)_{\theta=\gamma} = 0$$

In order to remove the concentrated force introduced at the origin (due to the discontinuity in $(\partial F/\partial x)$, F_1 is determined so that

$$\left(\frac{\partial F_1}{\partial r}\right)_{\theta=0} = \frac{1}{2} \text{ for } -\infty < \xi < +\infty$$

$$\left(\frac{\partial F_1}{\partial \theta}\right)_{\theta=0} = 0; \quad (F_1)_{\theta=\gamma} = 0; \quad \left(\frac{\partial F_1}{\partial \theta}\right)_{\theta=\gamma} = 0$$

F_1 is easily found by employing the simple solution to $\nabla^4 F_1 = 0$:

$$F_1 = A\theta r\cos\theta + B\theta r\sin\theta + Cr\cos\theta + Dr\sin\theta \ldots [22a]$$

Hence, by the boundary conditions for F_1:

$$\left(\frac{\partial F_1}{\partial r}\right)_{\theta=0} = C = \frac{1}{2}$$

[9] Riemann-Weber, "Differentialgleichungen der Physik," vol. I, p. 157.

$$\left(\frac{\partial F_1}{\partial \theta}\right)_{\theta=0} = Ar + Dr = 0$$

$$(F_1)_{\theta=\frac{3\pi}{2}} = -\frac{3\pi}{2} Br - Dr = 0$$

$$\left(\frac{\partial F_1}{\partial \theta}\right)_{\theta=\frac{3\pi}{2}} = \frac{3\pi}{2} Ar - Br + Cr = 0$$

Solving these and substituting in [22a],

$$F_1 = \frac{3\pi}{4-9\pi^2}\theta r\cos\theta + \frac{2}{4-9\pi^2}\theta r\sin\theta \quad \ldots\ldots [22b]$$

The first-degree terms have been omitted as they contribute no stress.

In order to determine F_0 we employ Equation [12] and formulate the given boundary conditions by differentiating the functions φ given by [11] and obtain:

$$\left(\frac{\partial F_0}{\partial r}\right)_{\theta=0} = \int_0^\infty \Big[A_1(\cos m\xi - m\sin m\xi) + A_4(m\cos m\xi + \sin m\xi)\Big]\,dm = \frac{1}{\pi}\int_0^\infty \frac{\sin m\xi}{m}\,dm$$

$$\left(\frac{\partial F_0}{r\partial \theta}\right)_{\theta=0} = \int_0^\infty \Big[-mA_2\cos m\xi - mA_3\sin m\xi + A_5\cos m\xi + A_8\sin m\xi\Big]\,dm = 0$$

$$(F_0)_{\theta=\gamma} = \int_0^\infty \Big[-A_5\cosh\gamma m\cos m\xi + A_6\sinh\gamma m\cos m\xi + A_7\sinh\gamma m\sin m\xi - A_8\cosh\gamma m\sin m\xi\Big]\,dm = 0$$

$$\left(\frac{\partial F_0}{r\partial \theta}\right)_{\theta=\gamma} = \int_0^\infty \Big[A_1\cosh\gamma m\cos m\xi - A_2\sinh\gamma m\cos m\xi - A_3\sinh\gamma m\sin m\xi + A_4\cosh\gamma m\sin m\xi - mA_5\sinh\gamma m\cos m\xi + mA_6\cosh\gamma m\cos m\xi + mA_7\cosh\gamma m\sin m\xi - mA_8\sinh\gamma m\sin m\xi\Big]\,dm = 0$$

where $\xi = \log(r/a)$ and $\gamma = 3\pi/2$.

By equating coefficients of $\cos m\xi$ and $\sin m\xi$:

$$A_1 + mA_4 = 0; \quad -mA_1 + A_4 = 1/m\pi; \quad -mA_2 + A_5 = 0; \quad -mA_3 + A_8 = 0$$

$$A_5\cosh\gamma m - A_6\sinh\gamma m = 0$$

$$A_7\sinh\gamma m - A_8\cosh\gamma m = 0$$

$$A_1\cosh\gamma m - A_2\sinh\gamma m - mA_5\sinh\gamma m + mA_6\cosh\gamma m = 0$$

$$-A_3\sinh\gamma m + A_4\cosh\gamma m + mA_7\cosh\gamma m - mA_8\sinh\gamma m = 0$$

and solving for A_n:

$$A_1 = -\frac{1}{\pi}\frac{1}{1+m^2}$$

$$A_2 = +\frac{1}{\pi}\frac{\cosh\gamma m\sinh\gamma m}{(1+m^2)(m^2-\sinh^2\gamma m)}$$

$$A_3 = -\frac{1}{\pi}\frac{\sinh\gamma m\cosh\gamma m}{m(1+m^2)(m^2-\sinh^2\gamma m)}$$

$$A_4 = +\frac{1}{\pi}\frac{1}{m(1+m^2)}$$

$$A_5 = +\frac{1}{\pi}\frac{m\cosh\gamma m\sinh\gamma m}{(1+m^2)(m^2-\sinh^2\gamma m)}$$

$$A_6 = +\frac{1}{\pi}\frac{m\cosh^2\gamma m}{(1+m^2)(m^2-\sinh^2\gamma m)}$$

$$A_7 = -\frac{1}{\pi}\frac{\cosh^2\gamma m}{(1+m^2)(m^2-\sinh^2\gamma m)}$$

$$A_8 = -\frac{1}{\pi}\frac{\sinh\gamma m\cosh\gamma m}{(1+m^2)(m^2-\sinh^2\gamma m)}$$

The stress function is then found simply by substituting the A's back into Equation [12] and the stresses are found from Equations [13], [14], and [15].

The stress function in the $^3/_4$-plane for unit tensile force concentrated at point $(r,\theta) = (a,0)$ after some reduction becomes: $F = F_0 + F_1 =$

$$F = \frac{1}{\pi}\int_0^\infty \frac{[xm^2 - (x\sinh\gamma m + ym\cosh\gamma m)\sinh m(\gamma-\theta)]\,(m\cos m\xi - \sin m\xi)}{m(1+m^2)(\sinh^2\gamma m - m^2)}\,dm + \frac{3\pi}{4-9\pi^2}\theta r\cos\theta + \frac{2}{4-9\pi^2}\theta r\sin\theta \quad \ldots\ldots [23]$$

where $\gamma = {}^3/_2\pi$; $\xi = \log(r/a)$; $x = r\cos\theta$; $y = r\sin\theta$.

The integral F may be evaluated by the method of contour integration in the complex plane,[10] making use of Cauchy's theorem of residues as outlined in the Appendix.

The stress functions valid for small and large values of r/a become: $F = F_0 + F_1 =$

$$F = a[0.101\,(r/a)^{1.545}\,g(\theta) + 0.125\,(r/a)^{1.909}\,h(\theta)] \quad \text{when } r/a \ll 1 \quad \ldots\ldots [24]$$

$$F = a\left[-0.340\,(r/a)^{0.455}\,g(\theta) - 2.629\,(r/a)^{0.091}\,h(\theta) + \frac{r}{a}\frac{6\pi}{4-9\pi^2}\theta\cos\theta + \frac{r}{a}\frac{4}{4-9\pi^2}\theta\sin\theta - \cos^2\theta\right] \quad \text{when } r/a \gg 1 \quad \ldots\ldots [25]$$

where

$$g(\theta) = \sin 0.545\,\theta\cos\theta - 0.545\cos 0.545\,\theta\sin\theta - 0.839\sin 0.545\,\theta\sin\theta$$

$$h(\theta) = \sin 0.909\,\theta\cos\theta - 0.909\cos 0.909\,\theta\sin\theta + 0.416\sin 0.909\,\theta\sin\theta$$

It is interesting to notice that the terms in [24], including those of higher order, are the biharmonics (solutions of $\nabla^4 F = 0$) which correspond to boundaries free of forces. This can also be seen by writing

$$F = Ar^n\cos n\theta + Br^n\cos(n-2)\theta + Cr^n\sin n\theta + Dr^n\sin(n-2)\theta \quad \ldots\ldots [26]$$

where n may be complex and finding the values of n which give possible solutions in case F and $\partial F/\partial\theta$ are both to be zero along both boundaries. The determinant of the four boundary equations gives exactly the roots corresponding to the exponents in [24]. It is, however, only possible to determine the ratios B/A, etc. in this way. The absolute values of the constants

[10] For explanation see MacRobert, "Functions of a Complex Variable."

naturally depend upon the location and magnitude of the concentrated forces, and these can only be specified by the use of Fourier integrals as above.

The writer is informed that Dr. H. M. Westergaard, professor of theoretical and applied mechanics, University of Illinois, in a communication to Dr. von Kármán, has pointed out the existence of these solutions, presumably obtained in the manner just described.

Check on boundary conditions:
By [24] and [25] it is easily seen that

$$\left.\begin{matrix} F = 0 \\ \dfrac{\partial F}{\partial \theta} = 0 \end{matrix}\right\} \text{ when } \theta = 0 \text{ and } \theta = \frac{3\pi}{2}$$

are satisfied. (See Fig. 4.)

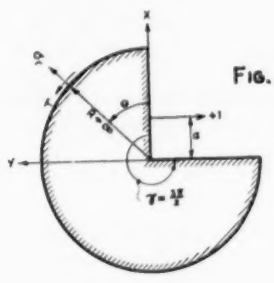

FIG. 4

In order to investigate if all boundary forces are in equilibrium we shall determine the stresses on a circle of large radius $r = R \to \infty$. By differentiating [25] and taking only such terms that contribute,

$$\sigma_r = -\frac{6\pi}{4 - 9\pi^2}\frac{2\sin\theta}{R} + \frac{4}{4 - 9\pi^2}\frac{2\cos\theta}{R}$$

$$\tau = \frac{a\sin 2\theta}{R^2}$$

Projecting on the X-axis and letting $R \to \infty$:

$$\Sigma X = \int_0^{\frac{3\pi}{2}} r\sigma_r \cos\theta\, d\theta = \left[\frac{3\pi}{4 - 9\pi^2}\cos 2\theta + \frac{4}{4 - 9\pi^2}\left(\theta + \frac{1}{2}\sin 2\theta\right)\right]_0^{\frac{3\pi}{2}} = 0$$

Projecting on the Y-axis:

$$\Sigma Y = \int_0^{\frac{3\pi}{2}} r\sigma_r \sin\theta\, d\theta = \left[-\frac{6\pi}{4 - 9\pi^2}\left(\theta - \frac{1}{2}\sin 2\theta\right) - \frac{2}{4 - 9\pi^2}\cos 2\theta\right]_0^{\frac{3\pi}{2}} = +1$$

Moments about the origin:

$$M_0 = \int_0^{\frac{3\pi}{2}} \tau r^2\, d\theta = -\left[\frac{a\cos 2\theta}{2}\right]_0^{\frac{3\pi}{2}} = +a$$

It will be seen that all equilibrium conditions are satisfied, the only other force being the unit tensile force at a. The stresses for large and small radii are now obtained from [24] and [25] by application of Equations [6], [7], and [8]. It will be noticed that stresses become infinite at the origin.

Evaluation of Stresses

If it is only desired to know the stresses at certain points or the distribution on a line, it is often simpler to specialize F (see [23]) before evaluating the integral. For example, to obtain the distribution of normal stress on the Y-axis, place $\theta = \frac{\pi}{2}$ in [23]:

$$F_{\theta=\pi/2} = \frac{r}{\pi}\int_0^\infty \frac{\cosh\gamma m \sinh\pi m}{(1 + m^2)(\sinh^2\gamma m - m^2)} \times (m\cos m\xi - \sin m\xi)dm + F_1 \quad [27]$$

$$\sigma_{\theta=\pi/2} = \frac{\partial^2 F}{\partial r^2} = \frac{1}{\pi r}\int_0^\infty \frac{m\cosh\gamma m \sinh\pi m}{\sinh^2\gamma m - m^2}\cos m\xi\, dm \quad [28]$$

Notice that F_1 contributes nothing to $\sigma_{\theta=\pi/2}$.

By [24] and [25] we obtain the correct stresses for small and large radii which usually are the most interesting, and only a few additional terms of higher powers in r would be needed to give the stresses in the region $r = a$. These can be obtained by the method of residues applied to [28] as explained in the Appendix. However, if only a plot of the stresses is desired, it is simpler to evaluate [28] for values of r in the neighborhood of a, by more primitive methods. The simplest of these would perhaps be to plot the integrand for various values of m and r and apply Simpson's rule. This need only be done for $m \leq 1$ because for larger values of m, [28] can be further simplified by placing

$\cosh\gamma m = \sinh\gamma m = \varepsilon^{\frac{3\pi m}{2}}$ and ignoring m^2 in the denominator. The integral then becomes

$$\frac{1}{\pi r}\int_0^\infty m\varepsilon^{-\frac{\pi m}{2}}\cos m\xi\, dm$$

The normal stresses on the line $\theta = \pi/2$ for large and small r/a are easily found by [24] and [25]:

$$\sigma_{\theta=\pi/2} = \frac{d^2F}{dr^2} = \frac{1}{a}\left[-0.084\left(\frac{r}{a}\right)^{-0.455} + 0.062\left(\frac{r}{a}\right)^{-0.091}\right]; \quad r \ll a \quad [29]$$

$$\sigma_{\theta=\pi/2} = \frac{d^2F}{dr^2} = \frac{1}{a}\left[-0.084\left(\frac{r}{a}\right)^{0.455} + 0.062\left(\frac{r}{a}\right)^{0.091}\right]\left(\frac{r}{a}\right)^{-2}; \quad r \ll a \quad [30]$$

The stresses $\sigma_{\theta=\pi/2}$ obtained by evaluating [28], [29], and [30] are plotted in Fig. 5. The corresponding stresses for the half-plane, $\gamma = \pi$, are also shown. It is interesting to notice the effect of the additional quarter-plane by comparing the two stress distributions, I and II.

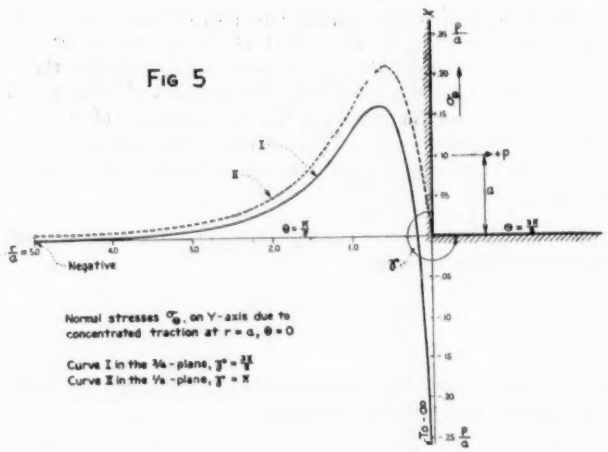
If several concentrated forces are applied on the boundary $\theta = 0$, the stress functions and stresses are obtained by superposing the functions computed for the various values of a. For a concentrated force acting on the boundary $\theta = 3\pi/2$, the stresses are obtained from the present formulas by substituting $(3\pi/2) - \theta$ for θ, maintaining the same coordinate system.

It is of interest to note that the function $g(\theta)$ in [24] is symmetric and $h(\theta)$ is antisymmetric about the bisector of the angle γ. This holds also for the corresponding functions for higher powers in r/a. This would mean that concentrated forces of equal magnitude located on each boundary at equal distance from the vertex would have stress functions (valid near the vertex):

$$F = 0.202a(r/a)^{1.545}g(\theta) \quad [24a]$$

if the unit forces are both tension

and



$$F = 0.250a(r/a)^{1.909}h(\theta) \quad [25a]$$

with traction on the boundary $\theta = 0$ and pressure on $\theta = 3\pi/2$. This shows that the stress at the vertex is always infinite for

partial loading of the boundaries. It is now also clear why there should be two terms producing infinite stresses.

It will be noticed that Equation [37] of the Appendix has no real roots, except $m = 0$, when γ is less than π. This means that in general a partial loading of the boundaries of a corner will produce finite stresses at the origin (vertex) if $\gamma < \pi$, but infinite stresses if $\gamma > \pi$, and the greater γ is, the sharper the infinity. The half-plane, $\gamma = \pi$, thus is the critical case, and the stresses at the origin are zero if it is chosen outside the loaded region.

Special cases of stress distribution in an infinite wedge have been treated by a number of investigators. We find J. H.

Michell who generalizes Boussinesq's solution for a concentrated force on the half-plane to a concentrated force at the vertex of an infinite wedge, M. Levy[11] who finds a solution for a linear load distribution over the boundaries, S. D. Carothers[12] who gives solutions for a couple at the vertex and uniform loads on the boundaries.

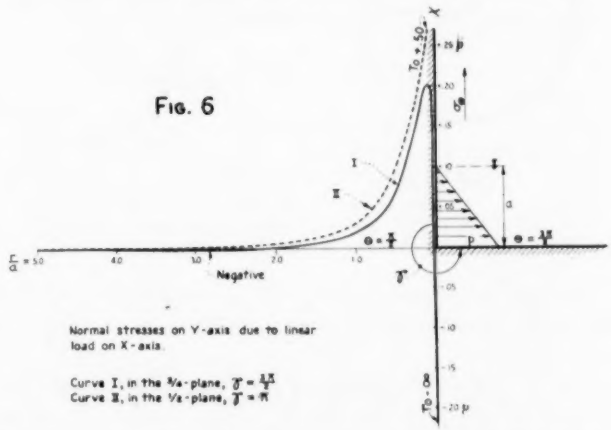
The stress function for continuous uniform pressure on the boundaries is easily determined by Equation [26]:

$$F = -\frac{p}{2} r^2 \cos^2 \theta \ldots\ldots\ldots\ldots\ldots [31]$$

corresponds to uniform pressure on the boundary $\theta = 0$. From this it will be seen that the stresses are finite at the vertex for any value of γ. We have seen that a partial loading produces infinite stress at the vertex if $\gamma > \pi$, so that we have the curious result that in this case the removal of a portion of the load raises the stress to infinity.

If uniform pressure acts on the boundary $\theta = 3\pi/2$ (as in the case of a dam with a full reservoir), the corresponding stress function is

$$F = -\frac{p}{2} r^2 \sin^2 \theta \ldots\ldots\ldots\ldots\ldots [32]$$



This is important in the design of dams, as it shows that the base will be under compression due to this load. In Fig. 6 is plotted the normal stress on the base, $\theta = \pi/2$, due to linear pressure distribution on the boundary, $\theta = 0$. It is important to notice that near the vertex the base is under high tension, i.e., opposite to the stress due to the uniform pressure on the boundary, $\theta = 3\pi/2$.

Levy's solution for linear normal pressure on the boundary of an infinite wedge (or triangle) shows linear distribution of all stresses along any straight line through the wedge. In practice this result is conveniently applied to masonry dams. However, the application is dubious because the height of a dam is of the same order of magnitude as the base width, so that great deviations from the linear stress distribution can be expected (at any rate near the base) due to the influence of the unyielding, or rather, infinite, foundation.

Engineers are well aware of this fact, and the present study grew out of an attempt to determine the stress distribution in triangular dams on infinite, rigid, and elastic foundations by the Ritz method. However, it was found that the stresses in the up- and down-stream faces at the base did not converge when more parameters were included in the solution. At points only slight distant from the up- and down stream corners Ritz's method gave reasonable results, which will be published in the near future.

The present method enables us to compute the stresses in dams of triangular and other shapes for any load, and far more accurate solutions can be reached in this way than by any previously employed.

Photoelastic experiments are at present being carried out at the California Institute by the author and Mr. Ralph M. Watson

for the purpose of verifying the theoretical results of this study. It is of special interest to find out how closely the equation $\nabla^4 F = 0$ holds for plates of finite thickness. The stress distribution is also being investigated in plates of arbitrary shapes, especially applicable to masonry dams, as also are the stress concentrations around openings corresponding to the inspection and drainage galleries which usually exist in high dams.

Appendix

Cauchy's theorem of residues

$$\int_S \psi(m)dm = 2\pi i \sum \text{Residues}$$

enables us to compute the definite integral in [23]

$$m \text{ is complex } = \alpha + i\beta$$

The residues are found by integrating around each pole in the positive direction.

F_0 may be written as

$$F_0 = \frac{1}{2\pi}\int_0^\infty \frac{mf(m)\cos m\xi\, dm}{m(1+m^2)(\sinh^2 \gamma m - m^2)} - \frac{1}{2\pi}\int_0^\infty \frac{f(m)\sin m\xi dm}{m(1+m^2)(\sinh^2 \gamma m - m^2)} = M_1 - M_2 \ldots [33]$$

[11] A. E. H. Love, "Elasticity," p. 212.
[12] Proc. Roy. Soc., Edinburgh, vol. 53 (1913), p. 292.

where the meaning of $f(m)$ is evident by comparing with Equation [23].

Consider the complex integrals:

$$G + iH = \frac{1}{2\pi}\int_S \frac{e^{im}f(m)dm}{m(1+m^2)(\sinh^2\gamma m - m^2)} \quad [34]$$

and

$$K + iL = \frac{1}{2\pi}\int_S \frac{m^{im}f(m)dm}{m(1+m^2)(\sinh^2\gamma m - m^2)} \quad [35]$$

taken along the contours S consisting of the real axis and the infinite half-circle above or below the real axis.

If $\xi = \log r/a < 0$ the half-circle below the real axis must be chosen because in this case the integral along this part of the path converges to zero as $|m| \to \infty$. For the same reason the upper infinite half-circle is chosen when $\xi > 0$, i.e., $r > a$. Consider, for example, the lower half-plane:

$$m = \alpha - i\beta$$

where β is real and positive; therefore, if $0 > \xi = -c$, where c is real and positive,

$$e^{im\xi} = e^{i(\alpha - i\beta)(-c)} = e^{-i\alpha c}e^{-c\beta} = \frac{\cos\alpha c - i\sin\alpha c}{e^{c\beta}}$$

which becomes zero in the limit, $\beta \to \infty$.

The singularities of the integrand are all simple poles and are the roots of:

$$\sinh^2\gamma m - m^2 = 0 \quad [36]$$

or if m is pure imaginary $= i\beta$

$$\beta = \pm\sin(\gamma\beta) \quad [37]$$

The complex roots may be found with very good approximation (except $n = 2$) by:

$$m = \alpha_n + i\beta_n = \pm\frac{1}{\gamma}\log\frac{\pi(2n+1) - \epsilon}{\gamma} \pm i\frac{\pi(2n+1) - \epsilon}{2\gamma} \quad [38]$$

where

$$\epsilon = \frac{4\log\dfrac{\pi(2n+1)}{\gamma}}{\pi(2n+1)} \quad [39]$$

and $n = 2, 3, 4, 5 \ldots$

$$\gamma = \frac{3\pi}{2}$$

For large values of n:

$$m = \alpha_n + i\beta_n = \pm\frac{2}{3\pi}\log\frac{4n+2}{3} \pm i\frac{2n+1}{3} \quad [40]$$

The lower roots are:

α	β
0	$\pm i0.539$
0	$\pm i0.909$
0	$\pm i$
± 0.231	± 1.629, corresponds to $n = 2$ in [38].

For $\alpha_{n=3}$, etc., use Equations [38] and [39].

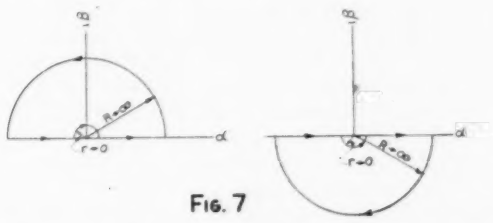


FIG. 7

It will be seen that for $|m| \leq 1$ the roots are located on the imaginary axis, i.e., are purely imaginary. For $|m| > 1$ all the roots are located near the imaginary axis.

Now returning to [34] and [35], integrating in the positive directions and observing [33], we find for: $\xi > 0$, i.e., $r > a$:

$$M_2 = H = \mathbf{I}\frac{1}{2\pi}\int_S \frac{e^{im\xi}f(m)dm}{m(1+m^2)(\sinh^2\gamma m - m^2)} = [i\,\Sigma\,\text{Residues}]_i = [+\,\Sigma R_2]_r \quad [41]$$

$$M_1 = K = \mathbf{R}\frac{1}{2\pi}\int_S \frac{me^{im\xi}f(m)dm}{m(1+m^2)(\sinh^2\gamma m - m^2)} = [i\,\Sigma R_1]_r = [-\,\Sigma R_1]_i \quad [42]$$

Due to $m = 0$ being a simple pole of the integrand in [41], the contour must be indented and half the residue at the origin must be included in ΣR_2. In [42], $m = 0$ is not a pole, so no indentation is necessary.

It should be noted that $R_1 = mR_2$, which facilitates the computations greatly.

For $\xi < 0$, i.e., $r < a$, and now integrating in negative direction:

$$M_{(-2)} = H = [-i\Sigma\,\text{Residues}]_i = [-\Sigma R_{(-2)}]_r \quad [43]$$

$$M_{(-1)} = K = [-i\Sigma\,\text{Residues}]_r = [+\,\Sigma R_{(-1)}]_i \quad [44]$$

The same remarks as above hold here and $R_{(-1)} = mR_{(-2)}$, where the subscript indicates integration in the negative half-plane.

The convergence of the power series is rapid, and even for values of r near a, only a few of the poles need be considered outside the unit circle $|m| = 1$. For very large $|\xi|$ only the poles inside the circle $|m| = 1$ contribute.

The stress function valid for small and large values of r/a was obtained by this method and is given in Equations [24] and [25] of the paper.

APM-55-7

Concentration of Stress Around Spherical and Cylindrical Inclusions and Flaws

By J. N. GOODIER,[1] TORONTO, ONT., CANADA

Solutions of the equation of elasticity are applied to investigate the disturbing effect of small spherical and cylindrical inclusions on an otherwise uniform stress distribution. Numerical results are found for gaseous inclusions (flaws), perfectly rigid inclusions, and for systems roughly representing slag globules in steel and reinforcing rods in concrete.

THE determination of the effects of holes and cavities, or flaws, in the elastic solid when the stress at points remote from the flaw is uniform, has been achieved for holes in the form of circular and elliptical cylinders,[2] and for cavities of spherical form.[3] These problems are special cases of the more general one involving a solid inclusion instead of a hole or cavity. Solutions for circularly cylindrical and spherical inclusions are derived in this paper. They yield confirmation of the known results for flaws, and afford a means of discussing such questions as the effects of foreign inclusions in metal, and the influence of a reinforcing rod in concrete on tensions perpendicular to its length.

For the purposes of calculation it is assumed at first that the solid surrounding the inclusion is infinite in extent, and subjected to uniform applied stress at infinity, besides having the ideal properties of elasticity, isotropy, and homogeneity. It is well, therefore, to lay down at once the considerations underlying the application of the results to finite bodies of actual material.

We know beforehand, from Saint Venant's principle, that the disturbance will be confined to the neighborhood of the inclusion. It appears in fact, from the solutions themselves, that at a distance of some four diameters away from the inclusion the stress distribution, which would be uniform without the inclusion, is in no case modified by more than about one per cent. In consequence the results are valid for inclusions which are, say, four diameters and more away from a boundary, or other inclusions or flaws. They are also valid, for the same reason, in regions where the stress, but for the inclusion, would not vary appreciably over distances measuring several diameters of the inclusion. In general this will be so if the inclusion is small in comparison with the ruling dimensions of the body in which it occurs. On the other hand, in seeking to interpret the behavior of actual solids, no conclusions can be taken over from the theory of elasticity unless it is legitimate to regard the material as *statistically* isotropic and homogeneous, as it is only if the inclusion is very large in comparison with the grain size of the crystalline aggregate. Then, provided the proportional limit be not exceeded, the "stress at a point" indicated by the theory is an estimate of the average stress on an area comprising a great number of crystals, and this average is the "stress" measured by the experimental methods of elasticity, and commonly referred to in engineering discussion. Its significance in relation to the initiation and propagation of fatigue cracks is discussed by Southwell and Gough.[4] Once started, the general direction of the crack follows the surface on which the greatest tensile stress (in the sense defined above) occurs.

In all the results obtained, the factor of stress concentration—the ratio of the maximum stress to the uniform stress at a distance—is independent of the absolute size of the inclusion. This is not peculiar to the spherical and cylindrical boundaries to which the detailed theory is confined, but is necessarily true for any given form of inclusion boundary, for dimensional reasons. We may then state the result thus: The intensification of applied stress due to a small inclusion not near a boundary depends on its geometrical form but not on its absolute size. The limitations just described apply to this result, since the dimensional argument by which it is demonstrated below depends on the theory of elasticity.

The solutions for spherical and cylindrical cavities and holes have been employed to elucidate the phenomenon of spiral fracture in shafts subject to alternating torsion.[5] They offer also an explanation of the manner of occurrence of fatigue cracks in weld metal,[6] which contains gaseous inclusions (blowholes) of spheroidal form and has a surface pitted with "pinholes."[7] The solutions for solid inclusions may be of interest in the study of non-metallic inclusions in metals. The effects of such inclusions, as measured by fatigue strength, are not very definite. There are instances where the endurance limit is only about one-half of, and others where it is somewhat higher than, that of the clean metal. As was to be expected, consideration of stresses gives no indication of anything but weakening effects, due to stress concentration, from any kind of inclusion which is large compared with the individual crystals, except that a metal containing only strong solid inclusions would have smaller stress concentrations than one containing cavities.

B. P. Haigh[8] suggests that the dominant effect of the inclusions is the stress concentrations they induce. The destructive action

of these may be aided by two other effects, chemical embrittlement of the metal by the inclusion, and local residual stress due to different contractions of metal and inclusion in cooling. We shall see that whether the inclusion be more or less rigid than the metal, the concentration of tension arising from the different rigidities will generally augment directly any residual tension due to the different thermal contractions.

The stress concentrations for several examples of especial interest are given in the following paragraphs.

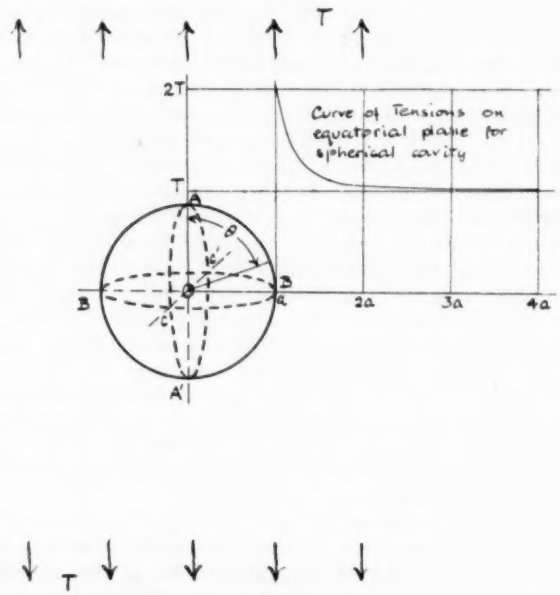

FIG. 1

CALCULATED STRESS CONCENTRATIONS

A uniform tension T, in one direction, applied at a distance from a spherical cavity produces a tensile hoop stress ($\widehat{\theta\theta}$, θ as in Fig. 1) on the "equator" $BCB'C'B$, in the same direction as the applied tension, of magnitude $\dfrac{27 - 15\sigma}{14 - 10\sigma}\,T$ (σ is Poisson's ratio) which is $^{45}/_{22}T$ for steel ($\sigma = 0.3$). The curve in Fig. 1 shows how rapidly the tension drops to the average value T within the solid. It falls away rapidly also as θ departs from 90 deg, so that the stress concentration is confined to a small belt about the "equator." There is a compressive "hoop" stress at A $\left(= -\dfrac{3 + 15\sigma}{14 - 10\sigma}\,T\right)$, and the hoop stress at the equator, at right angles to $\widehat{\theta\theta}$ ($\widehat{\psi\psi}$ in the notation of the analysis to follow) is tensile in steel, being $-\dfrac{3 - 15\sigma}{14 - 10\sigma}\,T$, or $^{3}/_{22}T$.

Combining these stresses with those due to an equal applied compressive stress at a distance, and perpendicular to the applied tension just considered, we obtain the effect of a spherical cavity in a region of pure shear T. There are two stress concentrations—a concentration of shear at C and C' (Fig. 2) of magnitude $\dfrac{15(1 - \sigma)}{7 - 5\sigma}\,T$, or $^{21}/_{11}T$ for steel—and a concentration of hoop tension at B and B' of magnitude $\dfrac{15}{7 - 5\sigma}\,T$, or $^{30}/_{11}T$ for steel. Since the endurance limit in shear is usually about one-half of the endurance limit in direct stress, it appears that the greatest shear, $^{21}/_{11}T$, may exceed the endurance limit for shear while the greatest tension still falls short of the endurance limit in direct stress. Once a crack is formed, however, it is to be expected that its general direction of propagation will be at 45 deg to the direction of the "distant" applied shear, for it is across planes in this direction that the greatest tension acts. This is illustrated by the spiral fracture of twisted shafts.[9]

Two equal principal stresses, of the same sign, are not so greatly affected by a spherical cavity, the greatest tension being $^{15}/_{11}T$. For three equal principal stresses we have a check in the Lamé solution for fluid pressures on thick spherical shells, which gives the value of the hoop tension at the surface of the cavity, when the stress at a distance is hydrostatic tension T, as $^{3}/_{2}T$.

In general, by superposing the effects of three simple tensions or compressions of magnitudes corresponding to any three principal stresses at a distance, we can obtain the factors of stress concentration due to a cavity in any field of uniform or, relative to the cavity, slowly varying stress.

The corresponding results for a circular hole in a plate, or cylindrical bore in a solid subject to plane strain, are well known. For simple tension T in one direction there is a maximum tension $3T$ at the hole, and for pure shear T, a maximum tension $4T$ and a maximum shear $2T$. Hydrostatic tension T induces a hoop tension $2T$. The tensions due to a cylindrical hole in shear

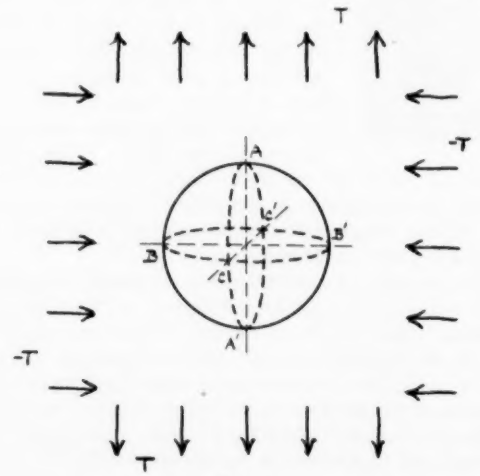

FIG. 2

are thus considerably greater than those due to a spherical cavity, but the shear stress is intensified to about the same degree by both.

We consider next a perfectly rigid inclusion, representing the worst possible case of an inclusion more rigid than the surrounding material. Such an inclusion, which adheres to the surrounding material, produces a different type of stress concentration. In simple tension, a perfectly rigid spherical inclusion intensifies the tension (adhesion stress) at A, A' (Fig. 3), in the same direction as the applied tension T, to $\left(\dfrac{2}{1 + \sigma} + \dfrac{1}{4 - 5\sigma}\right)T$, which is about $2T$ for values of Poisson's ratio ordinarily met with (0 to 0.5). The tension at the "equator," in the same direction is reduced to $\left(\dfrac{\sigma}{1 + \sigma} - \dfrac{5\sigma}{8 - 10\sigma}\right)T$. If $\sigma > {}^{1}/_{5}$, we have the curious result that this stress is compressive.

The rigid inclusion produces no appreciable intensification of shear. The radial (adhesion) stress in a region where the stress remote from the inclusion is a hydrostatic tension T, is a tension $3\dfrac{1 - \sigma}{1 + \sigma}\,T$, which will usually be nearly $2T$.

[9] R. V. Southwell and H. J. Gough, loc. cit.

A perfectly rigid cylindrical inclusion in simple tension T induces an adhesion tension at A, A' (Fig. 4) of magnitude $\frac{1}{2}\left(3 - 2\sigma + \frac{1}{3 - 4\sigma}\right) T$ (plane strain), about $1.5T$. The tension at B, B' is reduced to $\frac{1}{2}\left(1 + 2\sigma - \frac{3}{3 - 4\sigma}\right) T$. It becomes a compression if $\sigma > 1/4$. Two simple tensions T, at right angles, i.e., uniform all-around tension, produce an adhesion stress $2(1 - \sigma)T$. If the inclusion is spherical and consists of material having the same Poisson's ratio, but a Young's modulus one-quarter of that of the surrounding metal—taken as a plausible value for slag in steel—the stress concentrations have the same character as for a cavity, but are less in magnitude by about 20 per cent.

A cylindrical rod of steel set in cement, or in concrete with a fine aggregate, will induce a radial adhesion stress of about $1.5T$ when subject to simple transverse tension, and about $1.7T$ when subject to two such tensions at right angles. Poisson's ratio for the steel is taken as 0.3, for the concrete as 0.13, and the ratio of the Young's moduli as 15.

From the results for cavities and holes we conclude that, in

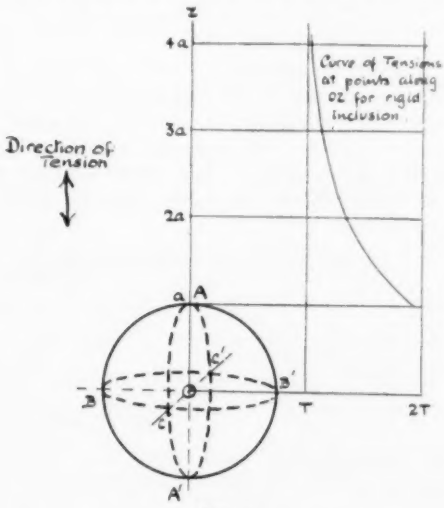

FIG. 3

simple tension, an inclusion appreciably less rigid than the surrounding material may be expected to intensify the tension at the ends of transverse diameters B, B'. Such an inclusion (e.g., slag in steel) would generally have the smaller coefficient of thermal expansion, and the residual stresses set up in cooling would involve tension at B, B' in the same direction. B. P. Haigh[10] has estimated that cooling through a temperature range of no more than 300 C would be sufficient to set up residual tensions of the same order as the yield stress, around an inclusion of slag in steel.

An inclusion which is appreciably more rigid than the surrounding material will behave like a perfectly rigid inclusion in intensifying the radial tension at the "poles" A, A'. Such an inclusion would probably have the greater thermal expansion, and the radial stresses, at A, A' and all other points on the boundary, which it would set up in cooling would be tensile. Hence the conclusion that residual cooling stresses will usually be directly augmented by the concentrations of applied tension.

AXIALLY SYMMETRICAL SOLUTIONS OF THE EQUATIONS OF ELASTICITY, IN POLAR COORDINATES

The Cartesian components of equilibrium displacement in the elastic solid free from body forces satisfy the three equations

$$\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right) \Delta + (1 - 2\sigma)\nabla^2(u, v, w) = 0 \quad \ldots\ldots [1]$$

where $\Delta \equiv \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}$ and ∇^2 is the Laplacian operator $\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$.

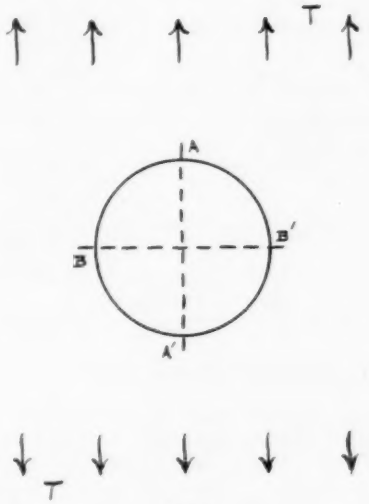

FIG. 4

A type of solution is given by

$$u, v, w = \left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right) \phi \quad \ldots\ldots [2]$$

where ϕ is any harmonic function.[11] Such solutions correspond to distributions of the singularity "center of pressure" or "center of compression,"[12] for which the displacement is purely radial and inversely proportional to the square of the distance from the singularity. This displacement can thus be regarded as derived from a potential $1/r$, and the displacement due to a distribution of such singularities will therefore be the gradients of a Newtonian potential function, as in [2]. The displacements will be everywhere normal to the equipotentials and will be proportional to the density of electric charge on an isolated conductor coinciding with the equipotential. The dilatation vanishes.

A second type of solution of Equation [1] is

$$u, v, w = r^2\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right) \omega_n + \alpha_n(x, y, z)\omega_n \quad \ldots\ldots [3]$$

where ω_n is a homogeneous solid harmonic of degree n. This satisfies [1] in virtue of the properties

$$\nabla^2(x\omega_n) = 2\frac{\partial \omega_n}{\partial x}, \text{ etc.}, \quad \nabla^2(r^m\omega_n) = m(m + 2n + 1)r^{m-2}\omega_n$$

and the Euler relation for any homogeneous function

$$x\frac{\partial \omega_n}{\partial x} + y\frac{\partial \omega_n}{\partial y} + z\frac{\partial \omega_n}{\partial z} = n\omega_n$$

provided that α_n is given the value

[10] Loc. cit.

[11] A. E. H. Love, "Mathematical Theory of Elasticity," 4th Ed., art. 172.

[12] Ibid., p. 187.

$$\alpha_n = -2\,\frac{3n+1-2(2n+1)\sigma}{n+5-4\sigma} \qquad [4]$$

The dilatation is $\Delta = [2n + (3+n)\alpha_n]\omega_n$.

To obtain solutions symmetrical about an axis OZ, Fig. 5, we may use zonal harmonics for the functions ϕ and ω_n, and transform [2] and [3] to polar coordinates. The displacements will be confined to meridian planes, having a component u_r along the radius r, and a component u_θ at right angles to it, in the direction θ increasing. From [2], since the displacement is simply the gradient of ϕ,

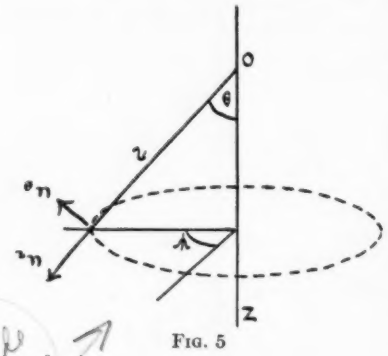

FIG. 5

$$u_r = \frac{\partial\phi}{\partial r}, \quad u_\theta = \frac{1}{r}\frac{\partial\phi}{\partial\theta} \qquad [5]$$

The general formulas for the strains are:

$$\left.\begin{aligned} e_{rr} &= \frac{\partial u_r}{\partial r}, \quad e_{\theta\theta} = \frac{1}{r}\frac{\partial u_\theta}{\partial\theta} + \frac{u_r}{r} \\ e_{\psi\psi} &= \Delta - e_{rr} - e_{\theta\theta}, \quad e_{r\theta} = \frac{1}{r}\frac{\partial u_r}{\partial\theta} + r\frac{\partial}{\partial r}\left(\frac{u_\theta}{r}\right) \end{aligned}\right\} \qquad [6]$$

which give, substituting [5],

$$e_{rr} = \frac{\partial^2\phi}{\partial r^2}, \quad e_{\theta\theta} = \frac{1}{r^2}\frac{\partial^2\phi}{\partial\theta^2} + \frac{1}{r}\frac{\partial\phi}{\partial r}, \quad e_{r\theta} = 2\,\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial\phi}{\partial\theta}\right)$$

The general stress-strain formulas are:

$$\widehat{rr},\ \widehat{\theta\theta},\ \widehat{\psi\psi} = 2\mu\left[\frac{\sigma}{1-2\sigma}\,\Delta + (e_{rr}, e_{\theta\theta}, e_{\psi\psi})\right], \quad \widehat{r\theta} = \mu e_{r\theta}. \qquad [7]$$

and since Δ vanishes for the ϕ-solutions, we have

$$\left.\begin{aligned} \widehat{rr} &= 2\mu\,\frac{\partial^2\phi}{\partial r^2}, \quad \widehat{\theta\theta} = 2\mu\left(\frac{1}{r^2}\frac{\partial^2\phi}{\partial\theta^2} + \frac{1}{r}\frac{\partial\phi}{\partial r}\right), \\ \widehat{\psi\psi} &= -(\widehat{rr} + \widehat{\theta\theta}), \quad \widehat{r\theta} = 2\mu\,\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial\phi}{\partial\theta}\right) \end{aligned}\right\} \qquad [8]$$

where μ is the modulus of rigidity.

For the second type of solution we observe from [3] that the displacement in any direction consists of the gradient of ω_n in that direction, multiplied by r^2, together with the component in the same direction of a vector $\alpha_n r\omega_n$ directed along the radius r. Hence

$$u_r = r^2\frac{\partial\omega_n}{\partial r} + \alpha_n r\omega_n, \quad u_\theta = r\,\frac{\partial\omega_n}{\partial\theta} \qquad [9]$$

The strains can be calculated by [6] and the stresses obtained from the stress-strain formulas [7]. Taking for ϕ the zonal spherical harmonics

$$\frac{1}{r} \quad \text{and} \quad \frac{1}{2r^3}(3\cos^2\theta - 1)$$

and for ω_n the second of these (ω_{-3}), each with an arbitrary multiplier, and superposing the resulting displacements and stresses, we find the following system for a region outside a spherical boundary:

$$\left.\begin{aligned} u_r &= -\frac{A}{r^2} - \frac{3B}{r^4} + \left[\frac{5-4\sigma}{1-2\sigma}\frac{C}{r^3} - 9\frac{B}{r^4}\right]\cos 2\theta \\ u_\theta &= -\left[\frac{2C}{r^3} + 6\frac{B}{r^4}\right]\sin 2\theta \\ \widehat{rr} &= 2\mu\left\{\frac{2A}{r^3} - \frac{2\sigma}{1-2\sigma}\frac{C}{r^3} + 12\frac{B}{r^5} + \left[-\frac{2(5-\sigma)}{1-2\sigma}\frac{C}{r^3} + 36\frac{B}{r^5}\right]\cos 2\theta\right\} \\ \widehat{\theta\theta} &= 2\mu\left\{-\frac{A}{r^3} - \frac{2\sigma}{1-2\sigma}\frac{C}{r^3} - 3\frac{B}{r^5} + \left[\frac{C}{r^3} - 21\frac{B}{r^5}\right]\cos 2\theta\right\} \\ \widehat{\psi\psi} &= 2\mu\left\{-\frac{A}{r^3} - \frac{2(1-\sigma)}{1-2\sigma}\frac{C}{r^3} - 9\frac{B}{r^5} + \left[3\frac{C}{r^3} - 15\frac{B}{r^5}\right]\cos 2\theta\right\} \\ \widehat{r\theta} &= 2\mu\left\{-\frac{2(1+\sigma)}{1-2\sigma}\frac{C}{r^3} + 24\frac{B}{r^5}\right\}\sin 2\theta \end{aligned}\right\} \qquad [10]$$

where A, B, and C are arbitrary.

The analogous system for the region inside a spherical boundary is obtained by taking for ϕ and ω_n ($= \omega_2$) the zonal spherical harmonic $\frac{1}{2}r^2(3\cos^2\theta - 1)$ with an arbitrary multiplier in each case, and superposing the "hydrostatic solution" for stress uniform in all directions (which corresponds to $\omega_n = \omega_0 =$ constant). We find

$$\left.\begin{aligned} u_r &= Hr + Fr + 2\sigma Gr^3 + [3Fr + 6\sigma Gr^3]\cos 2\theta \\ u_\theta &= -[3Fr + (7-4\sigma)Gr^3]\sin 2\theta \\ \widehat{rr} &= 2\mu\left\{\frac{1+\sigma}{1-2\sigma}H + F - \sigma Gr^2 + [3F - 3\sigma Gr^2]\cos 2\theta\right\} \\ \widehat{\theta\theta} &= 2\mu\left\{\frac{1+\sigma}{1-2\sigma}H + F - 5\sigma Gr^2 - [3F + 7(2-\sigma)Gr^2]\cos 2\theta\right\} \\ \widehat{\psi\psi} &= 2\mu\left\{\frac{1+\sigma}{1-2\sigma}H - 2F - (15-7\sigma)Gr^2 - (7+11\sigma)Gr^2\cos 2\theta\right\} \\ \widehat{r\theta} &= -2\mu\,\{3F + (7+2\sigma)Gr^2\}\sin 2\theta \end{aligned}\right\} \qquad [11]$$

where F, G, and H are arbitrary.

Uniform tension T (in the direction $\theta = 0$) in a *complete* elastic solid produces on a spherical surface of radius a the displacements and stresses

$$\left.\begin{aligned} u_r &= \frac{Ta}{2E}\left[(1-\sigma) + (1+\sigma)\cos 2\theta\right] \\ u_\theta &= -\frac{Ta}{2E}(1+\sigma)\sin 2\theta \\ \widehat{rr} &= \frac{T}{2}(1+\cos 2\theta) \\ \widehat{r\theta} &= -\frac{T}{2}\sin 2\theta \end{aligned}\right\} \qquad [12]$$

We can find values of the constants A, B, and C in [10] which give stresses $\widehat{rr}$ and $\widehat{r\theta}$ at $r = a$ equal and opposite to those of [12].

The corresponding system [10] superposed on the uniform tension T then gives the stresses for a spherical cavity of radius a. We can find another set of constants A, B, and C which give displacements at $r = a$ equal and opposite to those of [12], and the corresponding stresses from [10], superposed on the uniform tension, give the stresses for a rigid spherical inclusion.

For the elastic inclusion we distinguish the elastic constants in [10] by the subscript 1 (medium) and those in [11] by the subscript 2 (inclusion). The displacements and stresses outside the inclusion ($r > a$) are taken as those of [10] together with those due to uniform tension, and the displacements and stresses within the inclusion ($r < a$) are taken as those of [11]. Equating displacements and tractions at the common boundary $r = a$, enough equations are obtained to determine the six quantities A, B, C, F, G, H. The values of A, B, and C—which determine the stresses in the medium—are

$$\frac{A}{a^3} = -\frac{T}{8\mu_1}\frac{\mu_1 - \mu_2}{(7-5\sigma_1)\mu_1 + (8-10\sigma_1)\mu_2} \times \frac{(1-2\sigma_2)(6-5\sigma_1)2\mu_1 + (3+19\sigma_2-20\sigma_1\sigma_2)\mu_2}{(1-2\sigma_2)2\mu_1 + (1+\sigma_2)\mu_2} + \frac{T}{4\mu_1}\frac{\left[(1-\sigma_1)\dfrac{1+\sigma_2}{1+\sigma_1} - \sigma_2\right]\mu_2 - (1-2\sigma_2)\mu_1}{(1-2\sigma_2)2\mu_1 + (1+\sigma_2)\mu_2}$$

$$\frac{B}{a^5} = \frac{T}{8\mu_1}\frac{\mu_1 - \mu_2}{(7-5\sigma_1)\mu_1 + (8-10\sigma_1)\mu_2}$$

$$\frac{C}{a^3} = \frac{T}{8\mu_1}\frac{5(1-2\sigma_1)(\mu_1-\mu_2)}{(7-5\sigma_1)\mu_1 + (8-10\sigma_1)\mu_2}$$

The stresses in the medium are obtained by superposing the stresses in [10] with these values of the constants on the uniform tension.

The spherical cavity and rigid inclusion occur as limiting cases. For the cavity ($\mu_2 = 0$),

$$\frac{A}{a^3} = -\frac{T}{8\mu_1}\frac{13-10\sigma_1}{7-5\sigma_1}, \quad \frac{B}{a^5} = \frac{T}{8\mu_1}\frac{1}{7-5\sigma_1}, \quad \frac{C}{a^3} = \frac{T}{8\mu_1}\frac{5(1-2\sigma_1)}{7-5\sigma_1}$$

For the rigid inclusion ($\mu_2 = \infty$),

$$\frac{A}{a^3} = \frac{T}{4\mu_1}\left[\frac{1-\sigma_1}{1+\sigma_1} + \frac{3}{16-20\sigma_1}\right], \quad \frac{B}{a^5} = -\frac{T}{8\mu_1}\frac{1}{8-10\sigma_1},$$

$$\frac{C}{a^3} = -\frac{T}{8\mu_1}\frac{5(1-2\sigma_1)}{8-10\sigma_1}$$

Plane Strain and Plane Stress in Polar Coordinates

An analogous theory can be developed for two-dimensional systems. Taking the case of plane strain ($w = 0$), we shall have from [1]

$$\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}\right)\Delta + (1-2\sigma)\nabla^2(u, v) = 0 \quad \ldots\ldots [13]$$

where $\Delta \equiv \dfrac{\partial u}{\partial x} + \dfrac{\partial v}{\partial y}$ and $\nabla^2 \equiv \dfrac{\partial^2}{\partial x^2} + \dfrac{\partial^2}{\partial y^2}$

The solutions of the ϕ-type are

$$u\ v = \left(\frac{\partial}{\partial x}\ \frac{\partial}{\partial y}\right)\phi$$

where ϕ is a plane harmonic function. The dilatation vanishes. The solutions of the ω-type are

$$u, v = r^2\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}\right)\omega_n + \alpha_n(x, y)\omega_n$$

where $r^2 = x^2 + y^2$ and ω_n is a plane harmonic which is homogeneous, of degree n. These satisfy [13] in virtue of the properties

$$\nabla^2(x\omega_n) = 2\frac{\partial\omega_n}{\partial x}, \nabla^2(r^m\omega_n) = m(m+2n)r^{m-2}\omega_n$$

and the Euler relation for a homogeneous function of two variables

$$x\frac{\partial\omega_n}{\partial x} + y\frac{\partial\omega_n}{\partial y} = n\omega_n$$

provided that α_n is given the value

$$\alpha_n = -2n\frac{3-4\sigma}{n+4-4\sigma}$$

The dilatation Δ is

$$[2n + (2+n)\alpha_n]\omega_n$$

The stresses can be found from the stress-strain relations appropriate to plane strain when the strains have been calculated by the usual formulas from the displacements.

In polar coordinates we have, for the ϕ-type,

$$u_r = \frac{\partial\phi}{\partial r}, \quad u_\theta = \frac{1}{r}\frac{\partial\phi}{\partial\theta}$$

and for the ω-type,

$$u_r = r^2\frac{\partial\omega_n}{\partial r} + \alpha_n r\omega_n, \quad u_\theta = r\frac{\partial\omega_n}{\partial\theta}$$

For displacements and stresses which can be represented as Fourier series in θ we may use as plane harmonics of degree n the functions

$$r^n\cos n\theta, \quad r^n\sin n\theta$$

when n is not zero. As harmonics of degree zero we have $\log r$ and θ.

Taking for ϕ, $\log r$ and $(1/r^2)\cos 2\theta$ and for ω_n, $\omega_2 = (1/r^2)\cos 2\theta$ with arbitrary multipliers, we obtain, for the region outside a circular boundary,

$$\left.\begin{aligned} u_r &= \frac{A}{r} + \left[-\frac{B}{r^3} + \frac{2C}{r}(1-\sigma)\right]\cos 2\theta \\ u_\theta &= -\left[\frac{B}{r^3} + \frac{C}{r}(1-2\sigma)\right]\sin 2\theta \\ \widehat{rr} &= 2\mu\left[-\frac{A}{r^2} + \left(\frac{3B}{r^4} - \frac{2C}{r^2}\right)\cos 2\theta\right] \\ \widehat{\theta\theta} &= 2\mu\left[\frac{A}{r^2} - \frac{3B}{r^4}\cos 2\theta\right] \\ \widehat{r\theta} &= 2\mu\left[\frac{3B}{r^4} - \frac{C}{r^2}\right]\sin 2\theta \end{aligned}\right\} \ldots [14]$$

where A, B, and C are arbitrary.

The analogous system for the region within a circular boundary is derived from $\log r$ (ω_0) and $r^2\cos 2\theta$, and is

$$
\left.\begin{aligned}
u_r &= F_r + (Gr + 2\sigma Hr^3)\cos 2\theta \\
u_\theta &= -[Gr + (3 - 2\sigma)Hr^3]\sin 2\theta \\
\widehat{rr} &= 2\mu\left[\frac{F}{1-2\sigma} + G\cos 2\theta\right] \\
\widehat{\theta\theta} &= 2\mu\left[\frac{F}{1-2\sigma} - (G + 6Hr^2)\cos 2\theta\right] \\
\widehat{r\theta} &= -2\mu(G + 3Hr^2)\sin 2\theta
\end{aligned}\right\} \quad [15]
$$

Uniform tension T (in the direction $\theta = 0$) gives on the cylindrical surface $r = a$ the displacements and stresses (in plane strain)

$$
\left.\begin{aligned}
u_r &= \frac{Ta}{2E}(1+\sigma)[1 - 2\sigma + \cos 2\theta] \\
u_\theta &= -\frac{Ta}{2E}(1+\sigma)\sin 2\theta \\
\widehat{rr} &= \frac{T}{2}(1 + \cos 2\theta) \\
\widehat{r\theta} &= -\frac{T}{2}\sin 2\theta
\end{aligned}\right\} \quad [16]
$$

We can find the constants A, B, and C so that either the tractions $(\widehat{rr}, \widehat{r\theta})$, or the displacements of [14] eliminate those of [16], and so obtain solutions for the cylindrical hole or the perfectly rigid inclusion. For the elastic inclusion we combine [14] and the simple tension giving the boundary values [16], distinguishing the elastic constants by the subscripts 1 (medium) and 2 (inclusion). Equating the resultant boundary tractions and displacements to those of [15], representing the inclusion, we obtain equations for the six constants A, B, C, F, G, H. The stresses in the medium are determined by A, B, and C, which take the values

$$
\frac{A}{a^2} = \frac{T}{4\mu_1}\frac{(1-2\sigma_2)\mu_1 - (1-2\sigma_1)\mu_2}{(1-2\sigma_2)\mu_1 + \mu_2}
$$

$$
\frac{B}{a^4} = \frac{T}{4\mu_1}\frac{\mu_1 - \mu_2}{\mu_1 + (3-4\sigma_1)\mu_2}
$$

$$
\frac{C}{a^2} = \frac{T}{2\mu_1}\frac{\mu_1 - \mu_2}{\mu_1 + (3-4\sigma_1)\mu_2}
$$

For the cylindrical hole ($\mu_2 = 0$),

$$
\frac{A}{a^2} = \frac{B}{a^4} = \frac{T}{4\mu_1}, \quad \frac{C}{a^2} = \frac{T}{2\mu_1}
$$

For the perfectly rigid inclusion ($\mu_2 = \infty$),

$$
\frac{A}{a^2} = -\frac{T}{4\mu_1}(1-2\sigma_1), \quad \frac{B}{a^4} = -\frac{T}{4\mu_1}\frac{1}{3-4\sigma_1}
$$

$$

$$

Dimensional Analysis for Inclusions of Any Shape

Consider the process of obtaining from the general equations of the theory of elasticity a formula for any stress p near an inclusion of given geometrical form, when the stress at a distance is of a given type, say, simple tension T in one direction. The formula consists of a relation between the following quantities

$$
p, T, E_1, E_2, \sigma_1, \sigma_2, r, a, \theta, \psi, \alpha, \beta, \gamma, \ldots
$$

where E_1, σ_1, E_2, σ_2 are elastic constants for the medium and the inclusion, a is a representative length giving the absolute size of the inclusion, α, β, γ . . . are the ratios of the other necessary dimensions of the inclusion to a, and r, θ, ψ are polar coordinates specifying the point at which the stress p is to be found.

There are only two fundamental units involved, and they may be taken as those of stress and length.[13] The dimensionless arguments obtainable from the quantities concerned may be taken as

$$
\frac{p}{T}, \frac{E_1}{T}, \frac{E_1}{E_2}, \sigma_1, \sigma_2, \frac{r}{a}, \theta, \psi, \alpha, \beta, \gamma, \ldots
$$

The stress p must be proportional to T, by the principle of superposition. It follows that the formula for p takes the form

$$
p = T f\left(\frac{E_1}{E_2}, \sigma_1, \sigma_2, \theta, \psi, \frac{r}{a}, \alpha, \beta, \gamma \ldots\right)
$$

where $f()$ denotes an undetermined function.

Since r and a appear only in the ratio r/a, the stresses in two systems with inclusions of the same form but different sizes, other things being the same, are the same at similarly situated points (r/a, θ, ψ, the same). The greatest stress will occur at such points and will clearly be the same whatever the size of the inclusion.

[13] The basis of the procedure followed is discussed in "Dimensional Analysis," by P. W. Bridgman.

APM-55-8

The Elastic Behavior of Vulcanized Rubber

By H. HENCKY,[1] CAMBRIDGE, MASS.

Up to extensions of about 270 per cent the elastic behavior of vulcanized rubber can be represented analytically by a very simple function. The stress-strain diagrams for tension and compression are quite different; nevertheless this asymmetrical behavior is satisfactorily taken care of by employing only two elastic coefficients.

THE mental attitude of the engineer to an organic compound such as rubber is a very skeptical one if its elastic behavior has to be compared with that of metals; nevertheless experiments with rubber belts furnished by the Goodyear Tire and Rubber Company to the Massachusetts Institute of Technology have convinced the author of this paper that a comparison of the elastic properties of rubber with those of metals is justified and at the same time very instructive as regards the mechanics of finite deformations in general.

Naturally rubber is more easily influenced by temperature and by surrounding liquid and gaseous substances which eventually cause chemical changes. However, vulcanized rubber can now be manufactured of such excellent quality that the way is opened to uses hitherto not exploited. Of these may be mentioned the use of rubber tires for the wheels of steam locomotives, enabling the latter to climb steep grades, and the wide field of application on damping vibrations and changing unfavorable critical speeds, already exemplified in the automotive industry.

Such applications can only be industrially exploited if the elastic stresses in rubber obey a known, mathematically defined law. In this paper the author therefore develops the law for large deformations and shows its agreement with the results of experiments made with the two rubber compounds that were furnished.

General Law of the Ideal Elastic Body[2]

We call a material ideally elastic if, even after a considerable deformation, it assumes its original shape after removal of the constraints introduced and if the process of loading and unloading is not accompanied by transformations of mechanical energy into heat. Nearly all materials are ideally elastic if the deformation is infinitesimal, but in the case of most substances finite deformations are accompanied by losses of mechanical energy. It is not the aim of this paper to study these losses, but it may be mentioned that there is even in the realm of ideal elasticity an unexplored region indicated by the experimental fact that the law for infinitesimal elastic deformations does not hold good for finite deformations. It is only necessary to subject a rubber cylinder to tension and compression at comparatively small strains, when the lack of agreement becomes obvious.

At the foundation of all elastic theories lies the definition of strain, and before introducing a new law of elasticity we must explain how finite strain is to be measured.

Infinitesimal strain is measured by the ratio of the increase in length to the length itself. In defining a considerable strain λ of a fiber we assume this strain to be divided into small portions $d\lambda$. Each of these portions we define, as in the case of an infinitesimal strain, by the ratio:

$$d\lambda = \frac{dx}{x} \qquad [1]$$

where x is the length of a fiber in a certain state of strain. Integrating and taking the length of the fiber before stressing as a and after stressing as b, we get

$$\lambda = \log_e \frac{b}{a} \qquad [1a]$$

Our measure of finite strain is therefore the natural logarithm of the ratio of the two lengths.

On the basis of the general theory developed in the Appendix we obtain the law of the simple *uniaxial* tension and compression test of rubber in the following two forms:

Stress per Unit Area Referred to the Deformed State:

$$\sigma = 2G\lambda(e_\lambda + \frac{1}{2}e^{-\lambda/2}) \qquad [2a]$$

Stress per Unit Area Referred to the Undeformed State:

$$\sigma_0 = 2G\lambda\left(1 + \frac{1}{2}e^{-3\lambda/2}\right) \qquad [2b]$$

If P is the load, A_0 the area of cross-section of the unloaded specimen, and A the area after the load is applied, we have, for incompressible material, $A = A_0 e^{-\lambda}$. The stress σ_0 is the observed stress, because all testing machines measure directly the force applied and not the true physical stress σ.

The coefficient G is about 67 lb. per sq. in. for the material examined and is the same as the modulus of shear for infinitesimal deformations. For such deformations both Equations [2a] and [2b] yield

$$\sigma = \sigma_0 = 3G\lambda$$

On the basis of Equations [2a] and [2b] and taking $2G = 134$ lb. per sq. in., Table 1 has been calculated and the values plotted in Fig. 1.

Experiments

The rubber with which the experiments were made was delivered in form of closed belts of 2 in. × 0.32 in. cross-section and 38 in. circumference. Two different compounds (Nos. 4183 and 4799) were used and there were 12 belts in all. The values of the elastic constants are about the same for both compounds, but slight variations in the elastic constants occur even at different parts of one and the same specimen.

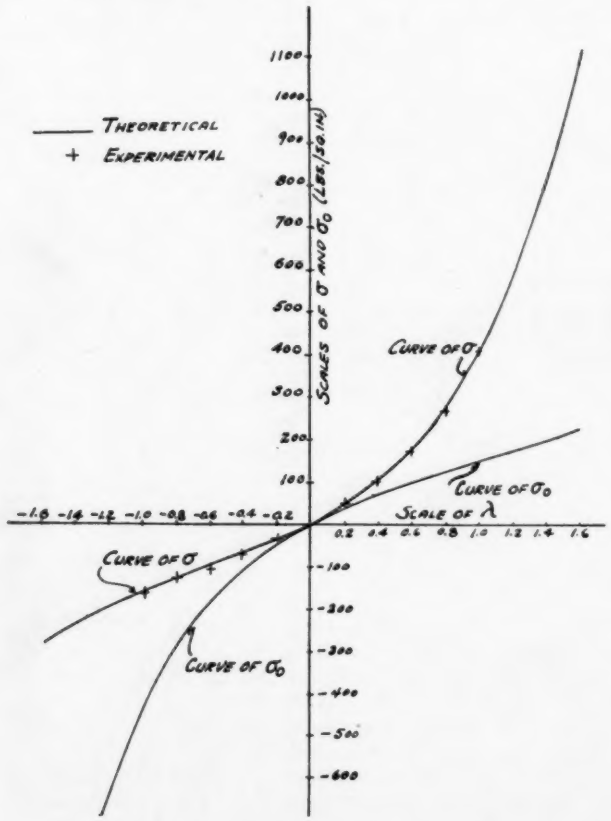

Fig. 1

The Bulk Modulus. To measure the bulk modulus, rubber cylinders 1 in. in diameter and 1.5 in. long were placed in a compression chamber and the distance between the pressure heads measured with Ames dials. The bulk modulus K was found to be 387,000 lb. per sq. in. or 27,200 kg. per sq. cm. (average of three experiments). This is somewhat larger than the modulus of water, which is 23,000 kg. per sq. cm., but agrees well with the fact that the specific gravity of rubber is about the same as that of water.

Considering the great difference between the shear and bulk moduli (their ratio is $G/K = 0.211 \times 10^{-3}$), it is justifiable to consider rubber as incompressible in the range for which validity is claimed for the elastic law [2]. The commonly used modulus of elasticity E is in that case equal to $3G = 200$ lb. per sq. in.

The Tensile Test. The tensile test under uniaxial stress is technically very easy to carry out. However, by an increase in length of 200 per cent or more, time effects and elastic strain hardening play an important role. The strain hardening is due to the microstructure of rubber and can only be taken into account by employing a statistical theory. This strain hardening has in some respects the character of internal friction; therefore the unloading curve coincides nearly with the author's theoretical curve.

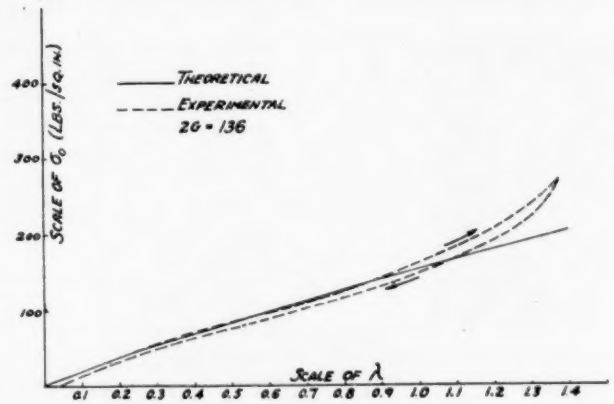

Fig. 2

The curves of Fig. 2 show the loading and unloading at a constant rate of applying strain and removing stress (time of loading and unloading, 4 hr. in all) with the stresses related to the original area of cross-section. Table 3 gives the values of the true stresses and strains for very slow loading and unloading. The observed values of λ are reduced to equal differences by interpolation, because it would not have been possible otherwise to take the average of the experiments with three specimens.

TABLE 3

$+\lambda$	Calculated stress σ (Equation [2a]), lb. per sq. in.	Measured stress σ, lb. per sq. in.
0.0	0.0	0.0
0.2	44.8	44.5
0.4	101.8	100.7
0.6	176.2	171.0
0.8	275.0	270.8
1.0	405.0	410.0

The Compression Test. The compression test is very difficult to perform and almost impossible to carry out for higher pressures if uniaxial stress has to be used. Not only is the state of uniform uniaxial stress unstable even for comparatively short rubber cylinders, but it is even difficult to realize such a state of stress. Despite careful greasing of the planes of contact with the pressure heads of the testing-machine, dry friction was detected. Evidently the grease is removed under too much pressure. Table 4 gives the calculated and measured stresses.

TABLE 4

$-\lambda$	Calculated stress σ (Equation [2a]), lb. per sq. in.	Measured stress σ, lb. per sq. in.
0.0	0.0	0.0
0.2	36.8	37.3
0.4	68.7	72.7
0.6	98.5	103.7
0.8	128.0	129.8
1.0	160.0	162.4

The change in the elastic behavior in going from positive to negative strains is very marked, but is satisfactorily represented by the theoretical formula. Fig. 2 shows the deviations from the theoretical curve at the larger strains.

Conclusions

As a consequence of the work described the author arrives at the conclusion that in the deformation range from 0 to 270 per cent only one elastic constant is needed for a full mathematical description, and that this constant is the modulus of shear defined for infinitely small deformations.

If models could be made of rubber at less expense, this material could be used for the integration of the equations of elasticity. The solutions could be easily corrected for the lack of compressibility and for the change in the common law of elasticity.

Appendix

Mathematical Derivations

Taking an element of a body and stressing it in three directions perpendicular to each other, x_1, x_2, x_3, we get the new lengths $\overline{dx_1}$, $\overline{dx_2}$, $\overline{dx_3}$ from the old ones dx_1, dx_2, dx_3. If we denote the principal strains by ϵ_1, ϵ_2, ϵ_3, the corresponding strains are, according to [1] and [1a],

$$\epsilon_i = \log_e \left(\frac{\overline{dx_i}}{dx_i} \right) \quad \ldots\ldots [3]$$

It is very convenient to take the average of these strains namely,

$$\epsilon = \frac{1}{3} (\epsilon_1 + \epsilon_2 + \epsilon_3) \quad \ldots\ldots [3a]$$

whence

$$3\epsilon = \log_e \left(\frac{\overline{dx_1}}{dx_1} \frac{\overline{dx_2}}{dx_2} \frac{\overline{dx_3}}{dx_3} \right) = \log_e \left(\frac{\overline{dV}}{dV} \right)$$

ϵ arises from that part of the strain which is equal in all directions. Consequently if we subtract ϵ from ϵ_1, ϵ_2, ϵ_3, and denote the result by φ_1, φ_2, φ_3,

$$\varphi = \epsilon_i - \epsilon \quad \ldots\ldots [3b]$$

will represent the pure deformation without the change in volume. We can resolve the stresses acting at any point in the same manner. $S = \frac{1}{3} (S_1 + S_2 + S_3)$ is that part of the stress which can exist in an ideal liquid. This hydrostatic part of the stress S is connected with the change of volume, the remainder of the stress, $S_i - S$, is connected with the change of form.

Now in the case of infinitely small strains it is not necessary to state that the stresses in the deformed states are to be employed when we formulate the elastic law. It does not make any difference for which state we give the stresses. With finite deformations, however, only the true physical stresses after equilibrium is attained can be used. For any homogeneous and isotropic material we can write down easily the simplest form the elastic energy can assume. We introduce into this two moduli, the modulus of shear G and the bulk modulus K, and choose the simplest possible analytical form, which becomes the expression of the classical theory of elasticity when we assume infinitely small displacements:

$$2W = 2G (\varphi_1^2 + \varphi_2^2 + \varphi_3^2) + 9K\epsilon^2 \quad \ldots\ldots [4]$$

W is the elastic energy per unit volume in the undeformed state. The energy must be related to the undeformed state because it is a physical entity connected with the mass of the body. Equation [4] is naturally an assumption and has to be checked by experiment.

But there is yet another doubt. Must we not relate the formula for the energy to the real bearer of the energy, the molecule? If the substance is built up from such units, should we not assume expression [4] as the energy of the molecule? Our experimental results indeed point in this direction. But before we study this question we shall formulate another expression for the work done which is independent of any law of elasticity.

If dV is the volume before and $\overline{dV}$ the volume after the deformation,

$$\delta W dV = S_1 \overline{dx_2}\, \overline{dx_3}\, \delta\, \overline{dx_1} + S_2 \overline{dx_1}\, \overline{dx_3}\, \delta\, \overline{dx_2} + S_3 \overline{dx_1}\, \overline{dx_2}\, \overline{dx_3}$$

or

$$\delta W = \frac{\overline{dV}}{dV} (S_1\delta\epsilon_1 + S_2\delta\epsilon_2 + S_3\delta\epsilon_3) = e^{3\epsilon} (S_1\delta\epsilon_1 + S_2\delta\epsilon_2 + S_3\delta\epsilon_3) \quad \ldots\ldots [5]$$

$e^{3\epsilon}$ is the relative volume, and will be denoted by v. Assuming now that Equation [4] is applied to isotropic and continuous matter, we can immediately derive the law of elasticity.

By differentiating [4],

$$\delta W = 2G [\varphi_1 (\delta\epsilon_1 - \delta\epsilon) + \varphi_2 (\delta\epsilon_2 - \delta\epsilon) + \varphi_3 (\delta\epsilon_3 - \delta\epsilon)] + 3K\epsilon (\delta\epsilon_1 + \delta\epsilon_2 + \delta\epsilon_3)$$

$$= \delta\epsilon_1(2G\varphi_1 + 3K\epsilon) + \delta\epsilon_2(2G\varphi_2 + 3K\epsilon) + \delta\epsilon_3(2G\varphi_3 + 3K\epsilon)$$

Comparing this expression with Equation [5],

$$S_i v = 2G\varphi_i + 3K\epsilon \quad \ldots\ldots [6a]$$

or in another form,

$$\left. \begin{aligned} S_i - S &= \frac{2G}{v} \varphi_i \\ S &= \frac{K}{v} \log_e v \end{aligned} \right\} \quad \ldots\ldots [6b]$$

The apparent increase of the modulus of shear for high compression measured by Bridgman is accounted for in Equation [6b], because v is in that case less than unity.

For rubber v differs but little from unity so long as S is in the range of 0–4000 lb. per sq. in.

Under these circumstances we can neglect the change in volume entirely, writing

$$S_i = 2G\varphi_i + S \quad \ldots\ldots [7]$$

for an ideal incompressible material.

But having considered an element dx_1, dx_2, dx_3 of continuous matter which led us to Equation [7], we now assume an element containing thousands of molecules. As it does not matter which form we assume them to be in, let us take them as small spheres. The true shape of the molecule of rubber is not known, but it probably is of a prismatic form. We must keep clearly in mind, therefore, that we are neglecting the true microstructure of rubber in assuming spherical molecules.

Here we no longer apply Equation [7] to the stresses, but to the forces with which the molecules act on one another, writing

$$P_i - P = 2G'\varphi_i \quad \ldots\ldots [8]$$

where $P = \frac{1}{3} (P_1 + P_2 + P_3)$.

If N is the number of molecules lying in the unit of area of a certain cross-section in the undeformed state, then after deformation there will be in the $\overline{dx_2}$, $\overline{dx_3}$ plane the number Ne^{φ_1} molecules, since

$$\frac{\overline{dx_2}}{dx_2} \cdot \frac{\overline{dx_3}}{dx_3} = \frac{\overline{dx_1}}{dx_1} = e^{-\varphi_1}$$

for $\epsilon = 0$.

Multiplying Equation [8] by Ne^{φ_1} gives the true stresses

$$Ne^{\varphi_1}(P_1 - P) = 2G'N\varphi_1 e^{\varphi_1}$$

$$Ne^{\varphi_2}(P_2 - P) = 2G'N\varphi_2 e^{\varphi_2}$$

$$Ne^{\varphi_3}(P_3 - P) = 2G'N\varphi_3 e^{\varphi_3}$$

These stresses now comprise an amount of hydrostatic stress which has to be subtracted. As the hydrostatic stresses in incompressible material are not elastically but statically determined, we can so determine them and, putting $G'N = G$, obtain

$$S_i - S = 2G\left[\varphi_i e^{\varphi_i} - \left(\frac{\varphi_1 e^{\varphi_1} + \varphi_2 e^{\varphi_2} + \varphi_3 e^{\varphi_3}}{3}\right)\right] \ldots [9]$$

Putting $\varphi_1 = \lambda$, $\varphi_2 = \varphi_3 = -\frac{1}{2}\lambda$, $S_1 = \sigma$, and $S = \frac{1}{3}\sigma$ in [9] we get Equation [2a], and then, after dividing by e^{λ}, Equation [2b].

It is easy to generalize the law [9] so that it can be applied to other substances.

We wish, however, to conserve under all circumstances the condition that the stresses can be derived from an elastic potential.

If we put

$$\left.\begin{aligned} S_i - S &= \frac{2G}{v}\left\{f(\varphi_i) - \frac{1}{3}[f(\varphi_1) + f(\varphi_2) + f(\varphi_3)]\right\} \\ S &= \frac{3K}{v}\psi(\epsilon) \end{aligned}\right\} \ldots [10]$$

the work done by the stresses, with $\epsilon_1 = \epsilon + \varphi_1$, $\epsilon_2 = \epsilon + \varphi_2$, $\epsilon_3 = \epsilon + \varphi_3$, will be, according to [5],

$$\delta W = [(S_1 - S)\delta\varphi_1 + (S_2 - S)\delta\varphi_2 + (S_3 - S)\delta\varphi_3 + 3S\delta\epsilon]v$$

Introducing the value of $S_i - S$ from [10],

$$W = 2G\left[\int_0^{\varphi_1} f(\varphi_1)\delta\varphi_1 + \int_0^{\varphi_2} f(\varphi_2)\delta\varphi_2 + \int_0^{\varphi_3} f(\varphi_3)\delta\varphi_3\right] + 9K\int_0^{\epsilon} \psi(\epsilon)\delta\epsilon \ldots\ldots [11]$$

The functions $f(\varphi_i)$ and $\psi(\epsilon)$ must therefore be obtained experimentally.

The use of Equation [11] is more satisfactory than that of expressions which can be considered only as interpolation formulas of the experiments, because, according to [11], the work done is independent of the manner in which the material is loaded.

In the study of the behavior of rubber under deformations greater than 270 per cent we cannot neglect the influences of the time effects comprising relaxation and creeping (see Fig. 2). The shape of the rubber molecules also plays an important part in the behavior under very large deformation.

The study of these deformations is not important for technical purposes because in practice such large strains are never used, but the subject is very interesting from the standpoint of physical chemistry, because it enables definite conclusions to be drawn concerning the microstructure of rubber.

Acknowledgments

Grateful acknowledgment is due to Prof. H. W. Hayward of the Massachusetts Institute of Technology for valuable aid and support, to the Goodyear Rubber and Tire Co. for furnishing the specimens, and to I. Silverman for his assistance in carrying out the tests.

Discussion

William Hovgaard.[3] The curves of stress and strain given in Fig. 1 show that the proportionality between these quantities existing in ordinary elastic materials, and expressed by the constancy of the modulus of elasticity E, does not exist in rubber. Hence all attempts at using the ordinary law of elasticity to rubber have failed, it being found that E was not constant. Now the author has shown that rubber nevertheless follows a very definite law, which he derives in the Appendix and which is expressed by the simple formulas [2a] and [2b]. This law differs radically from that given by Hooke, in that a new expression for the strain λ is introduced, being a logarithmic function of the length before and after strain at every point. In other words, instead of expressing the elongation or compression as a fraction of unit length, say ϵ_1 in uniaxial stress, he takes the logarithm of $1 + \epsilon_1$ as a measure of the strain. In the limit, when ϵ_1 is very small, this makes $\lambda = \epsilon_1$. He shows, moreover, that the volume strain in rubber is so small, relative to the deformation, that it can be neglected; Poisson's ratio becomes equal to 2, and the relation between stress and strain can be described by one elastic constant, G, within a deformation range of up to 270 per cent.

The curves given in Fig. 1 are, it is supposed, the result of a series of tests. It would be of interest to know more about the number of tests, the kind of material used, and its source. Was the material of one specially selected quality or did it represent various grades?

The statement that vulcanized rubber is suitable for tires for the wheels of steam locomotives, enabling them to climb steep grades, is very interesting and important. The writer would ask whether tests of this kind have been made and whether the qualities of rubber revealed in this paper explain the suitability of rubber for this purpose.

In the Appendix the mathematical development of the formulas is given. Dr. Hencky first writes down the elastic potential energy W in terms of the principal and average strains, dividing it into two parts, one representing pure deformation and the other pure volume strain. Differentiating this expression, he obtains a value for δW, which he equates to that obtained by applying the principle of virtual velocities, involving the stresses S_i. He thus obtains Equation [7], which gives an expression for the stress S_i acting on a continuous particle of matter or on a single molecule, which he conceives as a sphere capable of great deformation, but of constant volume. Equation [7] gives a linear relation between the stress and strain, which obviously does not conform to the behavior of rubber, but the author now passes to the consideration of the forces with which the molecules act on one another and introduces stress forces P_i acting on a great number of molecules. He thus, through a development which is somewhat difficult to follow, arrives at Equation [9], and applying this to the case of uniaxial stress, which he denotes by σ, he finally arrives at formulas [2a] and [2b]. It is suggested that the author elaborate and explain the development connecting Equation [7] with Equations [8] and [9] more fully; also, it is not seen clearly why $G'N = G$. This paper is of great practical importance. It brings to light remarkable and unexpected qualities of vulcanized rubber and furnishes a simple equation which represents its behavior with great accuracy.

retical and experimental work by the author has to be limited to the particular rubber compound fabricated under a particular manufacturing procedure that was investigated. It is probable that by way of further experiments it can be extended over a number of rubber compounds, but it is fairly certain that it cannot be applied to vulcanized rubber in general, as the title of the paper suggests.

The numerous products that are at present used commercially under the general classification of vulcanized rubber have in common the fact that among other ingredients they contain a substantial admixture of natural rubber, but differ very considerably in their elastic behavior. The writers were confronted recently with the rather unusual problem of finding a material that would meet the following set of specifications:

1 Specific gravity of 2.4
2 Uniform elastic properties without any pronounced directional qualities
3 Absence of skin or internal stresses
4 Low modulus of elasticity
5 Reasonably uniform values of the modulus of elasticity at various unit stresses
6 Low permanent set
7 Low plastic properties
8 Properties that will permit the material to be easily furnished in the required irregular shapes
9 Poisson's ratio close to 0.20
10 Uniform coefficient of thermal expansion.

This material was to be used in building a model of an arch dam, to be tested to determine the deflections and stresses.[6] The range of stresses of the material in the model was from 6 lb per sq in. tension to 20 lb per sq in. compression.

A search made among materials that are available commercially or any known materials that were investigated brought out the fact that no material will satisfy the specifications entirely. Very many materials can be found that will satisfy a single requirement of the specifications, but the number decreases with astounding rapidity with each additional requirement. The known rubber compounds gave good promises, but all of them had much lower specific gravities and rather uncertain elastic properties. The whole problem resolved itself into a research proposition of developing a proper rubber compound.

Directional Properties

It is a well-established fact that the shape of the particles of the fillers is to a large extent responsible for the directional properties, and in order to exclude rubber compounds with pronounced directional properties, only known isotropic fillers or fillers unknown so far as their isotropic properties are concerned were used. Besides that, a certain amount of responsibility is due to the manufacturing process that may introduce directional properties or that makes them more pronounced. That the milling process is the one that introduces the directional properties or exaggerates them, due to a definite orientation of the particles of the fillers, is a fairly well-accepted theory. It is clear that no final judgment can be passed on the elastic properties of a rubber compound unless its directional properties are investigated. This was done by the preparing and testing of three specimen cylinders.

The first specimen cylinder was made by cementing together a number of rubber-compound sheets and cutting out a cylinder with its axis at right angles to the surface of the sheets. Such cylinders were designated as "across the slabs" and are indicated on the tables and figures as X.

The second specimen cylinder was made by cutting it out of a number of sheets cemented together, with the axis of the cylinder parallel to the surface of the sheets, and also to the direction in which the uncured sheets were milled. These cylinders were designated "with slabs 1" and are indicated as W1.

The third specimen cylinder was made by cutting it out of a number of sheets cemented together with the axis of the cylinder parallel to the surface of the sheets and at right angles to the direction in which the uncured sheets were milled. These cylinders were designated "with slabs 2" and are indicated as W2.[7]

Discussion of the Tests

The tests made may be divided into the following groups:

1 Tests of different compounds
2 Tests to determine directional properties
3 Repeated tests.

Data pertaining to these three groups of tests are given in Tables 5, 6, and 7.

The stress-strain curves for some of these various compounds are shown in Figs. 3, 4, and 5. These curves are drawn in the usual way, but the closing line of each curve connects two observed points—the largest deformation and the permanent deformation observed after the removal of the loads.

The solid lines are the strains in the axial directions and the dotted in the lateral directions. The ratio between these two strains at any of the loadings gives the corresponding values of Poisson's ratio.

1 *Tests of Different Compounds.* Each of the compounds listed in Table 5 was tested in one direction. Specimens of the same composition which were fabricated at approximately the same time are numbered with the same number, followed by a letter, while specimens of the same composition which were fabricated and tested at a later date are numbered differently.

Specimen 3 showed a much lower Poisson's ratio than either 1 or 2, which was taken as an indication that by the use of a proper filler, Poisson's ratio might be decreased and a material obtained which would more nearly represent concrete in its elastic behavior. A study of the data given in Table 5 shows that while there may be a tendency for some fillers to decrease Poisson's ratio, there seems to be no consistent tendency unless it may be for zinc oxide and microcell.

The investigated compounds cover a wide range, starting with a modulus of elasticity as low as 490 lb per sq in. for the compound 1 and up to 10,400 lb per sq in. for the compound 22. The permanent sets range from 1.4 per cent for 1 and up to 27.5 per cent for 30. The Poisson's ratio varied from 0.26 for 22 up to 0.50 for a number of compounds. The samples with a favorable low Poisson's ratio did show high permanent set.

Graphical data for the more important compounds are given in Fig. 3. The compound 1 shows a practically straight line for the strain-stress curve in both axial and lateral directions and a negligible permanent set. The rest of the compounds show more or less pronounced curvature of the strain-stress curves and different values of the permanent set.

2 *Tests to Determine Directional Properties.* Table 6 shows that only a few compounds are satisfactorily uniform so far as the values of moduli of elasticity in the three directions are concerned. If the uniformity of the values of the Poisson's

[6] See discussion by A. V. Karpov of the paper of Benjamin F. Groat, M. Am. Soc. C. E., entitled "Theory of Similarity and Models," Trans. A.S.C.E., vol. 96, 1932, p. 308.

[7] For a description of the testing procedure see R. L. Templin and R. G. Sturm, "Methods for Determining the Physical Properties of Certain Rubber Compounds at Low Stresses," Proc. A.S.T.M., vol. 31, part 2, p. 882 (1931).

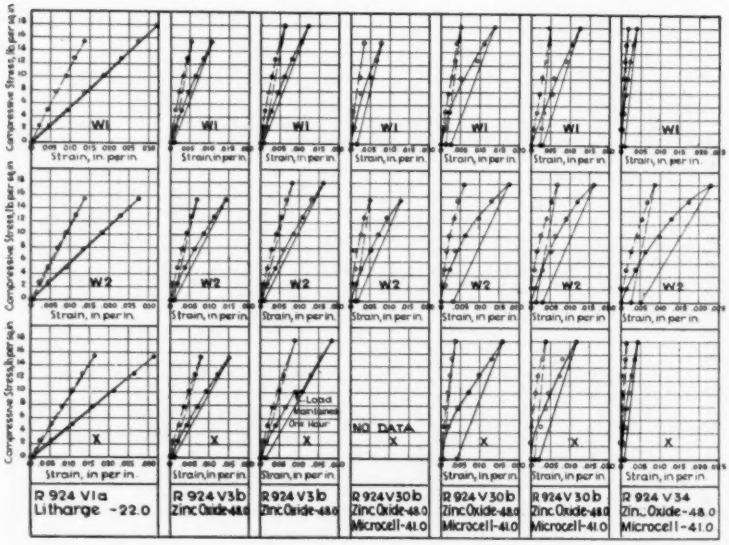

FIG. 5

ratio is also considered, then only the compound 1a shows satisfactory results.

Fig. 4 gives the graphical picture for a number of these compounds. The diagram is drawn in such a way that in every vertical column there are shown the stress-strain curves of a single compound in three directions. Here again it can be seen that the compound 1a shows the straight line strain-stress curve very similar for all three directions. The rest of the compounds show quite a variation in the three directions. The compounds 30, 31, 32, 33, 34, 35, 36, 41, and 42 contain practically the same fillers but show very different elastic properties that indicate the difficulties that may be expected if an attempt is made to obtain uniform material using this composition.

3 *Repeated Tests.* Two kinds of repeated tests were made: (1) To check the original tests, and (2) to determine the influence of high pressures on the elastic properties. The first kind of retests was made on compounds 12, 15, 21, 22, and 36, and the second was made on compounds 1, 1a, 3b, 30b, and 34.

The last-mentioned specimens were subjected to 5000 lb per sq in. hydrostatic pressure for a period of from 8 to 10 hours, after which they were again tested in the regular manner. On some of the specimens this treatment was repeated a few times. Fig. 5 shows the stress-strain curves of some of these specimens.

It may be noted by comparing the specimen 1a on Figs. 4 and 5 that this specimen, which was originally very uniform in all three directions, did not show any appreciable changes.

The specimens 3b, 30b, and 34, that originally did show very pronounced directional properties, changed rather considerably. It seems that in general the application of hydrostatic pressure resulted in a material with less-pronounced directional properties.

CONCLUSIONS

The conclusions based on this research can be summarized as follows:

1 The required specific gravity of 2.4 can be easily satisfied, and using commercially available fillers a large number of compounds can be formed with very different elastic properties. For each filler there seems to be a definite maximum amount of filler that can be added without impairing the workability of the compound in milling.

2 The heavily loaded rubber compounds as a general rule are unstable, cannot be exactly duplicated using the usual manufacturing procedure, show uncertain elastic, highly developed directional and plastic properties, and a large value for the permanent set.

3 It seems that fillers which do not have any chemical affiliation with the rubber and which enter into the compound merely as an ingredient which is mechanically mixed with the rubber are inferior to the compounds with such fillers, as, for instance, litharge, which enter into a chemical combination with the rubber.

4 The compounds containing some fillers in large volumetrical proportions show low values of Poisson's ratio, accompanied with pronounced directional and plastic properties. The satisfactory duplication of these compounds, keeping the value of Poisson's ratio constant, is impossible if the usual manufacturing procedure is used.

5 Compounds having directional properties can be improved by the application of sufficiently high hydrostatic pressure.

6 From the different compounds investigated, the rubber litharge compound was the one that showed the most remarkable uniform elastic properties, not very pronounced directional properties, a practical absence of plastic properties, and a negligible permanent set. This compound can be satisfactorily duplicated using the customary manufacturing procedure and is stable, being influenced very little by aging and repeated loadings. At the same time it possesses a high value of Poisson's ratio.

7 A material that would satisfy the specification should have properties similar to the rubber litharge compound but with a low Poisson's ratio. Such a material seems to be feasible but would require the discovery of the proper filler or fillers. Since no indications are available that would show in what direction a search of such kind is to be made, the possibilities are that a considerable amount of time will be necessary before such material can be found, because of the necessity of preparing and testing a large number of specimens using different fillers at random. Such research cannot be limited to the composition of the compounds only and necessarily have to include an investigation and possibly consequent changes of the manufacturing procedure.

8 The compound 1 was chosen as the material for the model[8] in spite of the high value of the Poisson's ratio in recognition of its remarkable elastic properties, uniformity, and ease of manufacturing.

Very recently, the United States Bureau of Reclamation used some 40,000 lb of this compound for the construction of a water-loaded model of Hoover dam. The bureau already had built and tested very successfully a mercury loaded model made of plaster of paris and celite material. The building and testing of a new type of model made of an entirely different material and the comparison of the test results of both models should give an excellent independent check, which is in line with the highly commendable and unusually thorough procedure established by the bureau in the designing and building of the highest dam ever attempted in engineering history.

AUTHOR'S CLOSURE

In answering Professor Hovgaard's remarks and questions I can remove some possibilities of misunderstanding overlooked at the time the paper was preprinted. In mentioning the modern possibilities of the use of rubber in machinery, as for instance

[8] For the description of this model see A. V. Karpov and R. L. Templin, "Building and Testing an Arch Dam Model," *Civil Engineering*, January, 1932.

for the construction of tires for locomotives, the intention was to stimulate research. The reference contained only the fact that such uses are contemplated in France; results were not given. With the law of elasticity given by Equation [9] of the paper, the practical value of such suggestions can be investigated without costly experiments. A technical description of a rubber tired car is given in *Railway Age* for November 12, 1932.

Considering the way in which I came to the elastic law given in Equation [9], the separation of the results from the mathematical appendix may have caused some confusion. A great number of tests were made with different kinds of rubber. The results showed that a striking agreement between theory and experiment could be reached only if compounds were used nearly isotropic in the unstrained state and free from excessive permanent set by small deformations. The elastic law, Equation [9], is not simply an interpolating formula to reproduce the experiments, but is based on the findings of colloid chemists.

It occurred to the investigators of the elastic properties of colloidal substances that only such materials are capable of undergoing finite strain in an almost reversible manner which possess long principal valence chains of a spiral form. Now we do not wish to say that such long molecules are just the same as spiral springs, but surely in stretching such a molecule an elastic resistance is encountered. Before the cohesive properties of the principal valence chain make themselves felt, the elastic resistance is due entirely to the resistance of the molecules against stretching the spiral form. Assuming now arbitrarily (it is true) for the elastic behavior of an individual molecular spring, the simplest possible elastic law given in Equation [7], and taking a statistical average over all springs, Equation [9] is reached. The difficulties in understanding the deduction for the general case are connected with the impossibility of separating the hydrostatic part of the stress if we give up the continuum conception. To illustrate this law the author took 12 rubber belts and 12 rubber cylinders and subjected them to the same tension and compression test; these experiments only were published in the preprint.

However, I am very glad indeed that in the meantime some remarkable papers appeared confirming my results.[9]

[9] Rudolf Weise, "Die elastischen Konstanten des Kautschuks bei grossen Spannungen," Kautschuk, 1932, pp. 106–110. J. R. Sheppard and W. J. Clapson, "Compressional Stress Strain of Rubber," *Engineering Chemistry*, vol. 24, 1932, pp. 782–790.

The work of Sheppard and Clapson is especially important, because they have found a way to overcome the difficulties of the compression test by testing thin rubber balloons under internal gas pressure. Although they did not deduce an elastic law, they stated that such a law must exist and gave the experimental records so completely that a comparison of formula [9] and the result of one typical experiment of Sheppard and Clapson disclosed a coincidence that is very satisfactory.

In taking a more precise law for the individual molecule, formula [9] could be modified so as to include even the elastic behavior of rubber close to fracture. I did not do that because, for the strains free from excessive permanent set, the simpler formula serves as well.

In answering Messrs. Karpov and Templin, I must say that the individual properties of a rubber compound are not worth while studying, at least not by applied mechanics, unless the results do not show that the behavior is typical. In saying that my results are not applicable to any other compound, the discussors assert indirectly that the elastic behavior of rubber is not a problem of applied mechanics. However, in reading their discussion I could not only not detect a proof of this statement, but also no relation to my own work. They investigate only such small deformations that the classical law of Hooke is good enough. But perhaps the objection is that the mere coincidence of experiment and theory cannot prove the existence of a general law. If the discussors intended to make this objection in reducing the validity of formula [9] to the rubber compound investigated, I can answer with the results of an experiment that I did not publish. The experiment can be performed, with the same results, with any compound free from admixtures lowering the cohesive resistance. A rubber string is loaded, and the period of the small vibrations caused by disturbing the equilibrium somewhat is observed. From the weight, the length of the string, and the stress the apparent modulus of elasticity can be calculated. The modulus of elasticity according to Equation [2a], which is only a special case of Equation [9], can be calculated by differentiating these equations with respect to the strain. The coincidence for small strains shows that the author's mechanical explanation of the possibility of undergoing finite deformations is correct. We maintain therefore that formula [9] is applicable not only to rubber compounds, but to all colloidal substances of like structure.

APM-55-9

An Experimental and Analytical Investigation of Creep in Bending

By GLEASON H. MacCULLOUGH,[1] WORCESTER, MASS.

This paper describes an experimental and analytical study of the phenomenon of creep as it occurs in bending. Creep tests upon a lead beam were made to determine the behavior of originally plane sections during pure bending accompanied by creep. From the results of these tests and of creep tests in tension and compression, a method is devised whereby the results of the usual tensile creep test may be utilized to predict the rate of creep for transverse sections of the beam. The paper concludes with several analytical examples involving creep as it occurs in pure bending.

1—Statement of the Problem

CREEP may be defined as the deformation of a material which occurs with time and which is caused by an externally applied stress. The existing analytical solutions of problems involving creep phenomena, as far as we know, are confined to cases involving tension and compression where neither bending nor actual twist (with one exception[2]) is present, and appear to be based on sound theory.

When one approaches the problem where creep is associated with pure bending, a natural starting point lies in making an assumption concerning the deformation of cross-sections of the beam.

Perhaps the most logical hypothesis is that made in the usual theory of elastic and plastic bending: namely, that cross-sections remain plane during bending. Because we were unwilling to accept this hypothesis as a basis for calculation without further verification when creep was involved, what has proved perhaps to be the major problem of this investigation arose; that is, to ascertain whether cross-sections do remain plane during bending when creep is taking place. The results, it will be seen, indicate that such is practically the case. A second experimental verification which has been attempted is to determine whether, from the results of tensile and compressive creep tests on the beam material, the creep rate of the beam may be predicted.

That the foregoing assumption concerning plane sections is a logical one for the case of pure bending we may see by the following argument. Suppose we take a beam subject to pure bending caused by a stress distribution like that shown at the ends [Fig. 1(*a*)]. The beam may be divided into a number of shorter lengths with the same type of stress distribution on each, of course, as in Fig. 1(*b*). With exactly the same stress distribution on each free body, there is no reason why one should be distorted differently than another. Yet, if all are distorted in the same manner [Fig. 1(*c*)], they cannot possibly fit together *unless all of the end sections have remained plane.*

2—Description of Apparatus

The equipment used in these tests consisted of four principal parts: a lead beam to be tested; a frame and knife edges for mounting the beam; means for applying a constant bending moment over the middle portion of the beam; and an accurate means of measuring the changes in length of the imaginary fibers of the beam. A general view of the set-up is shown in Fig. 2.

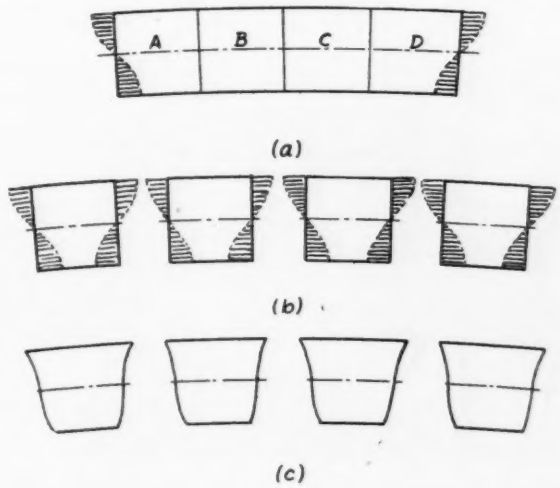

Fig. 1

It was early decided to carry out the experimental problem with lead as the working material, since lead at room temperatures behaves under loads producing creep about as steel and other metals at elevated temperatures. The use of lead therefore allows much more direct experimental methods to be employed than could be used in the case of steel at the necessary high temperatures, and should yield satisfactory qualitative results.

The lead beam was made from a slab of lead, 21 in. long, $7\frac{1}{2}$ in. wide, and $2\frac{1}{8}$ in. thick. A close-up view of the beam is shown in Fig. 3, while the dimensions of the beam and holders as originally designed are given in Fig. 4.

The actual determination as to whether plane sections remained plane was accomplished by measuring the extensions of longitudinal gaged lengths on the surface of the beam which took place under the action of creep in bending. These extensions, when plotted against distance from the center, should give a straight line. This necessitated the use of a strain-measuring device, which proved capable of giving readings under average conditions that varied by about 2 parts in 100,000 for a 10-cm gage length.

The tests were conducted in a room which was entirely free

from vibrations and in which the temperature variations could readily be controlled to within 0.2 deg. C.

3—Data and Results

Three complete series of tests of the lead beam under creep conditions were made. In series No. 1, seven equally spaced gage points were located in each of two vertical lines which were $12^1/_2$

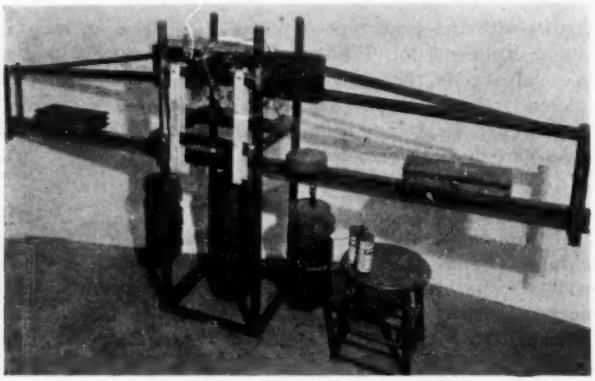

Fig. 2 The Flexure-Test Apparatus

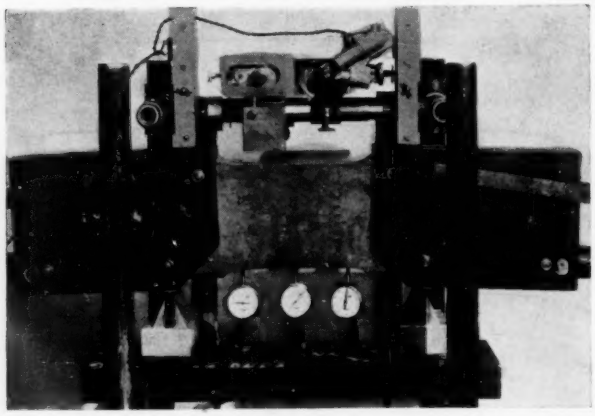

Fig. 3 The Lead Beam and Strain-Measuring Instrument

cm apart. Under the action of creep, the horizontal distances between the three top pairs were increased and those between the bottom pairs decreased. These extensions and contractions were compared with those if the straight and originally vertical lines had remained straight and always passed through the three middle points of each line. The top gage point lagged some 11 per cent behind this line, while the bottom point lagged some 5 per cent, showing that the plane sections did not remain truly plane.

It was suspected early in the course of series No. 1 that the gage sections unfortunately were too close to the supports—only 2 in. from the lower corner of the channel, which must have acted partially as a concentrated reaction—and that localized stress concentration extended even as far as the gage section. These questionable corners were therefore cut back 2 in. as shown in Fig. 3, before the tests of series No. 2 were made. It was also felt that perhaps the gage sections were too near the fillets and that the effect of stress concentration was being evidenced, so the gage distance was reduced from $12^1/_2$ cm to 10 cm in series No. 2. The beam was therefore straightened, remachined, and also given a much longer anneal (of three days in boiling water) before the next series was begun.

The results of this second series of flexure tests are given in Fig. 5. Plots are here shown of four sets of readings taken at various elapsed times. It will be observed that there is less variation from the straight line than in series No. 1, the top gage point now lagging but 7 per cent behind the straight line.

A third series of tests was made after the beam had again been straightened, each fillet cut back 2 in., the faces of the beam relieved so that they did not touch the channel holders until 1 in. back from the edges of the holders nearest the center of the beam, and given a much longer annealing—for seven days.

In this third series of tests two complete sets of gage points were used on each face of the lead beam. Each set consisted of eleven pairs of gage points (instead of seven as in the two previous series); the horizontal distance between the gage points in one set was 8 cm and in the second set 11 cm. All of the gage points in the vertical sections originally 8 cm apart, and all but the very top gage point in the set 11 cm apart, remained on their respective straight lines. This seems to prove rather conclusively that,

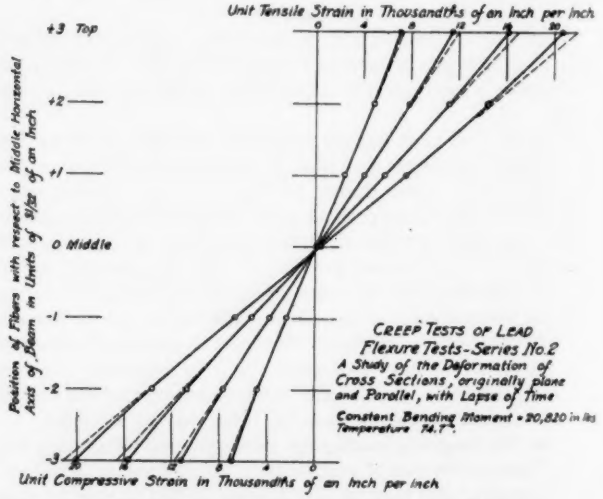

Fig. 5 Creep Tests of Lead (Flexure Tests)

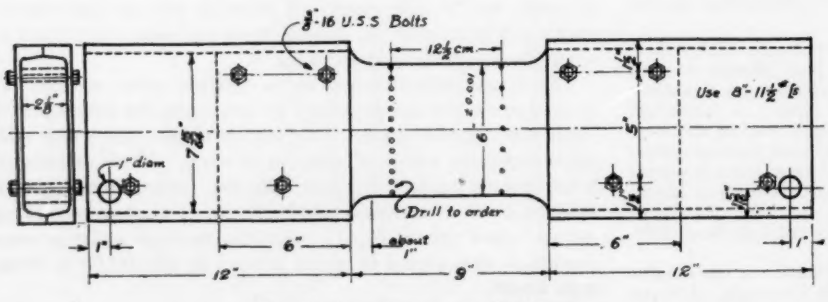

Fig. 4 Lead Beam and Holders

when the gage sections are sufficiently far removed from the clamped ends with their localized strains, plane sections remain plane in creep associated with pure bending.

Relation Between Fiber Extension and Deflection. The ordinary elastic theory shows that the elastic curve of a beam, acted upon by terminal couples only, is bent into the shape of a circular arc. This should also be true for pure bending accompanied by creep since transverse

slices at various places in the beam are all stressed alike. This test shows that the deflection obtained by experiment agrees within less than 1 per cent with that obtained from calculation, based on the assumption that the beam when bent assumes the form of a circular arc.

4—The Tension Tests

The specimens used in these tests were cut from the same lead slab as the beam used in the flexure tests. They were about $13^1/_2$ in. in overall length with a cross-section approximately $^1/_4$ in. sq. The pieces were carefully annealed for some three days in boiling water.

The method of applying the load was simple. Some inexpensive pliers were fitted up with a sort of toggle joint at the handle end of each pair (see Fig. 6) and were used as grips.

The strain-measuring apparatus used in the flexure tests was adapted to the tension tests, and the complete set-up is shown in Fig. 6.

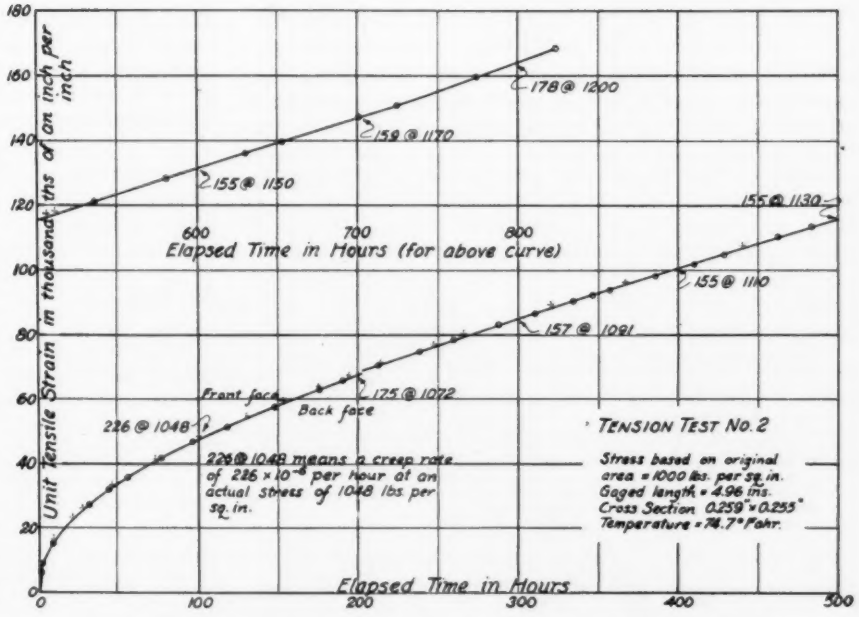

Fig. 7 Results of Tension Tests on a Highly Stressed Specimen (No. 2)

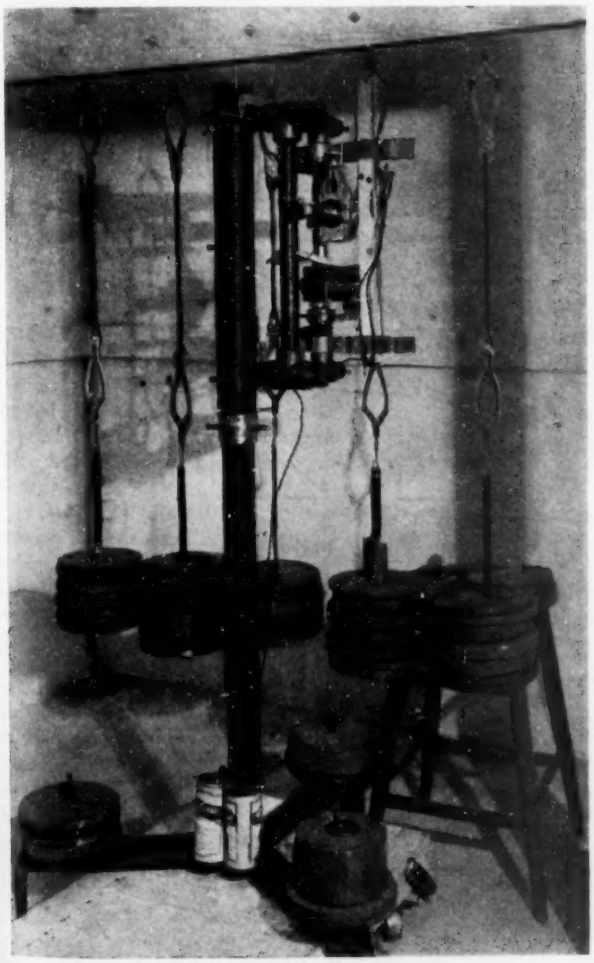

Fig. 6 The Tension-Test Apparatus

The results of the six tension tests run were plotted as in the sample curve shown in Fig. 7. This curve represents the results for a highly stressed specimen, No. 2. Three distinct stages are visible here: a stage of increasing creep rate, an intermediate stage where the creep rate is constant at 155×10^{-6} in. per in. per hr, and a final stage of increasing creep rate, doubtless showing the effect of the greatly reduced area, which is some 15 or 16 per cent less than at the beginning. The actual stresses indicated in Fig. 7 at the end of 100-hr intervals are computed on the basis that there is no volume change.

Another observed phenomenon is worth noting. Specimens Nos. 1 and 6 were subjected to approximately the same stress, 735 lb per sq in., but No. 6 had been overstrained initially so that it had been stretched about 2.2 per cent of its gaged length. By an examination of the two curves for these specimens (not shown), it was found that the creep rates of the two for equal amounts of strain are nearly identical. This agrees with a phenomenon observed by Dr. Everett[3] in his work on creep in torsion: namely, that the same minimum rate of strain could be reached more quickly by first overstraining the test specimen.

Fig. 8 shows the actual tensile stress, based on the reduced area, plotted against creep rate after various elapsed times upon semi-logarithmic paper. The resulting curves more or less assume the straight-line form which has sometimes been assumed by other experimenters, at least for the plot of the minimum creep rates. This means that the creep rate is related to the actual stress by an equation of the form

$$c = \epsilon^{a + b\sigma} \text{ or } \log_\epsilon c = a + b\sigma$$

where c = creep rate, σ = actual stress, ϵ = Napierian base of logarithms, and a and b are empirical constants.

5—The Compression Tests

Out of some five tests made, two were regarded as rather satisfactory, the amount of buckling produced not being excessive. These two tests gave creep rates in fair agreement with those obtained in tension.

[3] See F. L. Everett, "Strength of Materials Subjected to Shear at High Temperatures." Trans. A.S.M.E., APM-53-10, vol. 53 (1931), p. 126.

6—Correlation of the Results of the Flexure and Tension Tests

We are now in a position to study whether there is a possible way whereby the results of the common tensile creep tests may be utilized to predict the results that would be obtained in pure bending. In this particular study it is to be remembered that we

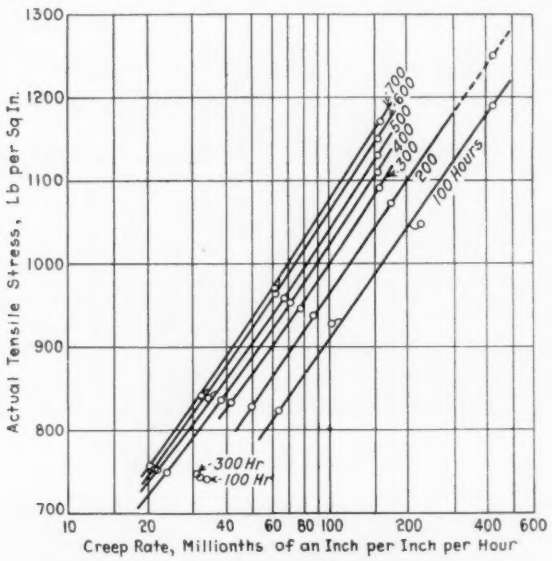

Fig. 8 Creep Tests of Lead (Tension Tests)

are restricting ourselves to the case of pure bending—bending unaccompanied by shear.

The general method of attack is this: Knowing the creep rate at the outside fiber of the beam and the manner of deformation of the cross-sections, we can find the creep rates for various fibers within the beam. If we should consider that the stresses producing these creep rates were equal to the stresses that would cause the same minimum rate of creep in tension or compression, then from a plot of "stress versus minimum rate of creep in tension," we could determine the corresponding stress in bending. Knowing the stress distribution for a few points in the cross-section of the beam, it is an easy matter to compute the moment of resistance of the bending moment acting on the section.

But the validity of this "minimum rate of creep" simplification is not settled. Perhaps the most puzzling problem which occurs in this attempted correlation, therefore, is that of deciding what creep stress to select from the tensile creep results corresponding to any rate of creep that we may select. Unfortunately the rate of tensile creep is not only dependent upon the tensile stress acting but also upon either the amount of strain that has occurred or upon the elapsed time since loading. Thus there are four variables mixed up in the problem: stress, strain, time, and a derived variable, the rate of creep. Consequently any one is dependent upon two others, not upon a single one. An expedient frequently used for reducing the number of variables is to tie up the *minimum rate of creep* with the stress, because then to every stress there corresponds but one (minimum) rate of creep. It is to be observed further that this minimum rate of creep occurs wherever the strain-time curve remains straight (which is the same as having a constant creep rate) or at a point of inflection.

From plots of creep for the outside fiber in bending against elapsed time, made by the author and not shown in this paper, it is seen that such creep-time curves assume nearly a constant rate of creep at the end of some 200 hr. Similarly at the end of 600 or 700 hr in the case of tensile creep, it is seen from a study of Fig. 8 that there is not much change in creep rate with increasing lapses of time. In fact, in series No. 2 of the flexure tests, the creep rate diminishes by the same percentage between 100 and 200 hr as between the 600th and 700th hour in the tension test. Since at both 150 or 200 hr elapsed time in bending and 700 hr elapsed time in tension, approximate minimum-rate-of-creep conditions prevail, it will therefore be assumed in the following calculations that the stress set up in bending for a given rate of creep equals the stress in tension which corresponds to the same rate of creep at an elapsed time of 700 hr.

7—Computation of the Bending Moment as Predicted From the Results of the Tensile Tests

Let us now endeavor to compute the moment acting on the beam in series No. 3 of the flexure tests at the end of 165 hr, using the creep rate observed for the top fiber of the "west" face with an initial gage length of 8 cm and the results of the tension tests as plotted in Fig. 8. This creep rate is observed to be 115.7×10^{-6} in. per in. per hr, but is really for a point 2.7 per cent of the half-depth below the top. At the top it would be about 119×10^{-6} in. per in. per hr. The creep rates at other fibers can be found by proportion on the assumption that displacements vary as the distance from the center.

Distance of fiber above center in inches	Creep rate at this fiber	Corresponding tensile stress, from "700-hour" curve, Fig. 8	Multiplied by distance from center
2.97	119×10^{-6}	1110	3290
2.475	99×10^{-6}	1070	2650
1.98	79×10^{-6}	1025	2030
1.485	$59\frac{1}{2} \times 10^{-6}$	970	1440
0.99	$39\frac{1}{2} \times 10^{-6}$	885	875
0.495	20×10^{-6}	755	375
0.00	0	0	0

Knowing the stress-distribution curve as of (*a*), Fig. 9, the moment can readily be computed for a beam of unit width by use of the σy distribution curve of (*b*), Fig. 9, where σ is the unit

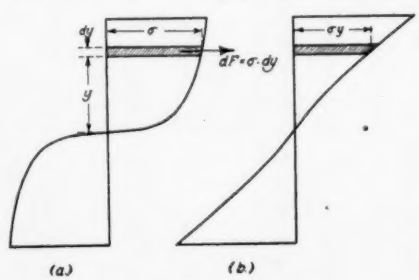

Fig. 9

stress. For, by reference to (*a*) it is seen that the total moment will be given by

$$M = \int (\sigma dy)y = \int (\sigma y)dy$$

and is nothing other than the area under a curve, such as Fig. 9(*b*), whose ordinates are y and whose abscissas are σy.

This area is readily computed by the use of Simpson's rule. Applying this rule, the area is

$$A = \frac{1}{3}\frac{2.97}{6}\left[3290 + 4\,(2650 + 1440 + 375) + 2\,(2030 + 875)\right]$$

$$= 4450 \text{ lb}$$

When multiplied by the width of the beam, 2.094 in., and doubled to care for the lower half of the section, the total moment is found

to be 18,650 in-lb, a value which is 97.2 per cent of the 19,170 in-lb actually acting on the beam.

A similar computation for series No. 2 gave a corresponding percentage of 89.8. The improvement in series No. 3 is attributed to the effect of the longer annealing upon softening the lead prior to this series.

It is to be noted that these calculations are based on the use of the 700-hr curve for stress versus rate of creep in tension. If the 200-hr curve had been used, for instance, the computed moment would be about 87 per cent of the actual moment. Therefore further investigation is desirable to settle just where to enter the family of "stress versus rate of creep" curves for those cases where the beam has not settled down to a steady rate of creep. In such a study it may even be found advisable to plot "stress versus rate of creep" curves with strain as the parameter, rather than time, in the family of curves.

In most practical problems, however, the elapsed time is sufficiently long for a steady rate of creep to have been attained, and the relation between stress and rate of creep to be used in such problems is that given by the "stress versus minimum rate of creep" curve.

Practically, the inverse of the problem just discussed is of greater interest: namely, knowing the moment acting on a beam which is in a state of creep, to determine the rate at which it is creeping, having as working data the results of tension and compression tests. This problem is discussed as an example of analysis in Art. 8, and the reader is referred to the method of solution there presented. Suffice it to say that if this method is applied to the problem discussed above, the computed and experimental creep rates will differ by some 14 per cent, the reason for the discrepancy being that creep rate is very sensitive to changes of load.

8—The Problem of the Stress Distribution and Rate of Creep in a Beam Subjected to Pure Bending

Several examples which have to do with creep in bending will now be discussed. They are all based on the assumption that plane cross-sections remain plane.

Case I—For a Rectangular Cross-Section and the Same Creep Characteristics in Tension and Compression. As an illustrative example, the beam of the experimental problem will be dealt with.

Given the lead beam of 5.940 × 2.094 in. cross-section acted on only by a bending couple of magnitude 19,170 in-lb (for stress-creep relations, use the 700-hr line of Fig. 8), to find the stress distribution and the rate of creep and rate of "deflection" of the beam.

The method of solution is an indirect one—the inverse of that used in Art. 7. It is based on the theory that plane cross-sections remain plane. The solution is obtained by trial, but the labor involved may be much reduced by starting with a good estimate of the value of the outside-fiber stress in the beam. A first estimate may be obtained by choosing a trial stress which is some 73 per cent of that obtained by the usual elastic theory, using the common formula, $\sigma = Mc/I$. The factor 73 per cent is arrived at from a study of the problem of Art. 7, and really assumes that the stress distribution is always of the form obtained in Art. 7. The *correct* choice of outside-fiber stress is obtained when the bending moment computed from this choice agrees with the given moment.

Solution. The "elastic" stress is

$$\sigma = \frac{Mc}{I} = \frac{M}{S} = \frac{19{,}170}{12.33} = 1555 \text{ lb per sq in.}$$

The assumed "creep" stress at the outside fiber is

$$\sigma = 0.73 \times 1555 = 1135 \text{ lb per sq in.}$$

The corresponding tensile creep-rate from the 700-hr curve of Fig. 8 is 134×10^{-6} per hr.

If plane cross-sections remain plane, the creep rates at fibers which divided the half-depth into six equal parts are, beginning at the outside, 134, 112, 89, 67, 45, 22, and 0. The corresponding stresses from Fig. 8 are 1135, 1100, 1050, 990, 915, 770, and 0. As in the problem of Art. 7, the best way to compute the moment is to multiply these values by their distance from the neutral axis and then plot as in Fig. 9(*b*). The corresponding products are 3370, 2720, 2080, 1470, 905, 380, and 0. Application of Simpson's rule gives

$$\text{Area} = \frac{1}{3}\frac{2.97}{6}\Big[(3370 + 0) + 4(2720 + 1470 + 380) + 2(2080 + 905)\Big] = 4560 \text{ lb}$$

Since this area represents only the moment of a section 1 in. wide and for the top half, the total moment is

$$M = 4560 \times 2.094 \times 2 = 19{,}080 \text{ in-lb}$$

If this is not in close enough agreement with the actual or given moment of 19,170 in-lb, a second approximation may be made using a new outside stress of magnitude (19,170/19,080) × 1135 or 1140 lb per sq in. A repetition of the above procedure using this new trial stress will doubtless give the correct moment of 19,170 in-lb. For this final outside stress, the corresponding creep rate is 136×10^{-6} in. per in. per hr for the outside fiber. This is the creep rate for the outer fiber which we set out to calculate. The stress distribution desired is practically that computed above.

Knowing the rate of creep of the outside fiber, it is a simple matter to compute the deflection, or the amount the beam is bowed away from a chord of length l. Assuming $l = 6$ in., and a creep rate of 136×10^{-6}, the relative rotation of plane sections 6 in. apart would be

$$\frac{136 \times 10^{-6} \times 6}{2.97} = 275 \times 10^{-6} \text{ radians per hr}$$

It is readily shown that the rate of change of deflection from the middle of a chord of length l under the action of a constant moment over the length l is

$$\frac{dy}{dt} = \frac{l}{8}\frac{d\vartheta}{dt}$$

where $d\vartheta$ is the angle of rotation between plane sections. For the assumed chord length, the deflection works out to be

$$\frac{dy}{dt} = \frac{6}{8} \times 275 \times 10^{-6} = 206 \times 10^{-6} \text{ in. per hr}$$

or 0.00495 in. per day.

If a known analytical relation exists between the stress and the resulting minimum rate of creep, such, for instance, as the familiar form, $\sigma = a + b \log_e C$, where C is the linear creep rate in tension or compression and the expression itself is valid for both tension and compression, then the problem may be solved analytically in some cases.

Case II—For a Rectangular Cross-Section and Unlike Creep Characteristics in Tension and Compression. This problem is somewhat more difficult than that of case I in that the position of the neutral axis is not known. In the following, a method of solution is outlined which is analogous to that[4] in pure bending when the material does not follow Hooke's law.

[4] For this method of solution, see, for instance, Timoshenko's "Strength of Materials," vol. 1, p. 233.

In this case we start as in Case I by assuming a reasonable stress in the tension fiber, greater than 73 per cent of the elastic stress if the creep rate in compression is more than in tension, and less than 73 per cent if the opposite is true. Under the condition that the compressive creep rate is the higher, the neutral axis will move away from the compressive fibers and the plane section will appear straight as in Fig. 10(*b*). Let us find the strain e_1 which corresponds to this stress, using the plot determined experimentally between tensile stress and minimum rate of creep.

Fig. 10(*c*) is similar but represents *any* strain-distribution curve following the linear law. In this last figure, let us locate the strain e_1. The stress-distribution curve corresponding to this linear deformation is plotted alongside it in Fig. 10(*d*) with both

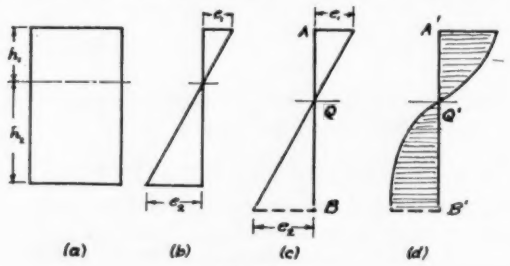

FIG. 10

the tensile and compressive portions shown. To locate correctly the neutral axis, assuming of course that no axial stresses are present, the condition that must be fulfilled is that the resultant force due to the stress distribution below the neutral axis must be equal and opposite to that above. Since these forces are proportional to the areas under the curves below and above the neutral axis, we first find the area between Q' and the top and then establish the position of the strain e_2 so that area between it and Q' shall be equal to that above. This can be done accurately enough by graphical means. The position of the neutral axis in the beam can evidently be located by the proportion $e_1/e_2 = AQ/BQ = h_1/h_2$.

Knowing the location of the neutral axis, the bending moment can be readily computed as in the preceding case. In this way one gets a moment that corresponds to the assumed stress in the top fiber. This moment of resistance probably will not agree with the given moment. A couple of further repetitions of this procedure will establish two more moments corresponding to other assumed stresses. If our choice of stresses for the top fiber has been anywhere near correct, these three points will enable us to plot a curve showing the relation between moment and stress in top fiber, and this curve can then be used to spot the top-fiber stress corresponding to the given moment. A final calculation based on this stress will undoubtedly give the correct stress distribution and creep rate.

Case III—For a Cross-Section Symmetrical With Respect to the Vertical Axes but Unsymmetrical With Respect to the Horizontal Axis. The creep characteristics in tension and in compression may or may not be alike.

This problem is even more complicated than the foregoing. The procedure will be about as follows:

The cross-section of the beam may be something like that of Fig. 11(*a*). Select arbitrarily a neutral axis, below the center of gravity of the cross-section if the creep rates in tension (the top fiber) are higher than in compression, otherwise above. Draw the linear strain relation of Fig. 11(*b*). Alongside this, plot the corresponding stress-distribution curve obtained from the experimentally determined "tensile stress versus minimum rate of creep" curve. Since the section is of non-uniform width, multiply each of these stresses by the width of the section at the corresponding point. The area under this curve represents the total force, and, as before, the resultant force or area above the neutral axis must equal that below. If the two areas work out to be equal, then the neutral axis is correctly located. If not, repeat with a slightly different assumed location for the neutral axis. When the neutral axis is correctly determined, then the moment can be computed as in case I.

A repetition of this procedure a couple of times for different

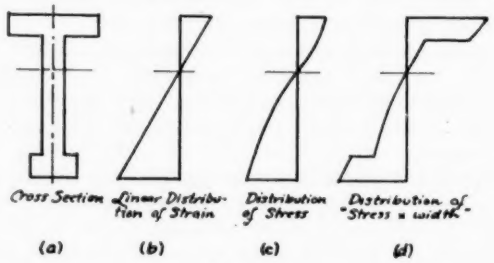

FIG. 11

assumed stresses in the outside fiber will enable one to get the corresponding moments and to interpolate between these moments and find the stress that will correspond to the given moment.

9—A SUMMARY OF CONCLUSIONS

From this investigation, the following conclusions may be drawn.

1 That transverse sections remain plane and normal to the axis of the beam during pure bending.

2 That deflections may be computed on the basis that the beam is bent into the form of a circular arc and that, conversely, deflection readings may be used for a rough determination, at least, of the creep of the fibers in pure bending.

3 That the minimum rate of creep in tension may be more quickly and just as accurately reached by first overstressing the specimen.

4 That the way is pointed toward a method of analysis whereby the results of tensile creep tests may be used to predict the behavior of a beam subjected to the action of creep under pure bending.

5 That the rate of creep is greatly affected by the previous mechanical and thermal treatment of the lead.

6 That the gage sections must probably be taken far away from fillets and other changes of section.

7 That the method of clamping the ends in pure bending probably plays a part in the deformation produced on cross-sections in the neighborhood of the clamping device.

ACKNOWLEDGMENTS

The author is particularly indebted to Prof. S. Timoshenko, who suggested this topic of investigation, and to the University of Michigan for providing the necessary equipment. Others, too numerous to mention, have also been of great assistance.

APM-55-10

The Creep of Metals

By A. NADAI,[1] EAST PITTSBURGH, PA.

In the following, a number of idealized cases of plastic flow of a more or less simple nature are discussed with primary intention of throwing light on how the speed of yielding influences the stresses under which metallic bars are permanently stretched or twisted at normal or at elevated temperatures.

I—Introduction

DURING the last few years considerable work has been done in the research institutions of the machine industry and in the laboratories of universities in the endeavor to obtain, mainly for important practical purposes, more reliable experimental data regarding the mechanical and physical properties of metals at high temperatures. The boiler tubes and heavy drums of the steam plant, the containers for the chemical and cracking industries, and various parts in steam turbines or internal-combustion engines have to withstand the prolonged action of large stresses or high pressures while they are at the same time heated to increasingly high temperatures. This has not only brought about an urgent demand to develop new materials of construction—and particularly new alloys—which would better resist the severe service conditions encountered in the modern boiler and engine plants than the materials formerly used, but has also put before the engineer a new task, namely, to search for facts which would help him to establish quantitative measuring scales for a comparison of the mechanical properties on which the behavior of the materials seems to depend at elevated temperatures. This has also largely served to draw more recently the attention of a number of investigators to certain experimental facts, which, although well known in connection with other physical phenomena concerning the slow movements of continuously distributed masses, were perhaps not so clearly conceived at first, and which for good reasons did not need to be considered in previous instances where the temperatures were low and where rates of flow could be neglected.

In comparing low and high temperatures for various metals definite ranges of temperature are not considered but rather a relative scale in which the absolute temperature in question is compared with the melting point of the material investigated, the ratios of the two being, according to P. Ludwik, the quantities to be compared ("homologous temperatures").

On the other hand, it is known that the forces necessary to produce plastic deformations at low temperatures may also depend to a certain extent on the speed of flow. Although at comparatively low temperatures this influence may in many cases be neglected, in a few it may become more pronounced. The rapid deformations resulting from an impact are such a case. The following statements may therefore also possess a certain value in dealing with rapid deformations at comparatively low temperatures.

Some of these facts concerning the behavior of materials which apparently are becoming increasingly important under present conditions, had already attracted the attention of early observers of the mechanical properties of solid matter, such as Clerk Maxwell and Lord Kelvin. These investigators created terms and introduced names for certain of these properties, which may prove still useful at the present time.

In connection with these phenomena, it may perhaps also be of interest to mention another set of facts where the extremely slow permanent changes of shape of solid bodies have produced effects. In nature, their consequences are evident on a large scale in the extremely slow movements of the strata of the upper earth crust, and, taking into consideration the extended period in which these movements occur, extremely small differences of stress, and in consequence infinitely small disturbances in the equilibrium conditions of the upper layers of the earth, must have been sufficient to produce some of the gigantic and magnificent effects visible in the signs of the uplifting of mountain chains.

Among the more recent investigations on the flow of metallic materials under stress must be mentioned particularly the work by H. J. Tapsell reported in his recently published book "Creep of Metals,"[2] by R. W. Bailey[3] and G. I. Taylor[4] in England, by P. G. McVetty[5] and by the collaborators of S. Timoshenko[6] in this country, by R. von Mises, L. Prandtl, T. von Kármán, and H. Hencky and by the K. W. Institute for Steel Research and by others in Germany. Further data on the experimental work on creep of metals are available in the volume published by the A.S.T.M. and A.S.M.E. in 1931 and embodying a report on the symposium on the effect of temperature on the properties of metals held in Chicago, June 23, 1931, to which further reference must be made. The phenomena of rapid and slow movements in solids have recently been the subject of most interesting investigations in their applications to geophysics by H. Jeffreys[7] and by B. Gutenberg,[8] to which special attention is called. With reference to the phenomena of elastic after-effects, internal friction, etc., which will, however, be excluded from treatment in what follows, the review by H. Fromm in his two articles on the limits of elasticity and elastic hysteresis

in the "Handbuch der physikalischen and technischen Mechanik" should be mentioned.[9] Finally, a number of papers have been published in the *Journal of Rheology*[10] in the last few years which mostly deal with the plasticity of non-metallic materials and cannot be referred to here in detail.

Although the phenomena indicated in solids have thus been observed very carefully and studied from various sides, including also the flow of rocks in nature, it seems that their mechanical laws need further and perhaps more detailed analysis, an introductory contribution to which is offered in the present paper.

II—Phenomenological Distinction Between Speed-Independent and Speed-Dependent Plasticity

1 As already indicated, a variety of cases of the permanent or plastic deformations of solids can be treated with sufficient accuracy without paying any attention to the variable time. If, for example, a tensile test with a ductile metal, such as steel or copper, is made on a testing machine and a stress-strain diagram is taken at a comparatively low speed and at normal temperatures, it will not make a difference of more than a few per cent in the yield stress whether the bar is stretched at one speed or at another.[11]

Under the comparatively low speeds used in testing materials at room temperature, very little effect will be exhibited, at least for materials having high melting points. For lower-melting metals, which start to recrystallize or to lose stress after permanent deformation at normal temperatures, this is, however, not the case. Ludwik[12] probably first called attention to this fact and suggested more quantitative relations. He tested tin wires, stretching them under constant speeds of the moving heads of a testing machine and found that the *true* stresses σ obtained by dividing the load P by the actual cross-sectional area A of the bar, while the load was acting, under which a given extension ϵ per unit of length (defined as $\epsilon = (l - l_0) : l_0$, where l_0 is the original length of the wire or bar and l the actual length) was produced, depended on the rate of flow $u = d\epsilon/dt$ or the unit extension per unit of time. With increasing u the yield stress σ becomes larger for the same ϵ. Ludwik suggested a logarithmic expression for σ as depending on u at a given value of ϵ. In a slightly changed form this is

$$\sigma = \sigma_1 + \sigma_2 \log_e \frac{u}{u_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where σ_1, σ_2, and u_0 are constants. H. Cassebaum,[13] while investigating the mode of yielding of mild-steel bars at room temperature, arrived independently at similar conclusions. His results, as far as they refer to mild steel, must, however, be taken today with precaution, because when computing ϵ or $d\epsilon/dt$ from his observations, he tacitly assumes that the whole length of the bar flows uniformly, which could not well be the case probably in many of his tests, on account of the effect of the upper and lower yield points characteristic for this material. These tests were repeated at room temperature by H. Deutler[14] with improved apparatus and with rates of flow u ranging from the ordinary speeds of a slow tensile test up to such as can be produced by impact (also using tensile bars). Within a range of speeds of from $u = 1$ to $u = 1{,}000{,}000$, Deutler verified the same relation, which also might be expressed by saying that if at a given unit elongation ϵ the stress ordinates $\sigma = \sigma_1, \sigma_2, \sigma_3 \ldots$ increase according to the terms of an arithmetical progression then the corresponding rates of flow u required to produce such stresses will satisfy a geometric progression of terms $u_1, u_2, u_3 \ldots$. To obtain the stresses $\sigma_1 = \sigma_0 + \Delta\sigma$, $\sigma_2 = \sigma_0 + 2\Delta\sigma$, $\sigma_3 = \sigma_0 + 3\Delta\sigma$, . . . for a given ϵ, the speeds u or rates of flow required must be chosen according to the relations $u_1 = u_0 c$, $u_2 = u_0 c^2$, $u_3 = u_0 c^3$, etc. From this it follows that the influence of the speed of deformation in slow tests on such materials as mild steel tested at normal temperature is comparatively insignificant, provided the speeds do not reach the order of magnitude of impact speeds, thus justifying the establishment of what may be termed the "static theory of plasticity."

However, conditions may change if the temperatures increase, with the result that the same changes in speed of deformation, if the temperatures are sufficiently high, may be followed by a very considerable change in the acting stress. Conversely, a slight change in stress which at low temperatures had a pronounced effect on the speed of deformation, at sufficiently high temperatures will affect but little the rate of flow. If, for example, it is slightly lowered from the value of a yield stress maintained at low temperature, yielding will cease, while, if relations similar to those set forth in Eq. [1] also hold at the higher temperatures, after a certain decrease of stress, yielding may not cease and the bar may creep and deform further.

R. W. Bailey in his paper presented before the World Power Conference, 1929, quoted above, arrived also at a logarithmic expression for the relation between stress and rate of creep at elevated temperatures. He compares creep rates somewhere near the minimum creep rate observed on a time-elongation curve and finds a straight-line relation when plotting stress values against logarithms of creep rates. He uses this information when discussing various cases of stress—for example, the distribution of stress in tubes subjected to internal pressure at elevated temperatures.

III—Load and Stress Surface for Tension. The Infinitely Slow Stress-Strain Diagram for Tension

Another consequence of these facts concerning the slow permanent deformation of metals or other solid materials is that while it was sufficient in a static test to assume the stress as depending on a single variable, namely, the unit elongation ϵ, and to plot a "stress-strain diagram" characteristic for the given material—at least one for each of the simple states of stress, such as pure tension, pure compression, or pure shear—now more independent variables are needed. One of them has already been introduced, namely, the rate of flow $u = d\epsilon/dt$. The question that immediately arises is how many variables or independent quantities are required to describe a series of states of plastic flow.

Let a number of bars of the same material be stressed from the unstressed state at the same temperature but under varying rates of flow u, each bar at a constant rate u. This can be done in some of the testing machines with a certain accuracy when the machine has one head which practically moves but little while the load increases, while the other head is moved by an electric motor with a constant speed (screw-drive type of testing machine); such conditions, however, may only be approached if the bar is stretched permanently to a considerable extent. If a gage length of the bar is thus instantaneously recorded while it stretches uniformly under increasing load (but not by stopping the test and by measuring the length on the unloaded bar)

and force values P are taken, a "stress-strain diagram" can be plotted in the shape of a curve $\sigma = f(\epsilon)$ taken under the given rate of flow $u = d\epsilon/dt = \text{const.}$, where $\sigma = P/A$ and A is the actual cross-sectional area (Fig. 1). For each speed of stretching u there will be a diagram. Combining the individual diagrams from the parallel sections into a common surface at a given temperature, a curved surface will be obtained which may be called the stress surface of the material at this temperature for tension, and in which the stress σ will appear as a function of the two independent variables ϵ and u (Fig. 1):

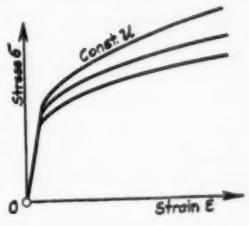

FIG. 1 STRESS-STRAIN CURVES FOR CONSTANT SPEEDS (u = CONST.)

$$\sigma = F(\epsilon, u) \ldots\ldots\ldots [2]$$

It will furthermore be assumed that the total unit strain ϵ observed is an entirely permanent one. A unit strain ϵ may in general consist of an elastic portion ϵ', which may be assumed to be proportional to the acting stress $\epsilon' = \sigma/E$, where E is the modulus of elasticity of the material, and of a permanent portion designated by ϵ''. Considering first only strains in which the plastic portion ϵ'' is predominant, and neglecting the elastic part, the state of plastic flow under these simplified conditions will depend on two quantities, ϵ and u, and the third, namely, the stress σ, will be given by the value of the corresponding ordinate σ of the stress surface of the material, $\sigma = F(\epsilon, u)$. Now if a point P having the rectangular coordinates x, y, z in space is moving on a curved surface, $z = F(x, y)$, the path along which it moves on this surface may be determined, for example, if the coordinates x and y are known functions of the time t. By eliminating the time t from x and y, a second condition will result, or an equation $y = \psi(x)$, which is the horizontal projection of the path of P on the surface, on the xy-plane. Similarly, if for a given material the stress surface is given: $\sigma = F(\epsilon, u)$, and, for example, it is known how the unit elongation ϵ changes with the time t, then $u = d\epsilon/dt$ will also be given, and by eliminating from both expressions the time t, the projection of the path of a point P will be given, which determines a curve on the surface $F(\epsilon, u)$. To describe a sequence of modes of plastic flow—that is, a "special test"—it will be necessary to prescribe besides the known shape of the stress surface $\sigma = F(\epsilon, u)$ a second condition, which may, for example, be a function of the form

$$u = \psi(\epsilon)$$

In practice, the additional condition which may determine a test may appear in various forms. One frequently met is that the load applied to keep the bar under stress is held constant; or the condition may be given more implicitly by the nature of the mechanism by means of which the bar is stretched and the forces are measured, new loads applied, speeds of stretching changed, etc.

An assumption on which the introduction and the use of such a "stress surface" $\sigma = F(\epsilon, u)$ for the tensile test is implicitly based must be particularly mentioned here. It is assumed that the phenomena to be described in the following are of such a nature that the strain ϵ and rate of flow u are the only factors and independent variables that determine the state of stress required to produce them at an instant t, *but that the time itself at which the quantities ϵ, u, σ are observed has no influence on the deformation.* In other words, if a given strain ϵ at a given rate of flow u is produced, then the corresponding yield stress of the material will always be the same, no matter how long the material was left under the influence of the temperature at which the test was made. Now it is well known from observations—for example, about hardness—that previously cold-worked materials may soften with time without being stressed, if subsequently exposed to comparatively low, but slightly elevated temperatures.

The author is particularly indebted to Mr. P. G. McVetty for having made available to him very valuable observations regarding this softening of previously work-hardened material, which are not yet available in published form. Further data concerning observations of an analogous nature on the softening of copper and other metals have been published by G. P. Halliwell and N. B. Pilling.[15] What is essential at the present moment is that these and similar phenomena have to be excluded from the following considerations. Mathematically speaking, however, it may be added that they may perhaps find their adequate expression later, including in the stress function $F(\epsilon, u)$ besides ϵ and u the variable time t, by writing explicitly

$$\sigma = F(\epsilon, u, t)$$

It may be said—and this will appear from what follows more conclusively—that portions of the theory of creep of metals under a simple state of stress may be treated in the first approximation by applying the kinematics of the movements of a material point P having the rectangular coordinates x, y, z on a given surface in space and moving along a prescribed path on this surface. As the basic coordinates x and y may be chosen in the case of the creep problem the strain ϵ and the rate of flow $u = d\epsilon/dt$, and as ordinates z may appear the yield stress σ. To any given path on the curved surface there will correspond a special yielding test, and the projection of this special curve or path on the σ, ϵ-plane is the "stress-strain diagram" corresponding to the special test.

To each constant temperature there will correspond a special surface $\sigma = F(\epsilon, u)$. To make the picture more complete, one may, if in certain cases it is required, also consider such cases of movements of a point P on a surface, in which this latter is either displaced without distortion relatively to a base or in which it will be distorted gradually with time t in a predetermined way. It seems obvious that particularly the second kind of movements will probably become complicated. Using the analogy—the cases where through chemical changes such as the slow precipitation of a component in an alloy, age hardening, etc., or through softening the hardness of the alloy or the yield stress changes with time—this might perhaps be described by gradually allowing a distortion of the stress function or surface $\sigma = F(\epsilon, u)$ with time t. By multiplying, for example, the right-hand side of the equation by an expression containing only the time t:

$$\sigma = F_1(t) \cdot F_2(\epsilon, u)$$

and choosing a particular form for $F_1(t)$, perhaps such cases might be treated in which the yield stresses or the hardness due to internal changes of the structure first increase and later again decrease (softening, age hardening, etc.) while the test goes on or a piece of a construction is subjected to a state of stress of long duration.

To the movement of a point P on a rigid surface which itself may be displaced with respect to some fixed system in space as a rigid body, there corresponds probably in the creep problem the resolution of the total strains ϵ into their elastic and permanent parts ϵ' and ϵ'', as will be shown later.

Finally there is another group of time effects, including the elastic after-effect, elastic hysteresis, and similar phenomena, and particularly those of the integral type studied by Boltzmann, von Kármán, Wiechert, Bennevitz, Gutenberg, and other

[15] Proc. A.S.T.M., vol. 25 (1925), part II, p. 97.

physicists, which must be mentioned briefly here because they are also beyond the scope of the present consideration and cannot be covered by the assumption that stress depends on ϵ and u alone. While elastic hysteresis cannot be treated here, present means will, however, allow us to consider various kinds of hysteresis phenomena due to the yielding of metals and the fact that plastic deformations require a certain time t in which to be produced.

2 If A designates the actual area of the cross-section of the bar and A_0 the original area, then for many purposes (large deformations) it will be sufficient to assume that the volume of the bar does not change during a tensile test:

$$Al = A_0 l_0 \quad \ldots\ldots [3]$$

If σ_0 designates the stress as referred to the original cross-sectional area A_0 and σ the "true stress" found by dividing the load P by A, then as

$$\sigma_0 = \frac{\sigma}{1+\epsilon} \quad \ldots\ldots [4]$$

we may distinguish in the case of larger extensions ϵ between a stress surface

$$\sigma = F(\epsilon, u) \quad \ldots\ldots [5]$$

referring to the "true stress" and a second surface or function of the same variables ϵ, u:

$$P = A_0\sigma_0 = A_0 \frac{F(\epsilon, u)}{1+\epsilon} \quad \ldots\ldots [6]$$

in which the load P or the stress σ_0 is plotted as ordinates.

Besides the first stress surface $\sigma = F(\epsilon, u)$ it may be necessary to consider the second one $\sigma_0 = H(\epsilon, u)$, particularly in the case of large deformations and when the question of stability of a series of subsequent states of stress has to be investigated. Both surfaces may be geometrically represented by plotting their ordinates σ respectively σ_0 above the same abscissas ϵ and u.

As speed of strain or rate of flow u, the derivative of the strain ϵ with respect to the time t was introduced above and will be used in the following. As this strain ϵ was referred to the original length l_0 of the bar and $\epsilon = (l - l_0)/l_0$, the speed of strain

$$u = \frac{d\epsilon}{dt} = \frac{1}{l_0}\frac{dl}{dt} \quad \ldots\ldots [7]$$

indicates the speed with which two points marked on the bar will move relatively to each other. For large deformations this definition for ϵ seems arbitrary and it would be more natural to define ϵ by the instantaneous increase of length divided by the actual length l at which ϵ is sought, or by

$$d\epsilon_n = \frac{dl}{l} \quad \text{or} \quad \epsilon_n = \int_0^l \frac{dl}{l} = \log_e \frac{l}{l_0} = \log_e (1+\epsilon) \quad \ldots [8]$$

The "natural speed of strain" would then be

$$u_n = \frac{d\epsilon_n}{dt} = \frac{1}{1+\epsilon}\frac{d\epsilon}{dt} = \frac{u}{1+\epsilon} \quad \ldots\ldots [9]$$

In the paper by H. Deutler, quoted above, u_n was erroneously defined as

$$u_n = u/(1+\epsilon)^2$$

3 For the following, it will be of interest to consider a few simple cases of stress (in contrast to the static case) encountered in testing methods or in practice.

(*a*) *Uniform Rate of Flow* (u = const.). We have already used one form of these conditions when defining the shape of the first stress surface by means of a set of parallel plane sections or profiles assuming in each u = const. Each curve (Fig. 1) refers thus to a tensile test, which was made under a uniform rate of stretching or of flow, so that the length of the bar or the total unit elongation ϵ was increasing uniformly with time t: $\epsilon = ut$, where u is a constant.

(*b*) *Varying Rate of Flow* (u). Instead of keeping u constant, the relative movement of both heads of the testing machine or the ends of a bar may be given by means of a time function either of the unit elongation $\epsilon = f(t)$ or of the rate of flow $u = d\epsilon/dt = g(t)$.

(*c*) *Constant Load* (P = const.). A very frequently encountered method of testing creep data in practice is to keep the load P constant during a test made at a given constant temperature. This means, then, that a test is conducted along a horizontal section P = const. of the second stress surface $H(\epsilon, u) = \sigma_0$ = const. If the ϵ and u values are determined from a test made under constant load P or a given value of σ_0 = const., which can be done by observing the time-elongation curve (see Fig. 2) under various but constant loads, $\epsilon = f(t)$, and taking derivatives

$$u = \frac{d\epsilon}{dt} = f'(t)$$

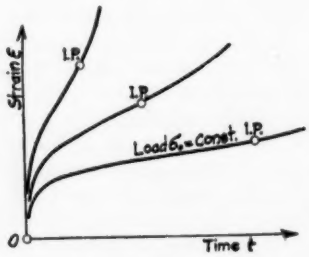

FIG. 2 TIME ELONGATION CURVES FOR CONSTANT LOADS (P OR σ_0 = CONST.)

then corresponding pairs of ϵ, u may be obtained from these last two relations and the curve $H(\epsilon, u) = \sigma_0$ = const. constructed point by point.

If this procedure is repeated subsequently for a number of values of σ_0 = const., a complete picture of the contour lines of the second stress function or the second stress surface will be obtained and thus the surface

$$\sigma_0 = H(\epsilon, u)$$

be experimentally determined, and from this finally the first stress function:

$$\sigma = (1+\epsilon)H(\epsilon, u)$$

(*d*) *Constant Stress* (σ = const.). To maintain a creep test under constant stress when the elongations ϵ are increasing requires a gradual decrease of the load P with the elongations according to

$$P = A\sigma = A_0 \frac{\sigma}{1+\epsilon}$$

or inversely as $1 + \epsilon$, which has been already suggested by some experimenters by having one end of the attachment used in stretching a thin wire plunge a weight into water.

(*e*) *Uniform Rate of Stress* (w = const.). The stress σ may increase directly as the time, $\sigma = wt$, where the rate of stress $w = d\sigma/dt$ = const. This would be realized in a test made with a wire stretched by the weight of a bucket, into which water or a stream of small shot runs uniformly, the quantity per unit of time decreasing inversely as $1 + \epsilon$.

(*f*) *Changing Rate of Stress or Load.* Instead of prescribing the law of the movement of the heads or grips of the testing machine as under (*a*) and (*b*), the law may be given in such a way that either the total load P, the true stress σ, or the rate of the true stress $w = d\sigma/dt$ may vary with the time t.

(*g*) *Relaxation* (ϵ = const.). An important case is that in which after a creep test or after the short elastic stretching or a continuous prolonged action of a load a bar is so constrained that it will not change in length. It will be shown later that for this kind of deformation to occur in a finite time an elastic member is essential and must be included in the system under consideration. Under *pure relaxation* there will be understood a gradual transformation of the elastic part ϵ' of the total unit elongation $\epsilon = \epsilon' + \epsilon''$ into a newly formed permanent elongation ϵ'', while the total unit elongation $\epsilon = \epsilon' + \epsilon'' = $ const. remains unchanged, so that ϵ'' increases at the expense of ϵ'.

Mixed and Compound Relaxation. It is difficult or practically impossible to realize pure relaxation in a test with a solid bar of one of the rigid materials, used in engineering practice and having a high modulus of elasticity. The heads of the test piece have to be attached by grips, screw threads, etc. to other parts, which will themselves also contribute to the elasticity of the system. Relaxation must then occur at the expense of the combined elasticities of the bar and the attachments. In practice mixed relaxation occurs only, for example, in tension members such as cylindrical bolts with screwed ends exposed to high temperature, etc. The piece in question may at the beginning of the process be represented by a scheme such as that shown in the left half of Fig. 3. The spring expresses the action of the elasticity of the adjoining machine parts, which are held under stress by means of the bar shown in the upper part of the figure. The weaker the elastic spring is with which the bar is constrained to stretch, the longer will be the extension in which it will relax, when creeping, until the stress disappears from it. The unloaded end position of the relaxed system is indicated at the right in Fig. 3.

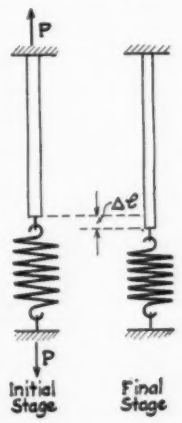

FIG. 3 RELAXATION

If the elastic-spring action is again due to the elasticity of the piece in question, but the stresses therein now vary from point to point (examples: a circular disk shrunk on a cylindrical pin, press fits), we may speak of compound relaxation.

4 *Time and Load Diagrams.* A test conducted in a predetermined manner is represented, as we have seen, by a *condition curve* on the stress surface, indicating a continuous series of modes of stress and strain. The shape of such condition curves may be studied as soon as the stress surface is known or has been determined empirically, and from them the creep-time laws may be derived for the particular case under consideration.

Conversely, time diagrams, such, for example, as those for the

the elongation..... $\epsilon = f(t)$
the true stress..... $\sigma = g(t)$
the rate of flow..... $u = d\epsilon/dt = f'(t)$, or
the rate of stress..... $w = d\sigma/dt = g'(t)$

which might be obtained from experimental observation, will help to determine the various sections u = const., σ = const., σ_0 = const., or other condition curves of the stress surface. It may be seen also that in one or the other of these cases it may be preferable to pursue a test or condition curve on the second of the two surfaces of stress, Eq. [6]. For example, a test made under a load P = const. is characterized on the second surface simply by a contour line, while the corresponding curves σ_0 = const. drawn on the first surface would be of a less simple nature.

This may be of importance if more complex cases in which the stress components vary from point to point in the body have to be studied, such as would be the case when bending, torsion, or other non-homogeneous states of stress have to be investigated. In these latter cases, the quantities determining the external loads, the maximum bending or twisting moment, the pressure in case of a tube subjected to internal pressure, can only be found by integration following the ordinates σ along some cross-section of the first stress surface. To study then the cases of non-homogeneous stress when an externally applied load is kept constant leads automatically to the construction of a particular quantity by an integration expressing a total load P, a moment or torque M, or a pressure p as a function in general of ϵ and of u. The curve P = const., M = const., or p = const. on a surface, whose respective ordinates are P, M, p, etc. plotted above ϵ and u, will then determine the corresponding tests made under constant P, or M, or p, etc.

5 *The Infinitely Slow Stress-Strain Diagram.* The experimental facts concerning the changing plastic behavior of a material with temperature may be expressed by saying that while the surface $\sigma = F(\epsilon, u)$ has a comparatively flat appearance at low temperatures in its sections ϵ = const., this is no longer the case when the temperatures are raised above the limits at which the softening of the material starts. Further, with decreasing rates of flow at normal temperatures, it seems as if the stress would approach a limiting curve, the ordinates of which have a considerable magnitude. To have such a limiting curve for $\sigma = F(\epsilon, 0)$ defined or a stress-strain diagram for a rate of flow equal to $u = 0$ introduced must be explained, because a tensile test cannot be made at an infinitely low speed. What is meant here is that if rates of flow $u = d\epsilon/dt$ are chosen corresponding to the usual duration of a slow tensile test (measured perhaps by hours or days and in every case by small, but finite, values of $u = d\epsilon/dt$), the stresses will then be of an order of several thousand pounds per square inch. But it does not conversely follow, however, that if u were to be further decreased to a much smaller order of magnitude the stress would still remain of the same order of magnitude as before. Rather it seems probable, as has already been stated above, that this may not be the case and that the application of low stresses for a sufficiently long period of time even at normal temperature may cause slow yielding. One reason for believing this is indicated by the behavior of solid matter at sufficiently high temperatures. At these not only are the slopes $\partial\sigma/\partial u$ of the stress function $\sigma = F(\epsilon, u)$ much greater than at normal temperatures, but tests have clearly shown that if such a thing as an infinitely slow stress-strain curve were to exist at these temperatures, its stress ordinates would be considerably smaller than at normal temperatures. Expressed in other words it would thus seem that polycrystalline or amorphous solid materials, at sufficiently elevated temperatures and sufficiently small values of u, more and more approach conditions which, at least within a limited range of ϵ and u, may be expressed by

$$\sigma = Cu = \left(\frac{\partial\sigma}{\partial u}\right)_{u=0} u$$

This is the property which has been called pure viscosity in the case of a slowly moving liquid. Whether a constant has to be added on the right side of this equation or not is perhaps disputable, but in any case it would be of a small magnitude at sufficiently high temperatures when compared with the values of yield stresses at low temperatures and small rates of flow.

As both slopes of the stress surface $\partial\sigma/\partial u$, $\partial\sigma/\partial\epsilon$ will figure more frequently in what follows, referring to the tensile test, it will perhaps be useful to denote both slopes of the stress surface by short names. Corresponding to the meaning attributed to what is called in hydrodynamics the coefficient of viscosity, we may call the slope of the stress function

$$\frac{\partial \sigma}{\partial u} = \phi$$

the "coefficient of viscosity" of the material at the state ϵ, u, and perhaps in an analogous way the second slope

$$\frac{\partial \sigma}{\partial \epsilon} = \psi$$

the "coefficient of work hardening for tension." Both coefficients are thus defined for pure tension only; if this state of stress were to be changed in another, such as compression or pure shear, other values of ϕ and ψ would have to be used. In the hydrodynamics of viscous fluids the coefficient of viscosity η is defined by assuming that a shearing stress τ is produced by a rate of shear v in the planes in which it acts equal to $\tau = \eta v$. It can easily be shown that for non-compressible materials, the coefficient of viscosity for pure tension ϕ is three times that for pure shear, or

$$\phi = 3\eta$$

Now, recalling again what was said about the logarithmic law, Eq. [1], which according to observations would seem to express the relation existing between speed of strain or rate of flow u and stress σ for a limited range of the unit elongation ϵ, we may finally assume that the logarithmic relation may hold excepting in the case of extremely slow rates of flow, at least at lower temperatures. For extremely small values of u, however, the logarithmic curve may gradually change into a straight line, meeting the ϵ-axis at stresses σ which may be close to or be taken as equal to zero (law of true viscous flow). For small values of u, L. Prandtl[16] arrived at a similar conclusion when attempting to express the phenomenon of elastic hysteresis and other related effects by means of a special mechanical model of a solid, which at higher rates of flow also led him to the logarithmic law.[16]

6 *Speed Diagrams.* With regard to the use of curves which express the rate of flow $u = g(\epsilon)$ as a function of the unit elongation ϵ and which are the projections of the condition curves σ = const. or similar curves on a P, M, or p surface on the ϵ, u plane, a few remarks may be in order. If a point P is moving along a straight line, its position being given by $x = f(t)$, one may instead of plotting a second time diagram for its velocity $u = \dot{x} = df/dt$, eliminate the variable time parameter from both equations, thus drawing, for example, a *diagram of the speed* in the form:

$$u = g(x)$$

For a given law of motion $x = f(t)$ there will be a corresponding speed diagram obtained by eliminating the variable parameter t from both equations. In such speed diagrams certain rules must be observed. If $u > 0$, x must increase, and if $u < 0$, x must decrease. The speed diagrams possible to pass through a given point P of the plane with a positive ordinate u must therefore run with their directions as indicated by the arrows in Fig. 4, and if $u < 0$, as indicated at the point Q below. The speed diagram of a continuous motion in which u changes its sign must necessarily cross the x-axis at right angles and in the way indicated in Fig. 5. [An exceptional case may be that indicated by Fig. 5 (right) in which the path becomes tangent to the x-axis; in this case both $u = 0$ and $du/dt = 0$, that is, also the acceleration vanishes.] A path can never cross the axis in the manner indicated in Fig. 6. If a path crosses or intersects the x-axis at an obtuse angle α, Fig. 7, the moving point must come to rest at the intersection point A, but movements are only possible in the directions of the arrows. If the angle α is an acute one, the movements start from rest (B, Fig. 7, following the arrows). Simple harmonic motion has an ellipse for its speed diagram, and uniformly accelerated motion a parabolic speed diagram. A straight path in the speed diagram corresponds to a motion of the type

$$x = C_1 e^{ct}$$

These rules must apply also to the "speed diagrams of plastic tests" $u = d\epsilon/dt = g(\epsilon)$ in the ϵ, u-plane. For example, such "speed diagrams" would be the projections of the important curves P = const. of the second stress surface $\sigma_0 = H(\epsilon, u)$ on the ϵ, u-plane, which would indicate how the speed during a long-time or creep tensile test of a bar will change with its elongation under a constant load P, or when, after some preliminary stretching of a bar according to some rule, the load is held constant for a while or for the remaining time (plastic after-flow). None of these curves is permitted to cross the ϵ-axis at an angle. If such a thing does occur, that is, if, for example, stretching of a bar in one direction is reversed into compression, or vice versa, then the corresponding speed diagram in the ϵ, u-plane must cross the ϵ-axis at right angles.

IV—VISCOUS MATERIAL IN TENSION[17]

(*a*) The simplest case of plastic flow depending on speed of deformation is that in which the stress σ produced by stretching a bar is proportional to the rate of flow

$$\sigma = \phi \frac{\partial \epsilon}{\partial t} = \phi u \ldots\ldots\ldots\ldots\ldots\ldots [10]$$

the constant ϕ is the coefficient of viscosity for tension and $\phi = 3\eta$, where η is the coefficient of viscosity for shear. The equation of the stress surface is the one just given, from which is seen that in this case

$$\sigma = F(\epsilon, u) = \phi u \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

σ does not contain ϵ and is a plane passing through the ϵ-axis. We immediately find the load function according to Eq. [4]

[16] *Zeit. f. ang. Math. u. Mech.*, vol. 8 (1928), p. 85.

[17] In this connection the various attempts by H. Hencky [*Z.V.D.I.*, vol. 69 (1925), p. 695, and in other papers] in which he combined in general terms viscosity, plasticity, and elasticity, should be mentioned here. As Dr. Hencky has kindly brought to the attention of the author, interesting applications of the theory of viscous flow to the movements in solids (glacier ice) are due to Lagally, of Dresden.

$$\sigma_0 = \frac{\sigma}{1+\epsilon} = \frac{\phi u}{1+\epsilon} \quad \ldots\ldots\ldots\ldots\ldots [12]$$

which is in this case a hyperbolic paraboloid (Fig. 8).

This last equation also furnishes the law according to which the unit extension ϵ will change with time t under a constant load $P = A_0\sigma_0 = \text{const}$. Writing for $u = d\epsilon/\partial t$ and integrating (assuming $\sigma_0 = \text{const.}$),

$$\frac{d\epsilon}{1+\epsilon} = \frac{\sigma_0}{\phi}\, dt \quad \ldots\ldots\ldots\ldots\ldots [13]$$

ϵ is found from

$$1 + \epsilon = \frac{\sigma}{\sigma_0} = e^{\sigma_0 t/\phi} \quad \ldots\ldots\ldots\ldots\ldots [14]$$

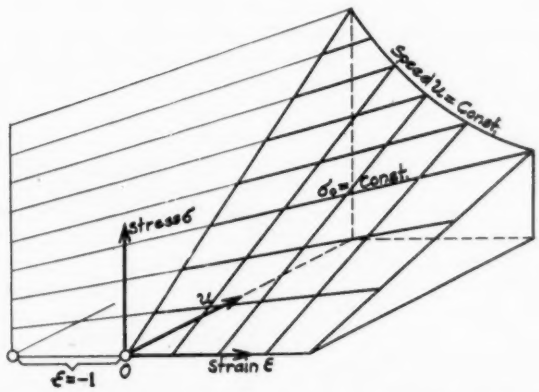

FIG. 8 SHOWING THE LOAD SURFACE $\sigma_0 = H(\epsilon, u)$ FOR VISCOUS FLOW TO BE HYPERBOLIC PARABOLOID

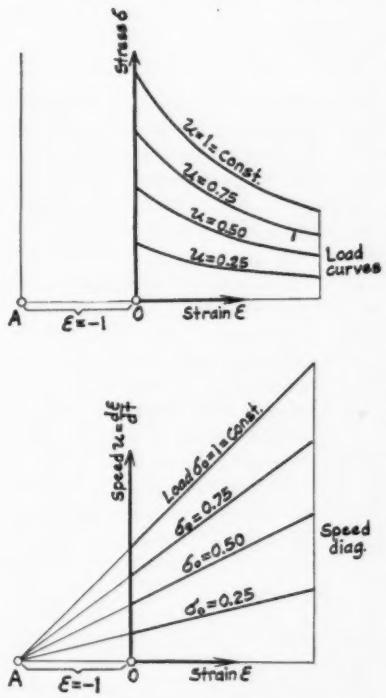
which is nothing but another expression of the simple rule mentioned above, namely, that if the "speed diagram" $u = f(\epsilon)$ is a straight line, the motion follows the exponential time law. Under a constant load the length of a bar of a viscous material will increase with the time according to an exponential function, and such a bar will always be in an unstable condition under any constant load, no matter how small. The rate of flow u will be proportional to the weight attached to the bar. This behavior is obvious on account of the continuously decreasing cross-section A of the bar, which will also change exponentially with the time:

$$A = A_0 e^{-\sigma_0 t/\phi} \quad \ldots\ldots\ldots\ldots\ldots [15]$$

Some of the characteristic curves for this case are as follows: the elongation-time curves are exponential functions; the stress-strain curves for uniform rate of flow are straight horizontal lines; the speed diagrams for constant load are a set of straight lines radiating from a common point (A, Fig. 10) with the abscissa $\epsilon = -1$; the load-elongation diagrams for constant rates of flow are equilateral hyperbolas having for their vertical asymptote the line $\epsilon = -1$. There are two sets of straight lines on the hyperbolic paraboloid, namely, the lines $\epsilon = \text{const.}$, having the equation



$$\sigma_0 = \left[\frac{\phi}{1+\epsilon}\right] u \quad \ldots\ldots\ldots\ldots\ldots [16]$$

where the term in the bracket is a constant, and the contour lines of the surface corresponding to constant loads or $\sigma_0 = \text{const.}$, namely,

$$u = \frac{\sigma_0}{\phi}(1+\epsilon) \quad \ldots\ldots\ldots\ldots\ldots [17]$$

Such a load surface, Eq. [3], is indicated in Figs. 8, 9, and 10.

(*b*) *Process of Necking of Bar.* Another consequence of the assumed laws for plastic flow of this kind would be that the slightest irregularity in the magnitudes of the cross-sections of a bar stressed under a constant load would finally cause the necking always to start at the smallest cross-section of the bar. It can readily be seen that if one of the cross-sections of the bar is slightly smaller than the others, the stresses will be correspondingly larger there. But as larger stresses must produce more rapid deformations, the smaller cross-sections will start to contract more rapidly than their larger neighbors, and thus necking will be localized more and more and accelerated at the place where it started. The necking process can easily be followed if the law of the variation of the original areas of cross-section is known and if the cross-sections do not change too rapidly along the bar.

FIGS. 9 AND 10 THE LOAD SURFACE $\sigma_0 = H(\epsilon, u)$ FOR VISCOUS FLOW REPRESENTED BY TWO PROJECTIONS

Let A be the variable cross-sectional area of the bar at the distance x and at the time t, and A^* be the original cross-sectional area at the same place and at the time $t = 0$ (Fig. 11). If the load P remains constant, then at any given distance x

$$P = A^*\sigma^* = A\sigma = \text{const.} \quad \ldots [18]$$

As each element dx of the bar will behave as one having a constant cross-sectional area, the areas A at a given distance x will change with time t according to Eq. [15], or

$$A = A^* e^{-\sigma^* t/\phi} \quad \ldots [19]$$

where σ^* designates the stress acting at the time $t = 0$. Replacing σ^* by P/A^*,

$$A = A^* e^{-Pt/\phi A^*} \quad \ldots\ldots\ldots\ldots [20]$$

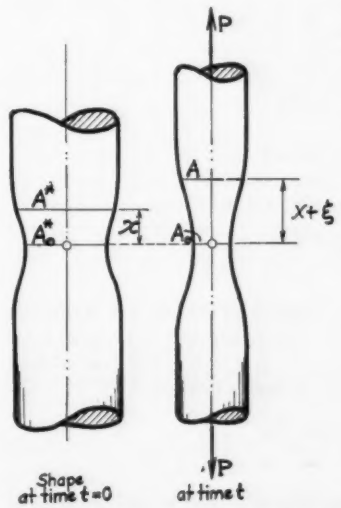


FIG. 11 NECKING OF BAR OF VISCOUS MATERIAL

which equation will determine how the cross-sectional areas A must change both with the distance x and the time t. In this last equation, the original cross-sectional areas A^* of the bar

must be given; A^* is a known function of x. In Appendix No. 1 it is briefly indicated how, for a given profile $A^* = f(x)$, the subsequent profiles of the bar at later times may be easily computed and thus the process of necking follows. Fig. 12 shows two stages of the necking of a bar in true scale after two equal time intervals t_0, assuming that the original profile of the bar was given in an interval $-a < x < a$ by an expression of the form:

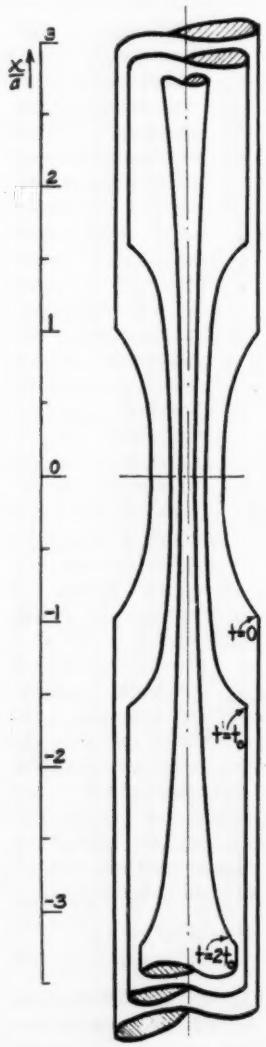

FIG. 12 THREE SHAPES TAKEN BY A BAR OF PURELY VISCOUS MATERIAL WHEN STRETCHED UNDER A CONSTANT LOAD

$$A = \frac{A_0^*}{1 - \beta^2 x^2/a^2} \quad \ldots [21]$$

where β, a, and A_0^* are constants and A_0^* is the minimum original cross-section of the neck. The widths shown refer to the *areas* (not to the diameters). After the minimum section is reduced to half of its former value, the bar stretches much more rapidly during the second time interval, producing a similar percentage decrease in section due to the increasing stresses in the necked portion.

(*c*) *Tensile Test With Constant or Varying Rate of Stress.* If a tensile test is conducted so that the stress σ uniformly increases with time t,

$$\sigma = wt \quad \ldots [22]$$

$$\frac{\partial \sigma}{\partial t} = w = \text{const} \quad \ldots [23]$$

The elongation-time curve is found from the tensile-stress surface

$$\sigma = F(\epsilon, u) = \phi u = \phi \frac{\partial \epsilon}{\partial t} \quad \ldots [24]$$

By equating Eq. [11] and Eq. [14]

$$\phi \frac{\partial \epsilon}{\partial t} = wt \quad \ldots [25]$$

from which

$$\epsilon = \frac{w}{2\phi} t^2 \quad \ldots [26]$$

assuming that for $t = 0$ the unit elongation ϵ is equal to zero: $t = 0$, $\epsilon = 0$. The rate of flow in such a test, or

$$u = \frac{\partial \epsilon}{\partial t} = \frac{w}{\phi} t \quad \ldots [27]$$

increases uniformly with time, and it is seen at once that for a viscous material a test in which the rate of stress w is constant produces uniformly increasing rates of flow u. Elimination of t from the expressions for σ and ϵ furnishes the equation of the stress-strain curves for constant rate of stress:

$$\sigma = \sqrt{2w\phi}\ \sqrt{\epsilon} \quad \ldots [28]$$

while elimination of t from the expressions for u and ϵ leads to the equation of the speed diagrams:

$$u = \sqrt{\frac{2w}{\phi}}\ \sqrt{\epsilon} \quad \ldots [29]$$

both of which curves are obviously ordinary parabolas (Fig. 13). If the rate of stress $\partial\sigma/\partial t$ is not constant, but σ is given as a function of time t,

$$\sigma = f(t) \quad \ldots [30]$$

then from

$$\sigma = \phi \frac{\partial \epsilon}{\partial t} = f(t), \qquad \epsilon = \frac{1}{\phi} \int_0^t \sigma dt \quad \ldots [31]$$

We may use these expressions also in the case of unloading. If, for example, a tensile test has been maintained under uniform rate of flow $u = u_1 = \text{const.}$ which produced the stress $\sigma_1 = \phi u_1$, and then the bar is unloaded under uniformly decreasing stress

$$\sigma = \sigma_1 \left(1 - \frac{t}{t_1}\right) \quad \ldots [32]$$

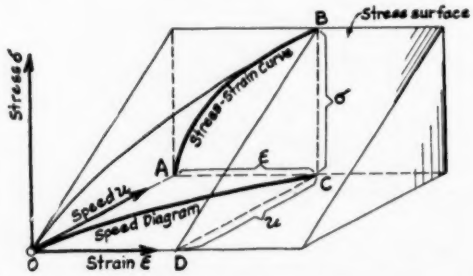

FIG. 13 STRESS-STRAIN CURVE AND SPEED DIAGRAM FOR A TENSILE TEST MADE ON VISCOUS MATERIAL AT A CONSTANT RATE OF STRESS

with the negative rate of stress $w = -\sigma_1/t_1$ then the unit elongations produced must be equal to

$$\epsilon = \epsilon_1 + \frac{\sigma_1(2t_1 - t)t}{2\phi t_1} \quad \ldots [33]$$

where ϵ_1 designates the value of ϵ for $t = 0$, at the instant from which unloading started.

From the last equation it follows that for $t = t_1$, when $\sigma = \sigma_1$, the *amount of after-flow*

$$\epsilon - \epsilon_1 = \frac{\sigma_1 t_1}{2\phi} = \frac{u_1 t_1}{2} \quad \ldots [34]$$

this is only *half* as much as the amount by which the bar would have yielded or crept during a time equal to the unloading time t_1 had the stress σ been kept constant and equal to σ_1.

If the bar is loaded at a slow but constant rate of stress and subsequently unloaded at the same rate, the resulting two branches of the stress-strain curve are congruent parabolas, thus enclosing half or—if the stresses are subsequently also reversed—a complete cycle of a hysteresis loop in the σ,ϵ-plane. The higher the speed w, the narrower become these loops. If the stress $\sigma = \sigma_0 \sin \omega t$ changes according to the harmonic motion, the corresponding hysteresis loops will be ellipses. Hitherto the elasticity in these loops of the material was not considered, but it can also be easily included, as will be indicated later.

V—CREEP IN PURE TORSION OR BENDING

In Appendix No. 2 a more detailed analysis of one of these cases, namely, the flow of a cylindrical bar subjected to torsion,

is given, assuming certain simplifications concerning the nature of the phenomena but an arbitrary law of plastic deformation, and including also the effect of speed upon these deformations. The case of torsion of a bar with a circular cross-section has been chosen as an example, but the basic considerations are essentially the same also for the case of pure bending of bars having simple cross-sectional shapes and a non-variable moment of inertia. The division of the total strain into an elastic and a permanent portion can also be considered, if necessary, but for the present this has been neglected. Other time effects, as the elastic after-effect or hysteresis, have, however to be treated by other assumptions.

Under the conditions stated in Appendix No. 2, a moment-torsion diagram may be constructed, if the stress surface

$$\tau = F(\gamma, v) \quad \ldots\ldots [35]$$

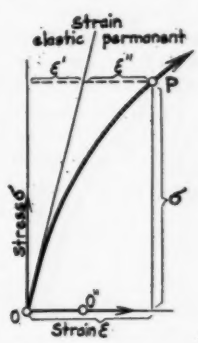
for pure shear is known and a condition curve is given which indicates how one of the variables τ, γ, or v shall change with time t. τ is the shearing stress in the bar, γ the unit shear, and $v = d\gamma/dt$ the rate of shear at a point distant r from the axis of the bar. A test conducted under certain conditions is represented by a certain section of the stress surface or a curve thereon. If, for example, a torsion test with a round bar is made by twisting it permanently at a uniform angular speed, then the section is a plane passing through the origin O (see Fig. 27) and perpendicular to the γ, v-plane, and this plane has to be rotated in a given manner. The values of τ will be given by the ordinates τ along this plane section, which will act along a radius of the circular cross-section of the bar.

VI—Resolving the Total Strain and Rate of Strain Into Their Elastic and Permanent Parts

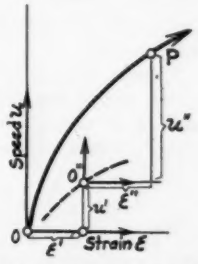
At larger permanent deformations produced by plastic flow the part of the total strain ϵ' which is elastic and will disappear as soon as the bodies are unloaded, is small compared to the total strain. In many cases it will therefore not be necessary to consider this part at all. If the permanent strains ϵ'', however, are comparable with the elastic strains ϵ', there is no justification in neglecting the latter. Also when a body has been deformed to a greater extent, it will in certain cases be necessary to take into consideration the elastic parts of the total strains. This is necessary, for example, if the system of residual stresses, which in general remains in a body unloaded from a non-homogeneous plastic state of stress, is to be determined. Another important case is that of the initial creep of a metallic piece at a comparatively low temperature, where creep has just slowly started, but has not yet had time enough to develop farther. This is perhaps the case in most of the design problems which depend on creep rates. On closer examination, it may become difficult to state more exactly which part of the strain at a given load is the elastic and which the plastic part, because of the well-known fact that for many materials there does not exist a distinct purely elastic state of stress and for them loading and unloading curves—if plastic yielding is excluded—may differ to a considerable extent (elastic hysteresis).

Excluding again similar cases of elastic after-effects, one may assume as a first approximation that the total strain ϵ is the sum of an elastic portion ϵ' and a permanent portion ϵ''. With regard to the elastic portion ϵ' one may assume that this depends only on the *actual* values of the stress σ (and not, for example, on the previous history of stressing, etc.), using the linear relation $\epsilon' = \sigma/E$, where E is the modulus of elasticity

$$\epsilon = \epsilon' + \epsilon'' = \frac{\sigma}{E} + \epsilon'' \quad \ldots\ldots [36]$$



Differentiating,



$$\frac{\partial \epsilon}{\partial t} = \frac{\partial \epsilon'}{\partial t} + \frac{\partial \epsilon''}{\partial t} = \frac{1}{E}\frac{\partial \sigma}{\partial t} + \frac{\partial \epsilon''}{\partial t} \quad \ldots\ldots [37]$$

Using again the notations $u = \partial\epsilon/\partial t$ and $w = \partial\sigma/\partial t$ for rates of strain and of stress, this last equation may also be written in the form:

$$u = u' + u'' = \frac{w}{E} + u'' \quad \ldots\ldots [38]$$

Assuming now certain laws, regarding the dependence of stress on the rate of flow u'' or on previous strain ϵ'' (work hardening), and that a condition curve in some form is known, we see that while such a condition curve in the ϵ,u,σ-space is described, the origin O from which the total strains ϵ and total rates of flow $u = \partial\epsilon/\partial t$ were measured remains at rest, and that a second origin O'' (Figs. 14 and 15) in the ϵ,u-plane must exist, the rectangular coordinates of which are the elastic strain ϵ' and the elastic rate of strain u' (Fig. 15). This second origin O'' will start in general to move in the ϵ,u-plane as soon as the point P moves along a given condition curve OP. To find the permanent strains ϵ'' or the permanent rates of flow $u'' = \partial\epsilon''/\partial t$, we shall have to define them as the *relative coordinates* of the moving point P with respect to the moving axes ϵ'' and u'' in this system ϵ'',u'' with the origin O''.

FIGS. 14 AND 15 ELASTIC AND PERMANENT PARTS OF STRAIN ϵ AND SPEED OF STRAIN u

This being established, we may now essay to follow in a few simple cases these relative movements in detail. Before doing so, however, it should be recalled that all this refers only to the parallel translation of axes, that is, assuming *no rotation of the stress vector σ relative to the stressed body.* If the stress vector σ rotated relatively to the body under plastic flow, conditions may become different. This interesting and more difficult case may be treated on a later occasion.

The shape of the curve described by the second origin O'' (from which the permanent strains and rates of strain have to be measured) will depend on how the stress σ varies or how the rate of stress $w = \partial\sigma/\partial t$ changes with the time. If this is known,

$$\sigma = f(t), \qquad w = \frac{\partial \sigma}{\partial t} = \frac{df}{dt} \quad \ldots\ldots [39]$$

the coordinates ϵ' and u' of the origin O'' are given by

$$\epsilon' = \frac{\sigma}{E}, \qquad u' = \frac{1}{E}\frac{\partial \sigma}{\partial t} = \frac{w}{E} \quad \ldots\ldots [40]$$

In general, however, σ will not be directly known as a function of the time t. The coordinate transformation:

$$\left.\begin{aligned} \epsilon &= \epsilon' + \epsilon'' = \frac{\sigma}{E} + \epsilon'' \\ u &= u' + u'' = \frac{w}{E} + u'' \end{aligned}\right\} \quad \ldots\ldots [41]$$

by which the total strains are connected to the permanent strains, indicates that the coordinates u may at certain points undergo discontinuous changes. This is important to note, because in the ordinary testing of materials it is a very frequent thing to change suddenly the speeds of deformation. If one associates the permanent part of the rate of strain with the stress, it will always require a certain time before a stress will adjust itself to a new rate of strain. What continuously changes is, in most cases, the permanent rate of strain u''. If the rate of stress w suddenly changes from w_1 to w_2, that is, if the time curve for the stress $\sigma = f(t)$ has a break of the tangent, the total rate of strain u will jump by an amount

$$u_2 - u_1 = \frac{w_2 - w_1}{E} \quad [42]$$

while the permanent rates u'' which are associated with the stress will still change continuously. We see, therefore, that in the speed diagrams where the total rates of flow u are shown depending on the total strain ϵ, discontinuities are permissible, and *it will be even necessary to introduce discontinuities* of u each time when the stress rate jumps or changes abruptly.

From the foregoing is seen that, for example, when the stress σ = const. ("after-flow or creep" under constant stress), the point O'' will move along the ϵ-axis, as u' remains zero. If, however, the rate of flow is kept uniform, u = const., and the bar is stretched with a uniform speed, then along the path, $\partial u/\partial t = 0$ and $w = \psi u$, hence

$$\epsilon' = \frac{\sigma}{E}, \qquad u' = \psi \frac{u}{E} \quad [43]$$

the rate of stress w is proportional to the rate of flow u, the proportionality factor being the coefficient of strain hardening $\psi = \partial\sigma/\partial\epsilon$.

Viscous Body Having Elasticity. This is characterized by an elastic part of the strain $\epsilon' = \sigma/E$ and by assuming that the rate of flow $u'' = \partial\epsilon''/\partial t$ of the plastic part is proportional to the stress $\sigma = \phi u''$. We have thus first

$$\epsilon = \frac{\sigma}{E} + \epsilon'' \quad [44]$$

and by differentiating this with respect to the time, we obtain

$$\frac{\partial\epsilon}{\partial t} = \frac{1}{E}\frac{\partial\sigma}{\partial t} + \frac{\partial\epsilon''}{\partial t} \quad [45]$$

where $\partial\epsilon''/\partial t = \sigma/\phi$. Hence

$$\frac{\partial\epsilon}{\partial t} = \frac{1}{E}\frac{\partial\sigma}{\partial t} + \frac{\sigma}{\phi} \quad [46]$$

Exactly this equation has been suggested by J. C. Maxwell describing the phenomena of relaxation.[18] Maxwell's law of deformation refers thus to a viscous body with perfect elasticity.[19] It is perhaps of interest to interpret this law of deformation, using the stress surface. Here this may be considered defined not for the *total* strains ϵ but for the permanent strains ϵ'' by the fundamental equation expressing the law of viscous flow:

$$\sigma = \phi u'' = \phi \frac{\partial\epsilon''}{\partial t} = F_1(\epsilon'', u'') \quad [47]$$

The stress surface for the permanent strains is thus given as an inclined plane containing the ϵ-axis. This equation of the stress surface has to be combined with the other equation

$$\epsilon = \frac{\sigma}{E} + \epsilon'' \quad [48]$$

A few examples may give simple applications.

1 *Constant Rate of Flow.* A test starting from rest with a constant rate of flow $u = u_1$ = const. is given by

$$\epsilon = u_1 t = \frac{\sigma}{E} + \epsilon'' \quad [49]$$

Replacing σ by

$$\sigma = \phi \frac{d\epsilon''}{dt} \quad [50]$$

we obtain the following differential equation for the permanent strain ϵ'':

$$\frac{\phi}{E}\frac{d\epsilon''}{dt} + \epsilon'' = u_1 t \quad [51]$$

from which

$$\epsilon'' = u_1 t - \frac{\phi}{E} u_1 + ce^{-Et/\phi} \quad [52]$$

The sum of the second and third terms of [52] is just equal to $-\epsilon'$. Assuming that for $t = \infty$ the elastic part of the strain $\epsilon' = \epsilon_1 = \phi u_1/E$ when $\sigma = \sigma_1$, we obtain finally

for the elastic strain $\epsilon' = \epsilon_1(1 - e^{-Et/\phi})$ [53]

for the stress $\sigma = \sigma_1(1 - e^{-Et/\phi})$ [54]

for the permanent strain $\epsilon'' = \epsilon - \epsilon'$ [55]

Replacing t by ϵ_1/u_1 and $\phi u_1/E$ by ϵ_1 from [55],

$$\sigma = \sigma_1(1 - e^{-\epsilon/\epsilon_1}) \quad [56]$$

Obviously this is *the equation of a "stress-strain diagram taken under a uniform rate of stress"* $u = u_1 = const.$ The stress curves for various speeds $u_1 = E\epsilon_1/\phi$ are exponential curves, tangent to an inclined line OA (Fig. 16) through the origin O, having the slope $(d\sigma/d\epsilon)_0 = E$, and approach rapidly the horizontal asymptotes $\sigma = \sigma_1$. The orbit of the second origin O'' having the coordinates ϵ' and u' in the ϵ,u-plane (Fig. 17), where

$$\left.\begin{aligned} \epsilon' &= \epsilon_1(1 - e^{-Et/\phi}) \\ u' &= \frac{\epsilon_1 E}{\phi} e^{-Et/\phi} \end{aligned}\right\} \quad [57]$$

is here the straight line $\overline{BC}$ with the equation

$$\epsilon' = \epsilon_1 - \frac{\phi}{E} u' \quad [58]$$

[18] H. Jeffreys distinguishes between two kinds of imperfections in the elastic behavior of matter. One is expressed by $\tau = G(\gamma + t_0\dot{\gamma})$, and the other by $\dot{\gamma} = \dot{\tau}/G + \tau/\eta$. The first is the classical expression of an elastic restoring force and a damping force as introduced in the ordinary theory of damped vibrations; the second expresses Maxwell's law of deformation. Jeffreys calls the first modes of imperfections "firmoviscosity," and the second ones "elasticoviscosity." (See "Earth . . .," p. 263.) He also calls attention to the fact that the theory of the first kind of imperfections for small deformations consists in simply replacing in the equation of "perfect elasticity," $\tau = G\gamma$, the elastic constant (the modulus of rigidity) G by a functional operator, namely, $G(1 + t_0\, d/dt)$, and that similarly in the case of elasticoviscous imperfections the constant G has to be replaced by the operator

$$G\left[1 + \frac{1}{t_1 d/dt}\right]$$

[19] Compare also the instructive detailed review of the phenomena of the elastic after-effect in the excellent articles by H. Fromm in "Handbuch der physikalischen und technischen Mechanik," vol. iv, 1, part 2, p. 533, Leipzig, 1931.

2 *Sudden Changes of Rate of Flow* must be accompanied by corresponding changes of the stress, which latter, however, will require a certain time for their development. The curve in the stress-strain diagram will be shifted up or down if the rate of flow is increased or decreased suddenly as indicated in Fig. 18. The jumps are exponential curves with a slope given by the elastic modulus of the material $d\sigma/d\epsilon = E$ at the point where the speed of stretching changes discontinuously.

3 *Rate of Stress Given. Hysteresis Due to Yielding.* Assuming any given time law, according to which the stress is changed, namely,

$$\sigma = f(t) \quad \ldots\ldots [59]$$

we may easily determine the corresponding curves

$$\sigma = F(\epsilon) \quad \ldots\ldots [60]$$

For example, loading under constant rates of stress w = const., including now also the elastic deformation, will again yield parabolas as stress-strain curves (Fig. 19). The difference between this and the similar case first treated (see Sec. IV-*c*) is now that all loading curves and parabolas will be tangent to a straight line having the slope $d\sigma/d\epsilon = E$ given by the elastic modulus E of the material in agreement with experiments (Fig. 19). An arc of a loading curve, assuming $\sigma = wt$ uniformly increasing with time or for a constant rate of stress w, will be given by the equation

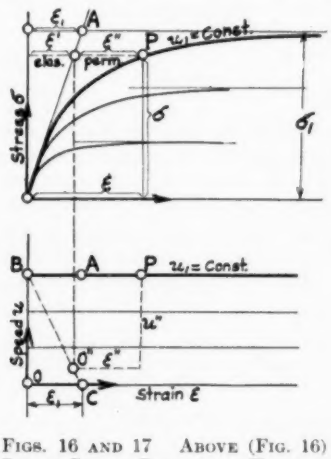
$$\epsilon = \frac{\sigma}{E} + \frac{\sigma^2}{2\phi w} \quad \ldots\ldots [61]$$

the speed of stretching by

$$u = \frac{w}{E} + \frac{\sigma}{\phi} \quad \ldots\ldots [62]$$

and the speed-strain relation by

$$\epsilon = \frac{\phi}{E}\left(u - \frac{w}{E}\right) + \frac{\phi}{2w}\left(u - \frac{w}{E}\right)^2 \quad \ldots\ldots [63]$$



An arc of an unloading curve under the same circumstances is given by:

$$\epsilon = \epsilon_1 - \frac{\sigma_1 - \sigma}{E} + \frac{\sigma_1^2 - \sigma^2}{2\phi w} \quad \ldots\ldots [64]$$

$$u = -\frac{w}{E} + \frac{\sigma}{\phi} = u_1 - \frac{\sigma_1 - \sigma}{\phi} \quad \ldots\ldots [65]$$

where ϵ_1, u_1, σ_1 refer to the initial state and $\sigma = \sigma_1 - wt$. That yielding or the production of a permanent strain or deformation requires a finite time for its development while an elastic strain may instantaneously be changed, will now find its adequate expression: All loading or unloading curves $\sigma = F(\epsilon)$ will have their tangents at the points where they pass through the ϵ-axis inclined under the slope given by $d\sigma/d\epsilon = E$. For constant rates of stress (w = const.) hysteresis loops will be obtained, such as those indicated in the Figs. 20–23. Their arcs are all parabolas, the axes of the loops in the σ, ϵ-plane being now inclined as required under a slope = E. The quicker a test is made, the slenderer the loop will become. The figures show three loops corresponding to speeds changing in the ratio 1:2:4. From the point of view of a clear analysis of these loading and unloading curves, it must be noted that the "corresponding speed diagrams" for these hysteresis loops will have discontinuities. After the loading under constant rate of stress w is reversed into unloading with the rate $-w$, the rate of stress jumps at the point of inversion. Consequently the total rate of flow must also jump discontinuously and by a corresponding amount, equal to $2u_0 = 2w/E$. This is indicated by the shifting of one-half of the loop with respect to the other half in the lower part of Figs. 20, 21, which indicates the shape of the speed diagram for the first example, or a projection of the hysteresis loop on the ϵ, u-plane. In this case the origins O'' move first on a parallel line $u = u_0$ = const. in Fig. 21 for one sense of the movement, and return on a second parallel line $u = -u_0$ for the reversed sense. A check for the preceding statements is that these two arcs in the plane of Fig. 21 become exactly perpendicular to the ϵ-axis at the two points where they cross this axis, in correspondence with the rules, which were established for speed diagrams. These arcs are also parabolas. The loops can be drawn by means of their tangents, as is indicated by the light lines in the Figs. 20–23.

In Fig. 24 another case is shown in which the stress changes according to a harmonic function of the time $\sigma = \sigma_0 \sin \omega t$; the corresponding "stress-strain curve" is now an ellipse, tangent to an oblique direction having an angle of inclination given by E. These tangents together with the horizontal ones are parallel to a pair of conjugate diameters of the ellipse. The higher the speed, the narrower becomes the ellipse. In the ϵ, u-plane a continuous diagram now appears as an ellipse. If a cycle is described the point P travels along the ellipse while the point

O'' describes another and smaller ellipse, which in Fig. 25 is indicated by a broken line; the figures 1, 2, 3, . . . refer to corresponding positions of the points P and O'', thus showing respectively the elastic and plastic portions of the strains and the rate of strain.

4 *Relaxation.* As already mentioned, the phenomenon of relaxation of stress is a particular consequence of the plastic properties of solids and it manifests itself in numerous ways, due to various reasons to which it may be attributed. In the following, only the classical case of Maxwell's relaxation theory will be briefly reviewed. We may approach it by first stretching a bar at a given temperature according to one of the various condition curves described in the preceding sections. If the stretching is then interrupted and the length of the bar thereafter kept constant, we have for the following period of relaxation the condition that the *total strain* ϵ remains constant, or that

$$\epsilon = \epsilon' + \epsilon'' = \frac{\sigma}{E} + \epsilon'' = \epsilon_1 \dots\dots [66]$$

where ϵ_1 is the strain at the time $t = 0$ when the relaxation of stress begins. Let σ_1 be the stress at the same instant. Then, differentiating with respect to time,

$$\frac{d\epsilon}{dt} = \frac{d\epsilon'}{dt} + \frac{d\epsilon''}{dt} = 0 \dots\dots [67]$$

or

$$u = u' + u'' = 0 \dots\dots [68]$$

We see, therefore, that while there is no further rate of flow and the total speed of strain u vanishes, a process of relaxation of stress is still characterized by existing finite rates of elastic or plastic strain u' and u'' as the elastic part of the strain ϵ' will gradually be transformed into a permanent strain ϵ''.

Using now the law of viscous flow for the permanent part of the strain:

$$\sigma = \phi u'' = \phi \frac{d\epsilon''}{dt} \dots\dots [69]$$

we obtain from Equations [66] and [67]

$$\frac{1}{E}\frac{d\sigma}{dt} + \frac{\sigma}{\phi} = 0 \dots\dots [70]$$

or

$$\sigma = \sigma_1 e^{-Et/\phi} \dots\dots [71]$$

Stress, according to Maxwell's law of deformation, relaxes according to an exponential function of time, and the time t required for a given decrease of stress from a value σ_1 to a value σ is equal to

$$t = \frac{\phi}{E} \log_e \frac{\sigma_1}{\sigma} \dots\dots [72]$$

The more elastically rigid (E large) or the less viscous (ϕ or η small) a material is at a given temperature, the shorter will be the time of relaxation required for a given decrease of stress, and, on the contrary, the more elastic or the more viscous it is, the longer it will last, until stress vanishes. We see also that if such a relation would hold for the metallic materials, and there are certain reasons to believe that for extremely small rates of flow at least perhaps something similar may be not far from being true, the coefficient of viscosity η (or ϕ for tension) must decrease much more rapidly with increasing temperatures than the modulus of rigidity (or of elasticity). This is indeed well known for liquids or glasses (amorphous solids) because temperature seems to change the viscosities of liquids much more rapidly (according to exponential functions) than their volume elasticity (compressibility).

The idea of increasing the time of relaxation of a metallic bar exposed to an elevated temperature by allowing it to expand permanently against the contraction of additional elastic-spring members has been recently suggested by W. Barr and W. E. Bardgett[20] as a method for testing creep.

If a bar in tension be forced to creep while it is connected to a helical spring, the same formula would hold for an elastico-viscous material as that just derived, but with the difference that instead of the modulus of elasticity E of the bar, an "apparent modulus" of elasticity E would have to be applied, which would be given by:

$$E^* = \frac{E}{1 + cAE/l} \quad [73]$$

where E is the modulus of elasticity of the bar, A its area of cross-section, l the length, and c the spring constant of the helical spring. The time of relaxation would thus be increased in the proportion $E:E^*$ to

$$t = \left(1 + \frac{cAE}{l}\right)\frac{\phi}{E}\log_e\frac{\sigma_1}{\sigma} \quad [74]$$

where c will many times be larger than l/AE.[21]

It may be of interest here to note that it has been recently also suggested by W. Rohn[22] that creep of metals be tested by keeping the lengths of the bar as well as the stress constant, the creep being balanced against the thermal contraction due to decreasing temperature while the test is made. This is a somewhat different case of relaxation in which, however, primarily temperature is changed. It is well known that the elastic modulus as well as the thermal-expansion coefficient do change with temperature. From this it is seen that simple conditions in such a test will probably not be realized because at the same time at least three variables, namely, temperature, coefficient of thermal expansion, and the elastic modulus, are changing while creep occurs.

Summary

In the preceding, a number of idealized cases of plastic flow of a more or less simple nature have been reviewed with the primary intention of eliminating the effect of the speed of yielding on the other quantities to be observed when metallic bars are permanently stretched, twisted, or bent at normal or at elevated temperatures. Some of the main attempts to obtain or to derive quantitative results must be considered as of a preliminary nature until it has been sufficiently investigated, both theoretically as well as experimentally, whether such results can be established with a sufficient degree of exactness by using expressions in a finite form, or whether these results will have to be derived from differential relations connecting only the differentials of a path or a condition curve, to be integrated subsequently.

Acknowledgments

Acknowledgments are particularly due to Mr. P. G. McVetty, with whom during the last few years the questions referring to creep have been frequently discussed from various points of view. The author expresses further his indebtedness to Mr. L. W. Chubb, Director of the Research Laboratories of the Westinghouse Electric & Manufacturing Company in East Pittsburgh, and to Mr. R. E. Peterson, Manager of the Mechanics Division of that same company, for facilities afforded to him.

Appendix No. 1

Necking of a Bar of Viscous Material Under a Constant Load

Let P be the load. Let A be the variable cross-sectional area of the bar at the distance x and at the time t; A^* the original cross-sectional area at x for the time $t = 0$; A_0 the area at distance $x = 0$ and $t = 0$; and σ, σ^*, σ_0, σ_0^* the corresponding stresses [the asterisk refers to the original stage at time $t = 0$, the subscript zero to a given point ($x = 0$) of the bar—for example, the minimum section in the neck]. We then have

$$P = A^*\sigma^* = A\sigma \quad [75]$$

and as

$$A = A^*e^{-\sigma^* t/\phi} \quad [76]$$

$$A = A^*e^{-Pt/A^*\phi} \quad [77]$$

which shows how the cross-section A at a distance x will be changed with time t. For a numerical computation, it is convenient to introduce the ratios

$$k = A/A_0, \quad k^* = A^*/A^*_0 \quad [78]$$

The original profile of a bar will be thus given by the function k^* and this will depend only on x, while k will contain both x and t. Writing down now Eq. [77] for the minimum cross-section which shall be chosen at point $x = 0$, we must also have

$$A_0 = A_0^*e^{-Pt/A_0^*\phi} \quad [79]$$

It is convenient to introduce here the "time of half value" t_0. By this is to be understood the time at which the minimum area A_0 of the bar would neck down to half of its magnitude, so that for

$$\frac{A_0}{A_0^*} = \frac{1}{2} = e^{-\frac{Pt_0}{A_0^*\phi}} \quad [80]$$

we see that the half-value time t_0 is given by

$$t_0 = \phi\frac{A_0^*}{P}\log_e 2 = \frac{\phi}{\sigma_0^*}\log_e 2 = 0.693\frac{\phi}{\sigma_0^*} \quad [81]$$

We then have

$$A_0 = A_0^*e^{-\frac{t}{t_0}\log_e 2} \quad [82]$$

and

$$k = k^*e^{-\frac{(1-k^*)}{k^*}\frac{t}{t_0}} \quad [83]$$

---

[20] "An Accelerated Test for a Determination of the Limiting Creep Stress of Metals," *The Engineer*, vol. 153 (1932), p. 241.

[21] At the time $t = 0$ the sum of the elastic extensions for the bar and spring is

$$\Delta l_0 + \Delta L_0 = \frac{Pl}{AE} + cP_0$$

and similarly, at the time t

$$\Delta l + \Delta L = \Delta l_0 + \Delta L_0,$$

from which, by introducing the unit elongations $\epsilon = \Delta l/l = \epsilon' + \epsilon''$ and stresses $\sigma = P/A$ for the permanent strain,

$$\epsilon'' = \frac{\Delta l}{l} - \frac{\sigma}{E} = \frac{(\sigma_0 - \sigma)}{E}\left(1 + \frac{cAE}{l}\right)$$

is found. The derivative of ϵ'' with respect to time is thus found to be

$$u'' = -\left(1 + \frac{cAE}{l}\right)\frac{1}{E}\frac{d\sigma}{dt}$$

instead of the former expression $u'' = \frac{1}{E}\frac{d\sigma}{dt}$.

[22] Festschrift zum 70. Geburtstage von Dr.-Phil. Dr.-Ing. E. H. Wilhelm Heraeus. Hanau. Verlag von G. M. Albertis, Hofbuchhandlung Bruno Clauss, 1930, p. 80.

which last equation indicates how the original profile given by the function k^* of the variable x has changed into the new bar profiles given by k at the time t.

To find the location of the area A after the stretching, we have to compute the displacement ξ of this cross-section:

$$\xi = \int_0^x \epsilon dx \quad \ldots\ldots [84]$$

Between the unit elongations ϵ at the variable distance x and the cross-sectional areas, A we have the relation

$$1 + \epsilon = \frac{A^*}{A} = e^{Pt/A^*\phi} \quad \ldots\ldots [85]$$

which furnishes the new coordinate $x' = x + \xi$ at which the new cross-section A will be found at the time t:

$$x' = x + \xi = \int_0^x e^{Pt/A^*\phi}\, dx \quad \ldots\ldots [86]$$

The two expressions, Equations [83] and [86], for k and x' determine the new profile of the bar. As an example, the case was worked out of a bar having originally a symmetrically constrained portion with the profile

$$A^* = \frac{A_0^*}{1 - \beta^2 x^2/a^2} \quad \ldots\ldots [87]$$

Here A_0^* designates obviously the minimum original section occurring at $x = 0$, β is a constant and a is half of the length of the constrained portion. Making the substitution

$$c^2 = \frac{Pt}{A_0^*\phi} \quad \ldots\ldots [88]$$

we find that

$$x' = \int_0^x e^{\frac{Pt}{A_0^*\phi}\left(1 - \frac{\beta^2 x^2}{a^2}\right)} dx = e^{c^2} \int_0^x e^{-\frac{\beta^2 c^2 x^2}{a^2}} dx. \quad [89]$$

or by using z as a new variable for the integration

$$z = \beta c x/a \quad \ldots\ldots [90]$$

$$x' = e^{c^2} \frac{a}{\beta c} \int_0^z e^{-z^2} dz \quad \ldots\ldots [91]$$

the probability function

$$\phi(z) = \frac{2}{\pi} \int_0^z e^{-z^2} dz \quad \ldots\ldots [92]$$

$$x' = \frac{a e^{c^2} \sqrt{\pi}}{2c\beta} \phi(z) \quad \ldots\ldots [93]$$

The bar profiles for this case were computed with $\beta^2 = 1/2$ for the two times $t = t_0$ and $t = 2t_0$. The original profile of the bar was

$$A^* = \frac{A_0^*}{1 - x^2/2a^2} \quad \ldots\ldots [94]$$

It may be seen from Fig. 12, which contains the results of the computation, that while in the first time period equal to the half-value time t_0, the minimum section of the bar was decreased to half of its original magnitude and the constrained portion of length $2a$ was stretched by 60 per cent, during the following equal time period, which produced an equal proportional reduction of area at the neck, the constrained portion was stretched to 3.24 times its original length.

The following table shows how the shape of the bar has changed:

Original distance from neck:	$x = 0$	$0.25a$	$0.50a$	$0.75a$	1
Ratio of areas originally, at time $t = 0$	$A/A_0^* = 1$	1.03	1.14	1.39	2
Distance x' from neck at time $t = t_0$	$x' = 0$	..	0.98	1.41	1.60
Ratio of areas at time $t = t_0$	$A/A_0^* = 0.05$	..	0.65	0.92	1.65
Distance x' from neck at time $t = 2t_0$	$x' = 0$	0.94	1.89	2.65	3.24
Ratio of areas at time $t = 2t_0$	$A/A_0^* = 0.25$	0.28	0.37	0.61	1.36

Appendix No. 2

CREEP OF CYLINDRICAL BAR IN TORSION[23]

As a last application may be considered the case of a cylindrical bar which is twisted by a couple, assuming an arbitrary law of deformation.

Let r = distance of a point P of the bar from its axis (Fig. 26)
a = radius of the bar
t = time
ϕ = angle of twist per unit of length of the bar
$\omega = d\phi/dt$ = angular speed with which it is twisted
γ = unit shear at the distance r from the axis of the bar
$v = d\gamma/dt$ = rate of shear at distance r
τ = shearing stress at distance r
M = torque, and
$\tau_a\ \gamma_a\ v_a$ = quantities referring to the outer surface ($r = a$) of the bar.

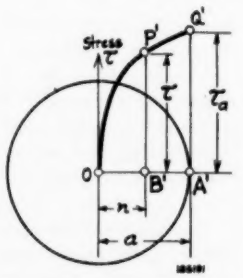

FIG. 26 TORSION SHEARING STRESSES [$\tau = f(r)$] IN ROUND BAR

As the case of plastic static torsion has already been treated by the author,[24] the following will refer to the influence of the speed of deformation only. All points in the interior of a round bar in torsion are subjected to similar states of stress, namely, pure shear. Due to the relative twist of two cross-sections of the bar a unit of length apart, unit shear γ is produced at the distance r from the axis which is equal to

$$\gamma = r\phi \quad \ldots\ldots [95]$$

This equation differentiated with respect to the time t gives

$$\dot{\gamma} = r\dot{\phi} \quad \ldots\ldots [96]$$

whence the rate of shear is found equal to

$$v = r\omega \quad \ldots\ldots [97]$$

A small element on the circumference of the circular cross-section ($r = a$) will deform with a rate of shear equal to

$$v_a = a\omega \quad \ldots\ldots [98]$$

while it will be distorted to a unit shear

$$\gamma_a = a\phi \quad \ldots\ldots [99]$$

[23] Creep tests in torsion with metals are described by R. W. Bailey (paper presented at Tokio World Power Conference, 1929), to whose work special reference is made. Cf. also Everett's paper already quoted.

[24] Trans. A.S.M.E., 1929.

From these equations, we see that at any time t

$$\frac{\gamma}{v} = \frac{\gamma_a}{v_a} = \frac{\phi}{\omega} \quad \ldots\ldots [100]$$

the rates of shear v in the bar are proportional to the unit shears γ. It will be assumed that for the state of pure shear a stress surface

$$\tau = F(\gamma,v) \quad \ldots\ldots [101]$$

is known. This function could perhaps be obtained from experiments made under constant angular speeds in a way similar to that by which the stress-strain curve for pure shear was derived from a static torsion test with a round bar. If a bar is twisted through an angle ϕ at an angular speed ω, the distorsion γ_a of a small element at a point A on the circumference $r = a$ of the bar will be known and given by [95] and the rate of shear v_a at the same points will be given by [97]. To these values of γ_a and v_a (Fig. 27) as abscissas will correspond a given shearing

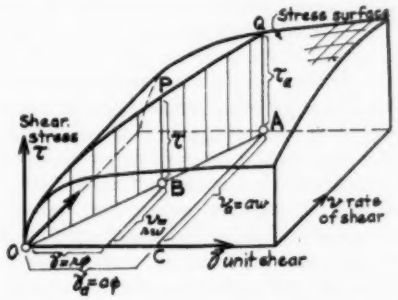

FIG. 27 STRESS SURFACE FOR PURE SHEAR

stress τ_a as the ordinate AQ in the stress surface [101]. Thus the maximum shearing stress τ_a acting in the point A' of the cross-section (Fig. 26) at the time t will be known. With this also the shearing stresses τ at any other point B' (Fig. 26) will be given, because at any point B' distant r from the axis of the bar, according to [95], [97], and [100] γ and v are known. Interpreting the variables γ and v as rectangular coordinates, Equation [100] or

$$\frac{\gamma}{v} = \frac{\gamma_a}{v_a} \quad \ldots\ldots [102]$$

is the equation of a plane passing through the origin O and the point A in the basic plane of the stress surface, Fig. 27. This plane evidently intersects this surface in a plane section, the ordinates of which represent the shearing stresses τ acting at the time t in the bar. The section $OBAQP$ of Fig. 27 has to be drawn over the radius $O'A' = a$ of Fig. 26, using the same ordinates τ but changing the scale in the horizontal direction in the proportion of the length $O'A':OA$. The equation of the section through the stress surface [101] is given by

$$\tau = F\left(\gamma, \frac{\gamma\omega}{\phi}\right) \quad \ldots\ldots [103]$$

and the torque M is thus given by the integral

$$M = 2\pi \int_0^a \tau r^2 dr = \frac{2\pi a^3}{\gamma_a^3} \int_0^{\gamma_a} F\left(\gamma, \frac{\gamma\omega}{\phi}\right) \gamma^2 d\gamma \ldots [104]$$

where the upper limit is

$$\gamma_a = a\phi \quad \ldots\ldots [105]$$

This is the moment required to twist a round bar by an angle ϕ and at an angular speed ω.

TORSION TESTS MADE AT A UNIFORM ANGULAR SPEED ω = CONST.

In this case the angle of twist of the round bar is

$$\phi = \omega t \quad \ldots\ldots [106]$$

At a time t the unit shear γ_a at the circumference $r = a$ of a section will be

$$\gamma_a = a\omega t \quad \ldots\ldots [107]$$

and the rate of shear at this point (represented by AC in Fig. 27) will be given by

$$v_a = a\omega = \gamma_a/t \quad \ldots\ldots [108]$$

If now ω = const., the rate of shear v_a will also be v_a = const. and the unit shear $\gamma_a = v_a t$ will increase uniformly with the time. This means that the vertical section $OAQO$ through the stress surface will have to be turned around point O so that point A describes a line AE parallel to the γ-axis. To obtain subsequent distributions of stresses $\tau = f(r)$ in the bar for various angles of twist $\phi = \omega t$, the vertical section $OAQP$ (Fig. 27) which cuts this distribution out from the stress surface $\tau = F(\gamma v)$ has to be turned around the origin in such a way that its end point A moves along the straight line v_a = const. or along AE with uniform speed. Reducing these sections (in the horizontal direction always) to the length $O'A' = a$ of Fig. 26 furnishes the various stress curves $\tau = f(r)$ above the radii r, and the corresponding torques M according to Eq. [104]. A torsion test made under a uniform angular speed thus produces a maximum uniform rate of shear v_a = const. at the circumference of the cross-section of the bar.

These relations may be applied to forms of the stress surface which are expressible by analytical means, such as power functions or others, or are known by graghs. If the influence of the speed of deformation could perhaps be expressed by a stress function of the form

$$\tau = \tau_0(1 + \eta v) \quad \ldots\ldots [109]$$

where τ_0 would depend only on the unit shear γ, but not on the rate of shear v:

$$\tau_0 = f(\gamma) \quad \ldots\ldots [110]$$

then a torsion test made by twisting a round bar at a uniform angular speed ω = const. could produce a rate of shear v at any point distant r from the axis, which would be equal to

$$v = \frac{v_a}{\gamma_a}\gamma = \frac{\omega}{\phi}\gamma \quad \ldots\ldots [111]$$

Hence along the section of the stress surface [109] in which v would depend on γ as expressed by [111], the shearing stress τ would be

$$\tau = f(\gamma)\left[1 + \frac{\eta\omega}{\phi}\gamma\right] \quad \ldots\ldots [112]$$

and the corresponding torques would be equal to

$$M = 2\pi \int_0^a \tau r^2 dr = \frac{2\pi a^3}{\gamma_a^3} \int_0^{\gamma_a} \left[1 + \frac{\eta\omega}{\phi}\gamma\right] f(\gamma)\gamma^2 d\gamma. \quad [113]$$

or

$$M = \frac{2\pi a^3}{\gamma_a^3}\left[\int_0^{\gamma_a} f(\gamma)\gamma^2 d\gamma + \frac{\eta\omega}{\phi}\int_0^{\gamma_a} f(\gamma)\gamma^3 d\gamma\right]. \quad [114]$$

This can be written also in the form

$$M = M_0 + M_1 \ldots\ldots\ldots\ldots\ldots\ldots [115]$$

where M_0 designates the part obtained using the first term in the expression [114] of the torque M, and M_1 the remaining term. To both terms there could be attributed a simple physical meaning. The stress function $\tau_0 = f(\gamma)$ would be what could be called *the infinitely slow stress-strain diagram for pure shear.* The function $\tau_0 = f(\gamma)$ would express the fact that for the rate of shear here a finite diagram exists and the first portion M_0 in the expression [114] for the torque M,

$$M_0 = \frac{2\pi a^3}{\gamma_a{}^3} \int_0^{\gamma_a} f(\gamma)\gamma^2 d\gamma \ldots\ldots\ldots\ldots [116]$$

would be the "static torque," as derived from the static theory of torsion, corresponding to a maximum unit shear $\gamma_a = a\omega t$ or an angle of twist $\phi = \gamma_a/a = \omega t$. The second term in [114],

$$M_1 = \frac{2\pi a^3 \eta\omega}{\gamma_a{}^3\phi} \int_0^{\gamma_a} f(\gamma)\gamma^3 d\gamma \ldots\ldots\ldots\ldots [117]$$

would be the "correction due to the effect of speed of deformation" which would have to be added to M_0.

If, for example, the static stress-strain curve $\tau_0 = f(\gamma)$ for pure shear could be approximated by a power function[25] of γ:

$$\tau_0 = \tau_1 \left(\frac{\gamma}{\gamma_1}\right)^n, \quad (0 < n < 1) \ldots\ldots\ldots\ldots [118]$$

then the static torque required to twist a round bar to a maximum shearing stress τ_a would be equal to

$$M_0 = \frac{2\pi a^3 t_a}{n+3} \ldots\ldots\ldots\ldots\ldots\ldots [119]$$

and the actual torque M would be given by:

$$M = M_0 \left[1 + \frac{n+3}{n+4}\eta a\omega\right] \ldots\ldots\ldots\ldots [120]$$

In the well-known case of true viscous flow, which has been frequently considered in the literature,[26] neglecting the elasticity of the material, the stress surface $\tau = F(\epsilon, v)$ is a plane:

$$\tau = \eta v \ldots\ldots\ldots\ldots\ldots\ldots [121]$$

and for a torsion test made at a uniform angular speed ω = const. or with $v_a = a\omega$ = const.,

$$\tau_a = \eta v_a = a\eta\omega$$

the shearing stress τ is

$$\tau = \tau_a \frac{r}{a} = \eta\omega r \ldots\ldots\ldots\ldots\ldots\ldots [122]$$

and the torque

$$M = \frac{\pi\eta\omega a^4}{2} \ldots\ldots\ldots\ldots\ldots\ldots [123]$$

This would remain constant as the bar is twisted further with the uniform angular velocity ω = const., but would change proportionally to ω if ω assumed another value.

It is comparatively easy to derive analogous expressions using other laws of deformation, for example, for the case of a logarithmic law of speed, which will not be further considered here. We may also use the stress surface to solve or answer questions which refer to torsion tests made under a given torque M = const. This would perhaps be of some interest also, for various suggestions have been made recently to use the torsion test of a round bar in creep tests, keeping the torque constant. Analogous to what was said previously with reference to tensile tests made under constant loads, it is required now to plot the torques M which were obtained, for example, from torsion tests made under uniform rates of shear or uniform angular velocities ω = const., above the same coordinates γ and v used in the expression of the stress surface $\tau = F(\gamma, v)$. Thus a second surface and an M or torque surface would be obtained, and it would be necessary to study finally the shapes of the curves M = const. on this torque surface:

$$M = H(\gamma, v) \ldots\ldots\ldots\ldots\ldots\ldots [124]$$

The family of condition curves M = const. on this surface, that is, the contour lines thereof, as they appear in a projection on the base plane γ, v would describe the torsion tests made under a constant torque. It is intended to treat this subject on a later occasion in more detail, when more experimental evidence regarding the shape of actual stress surfaces may be available. It is obvious that constructing the M-surface for the torsion tests will be a somewhat more tedious process than introducing the simpler P-surface in the tension test, because the values of the torques can be obtained only by an integration process from the shearing stresses τ and conversely, deriving τ-values of observed torques or M-values may require a somewhat tedious process of differentiation. It has already been mentioned that the problem of creep in pure bending for a bar having a simple and uniform cross-section leads to quite an analogous or, in special cases, nearly identical theory to that which has been briefly indicated for the case of torsion of a round bar.

Discussion

MAYO D. HERSEY.[27] The author's method of representing creep phenomena by a series of ideally simplified limiting cases should be of considerable scientific and educational value. In a similar attempt of a less comprehensive scope it was shown how certain types of material might give an ellipse on the load vs. deformation diagram when the load is applied sinusoidally;[28] also a diagram was constructed indicating how certain phenomena would appear when the deformation is represented as a function of two variables, the applied load and the time elapsed.[29] It is interesting that the results of these various studies have so much in common when the underlying assumptions are so different.

R. G. STURM.[30] This paper, which presents a number of idealized cases of plastic flow, certainly aids in visualizing what might be taking place as a metal continues to deform under a sustained load.

Nearly all of the references mentioned by the author deal with creep at high temperatures. The fact that the temperatures were not the same complicates the processes of arriving

[25] This formula cannot be a correct expression of the stress for very small unit shears γ, because in this region it would correspond to an infinite modulus of shear. For a larger γ however, it may perhaps be used to obtain numerical data in the first approximation.

at some fundamental relations between creep, stress, time, temperature, etc. Creep tests on a number of metals, including copper, aluminum, steel, and monel metal, have been made at room temperature at the Aluminum Research Laboratories at New Kensington. In these tests creep in direct stress was measured on sheet and wire specimens, and creep in bending was measured on simple beams and constant-stress cantilevers. The results thus far obtained indicate that many metals will creep a very small but definite amount at very low stresses at room temperatures; also that creep continues for an indefinitely long period of time. In view of these indications it would seem that the determination of a limiting creep stress below which no creep occurs would depend upon the sensitivity of the measuring apparatus much the same as does the determination of the proportional limit.

The determination of the maximum limit of creep would also be very indefinite because, after a period of six years, specimens have been found to continue to deform. In view of the results of the tests made at room temperature and the great number of results of tests at high temperatures recently published, it would seem that the designation of creep should include not only the amount of creep in a definite period of time for various stresses, but also a factor representing the rate of change of creep at the end of this period of time. Such a definition of the creep characteristics of a metal would necessarily be of an arbitrary nature, but the values could be readily used by the designer and at the same time could be definitely determined in tests, and the results obtained by various investigators correlated. Just what values of time and creep should be used for defining the creep characteristics of materials cannot be definitely established until more information in regard to creep at a given temperature is available.

C. Richard Soderberg.[31] In the earlier investigation of the physical properties of materials under elevated temperatures, the existence of a stress-strain curve was tacitly assumed. A considerable amount of the information collected during the past ten years has been based on this fallacious assumption, with the result that much of it is worthless, particularly the results obtained by vaguely defined short-time tests. The long-time creep tests have yielded much valuable information, but when the results are judged in the light of the expense and effort applied, the overall efficiency of the work is disappointingly low.

It is not given to human beings to be able to carry out well-controlled laboratory tests extending over years; something invariably happens to spoil the continuity, and the point of view is continually changing. This does not mean that the efforts applied so far have been entirely wasted, but it is beginning to be understood that real progress on this subject will require fundamentally different methods.

[31] Turbine Apparatus Division Engineer, Westinghouse Elec. & Mfg. Co., Philadelphia, Pa. Mem. A.S.M.E.

The paper represents a valuable contribution in this respect. It will probably be criticized by many as academic and somewhat remote from the sphere of practical applications, but the writer is convinced that it represents the beginning of a rational treatment of the subject. It is only through efforts along the lines of systematic research suggested that we shall arrive at an understanding of the twilight region between the elastic and viscous behavior of our engineering materials.

At present there appears to be more uncertainty with regards to the most profitable methods of testing in high-temperature work than formerly. The short-time tensile test is admittedly of no value without control of the creep rate; the long-time creep test is entirely too cumbersome. The most promising method of approach appears to be tensile tests under high values of creep rates. The extrapolation to lower creep rates of immediate practical importance must be accomplished through empirical formulas of the type given by Equation [1].

The definite establishing of the stress-creep rate equation for our engineering material is thus one of the most important problems at the present time.

Author's Closure

As stated in the paper, details with reference to elastic after-effects have been intentionally omitted in what precedes, the investigation being confined to pure creep phenomena or to a few of the simplest imaginable relations existing between rates of flow and stresses, including also the action of elasticity. The author is aware of not having quoted work as far as this referred also to the elastic after-effects, and he acknowledges the remarks made by Dr. M. D. Hersey, indicating that similar relations were described by him under other assumptions as to the nature of these effects.

The observations to which Mr. R. G. Sturm refers, pointing to the extensive experimental work done at the Research Laboratories of the Aluminum Company in New Kensington on the creep of aluminum at normal temperature, are valuable because of the additional experimental evidence to which they point of the non-existence of the so-called creep limit for a metal such as aluminum when tested at temperatures at which recrystallization does not yet become appreciable.

The author appreciates the remarks by Mr. C. R. Soderberg. They seem to point to the demands of the designers of heavy machinery to have more reliable or simpler rules at their disposal when machine parts are to be built which will have to withstand prolonged stresses at elevated temperatures. Here, as in other similar cases, the gathering of information of an empirical nature has preceded other attempts. The value of the long-time creep test was, and still is, to furnish the first reliable data on which such considerations can be based. It can be hoped that the results of these tests in conjunction with a rational description of rules may help also sooner or later to pave the way for a simplification also of the technique of these tests.

Model Testing as Applied to Strength of Materials

By R. E. PETERSON,[1] EAST PITTSBURGH, PA.

This paper is primarily concerned with the effect of size on the ordinary strength properties of materials. The use of models in stress analysis is described briefly. The effect of size in tension, fatigue, and impact tests is considered in detail. Possible explanations for departure from the law of similarity are stated.

THIS paper is concerned primarily with the effect of size on the strength properties as determined from specimens and models tested to destruction. Models are, however, often used in the elastic range, particularly in the field of stress analysis. A few such applications will now be mentioned, but very briefly, since no problem of size effect exists so long as elastic conditions are maintained. Problems of plane stress can be solved photoelastically[2] by the use of models of transparent material (such as celluloid or bakelite) stressed in a field of polarized light. Statically indeterminate structures can be studied by means of the deformator method,[3] making use of celluloid or fine-quality cardboard. Based on the torsion analogy of Prandtl, a soap-film method[4] has been used to determine stress distributions of irregular sections in torsion. Rubber models also have been used with some success in studying stress concentration; a recent promising method[5] involves measurements at a series of deformations, the plotted results being extrapolated to zero deformation. The foregoing methods all apply to the elastic range of materials, and as previously mentioned, the size of the model has no effect on the results.

However, in the field of strength of materials where models are tested to destruction, it is necessary to consider carefully the effect of size on the ordinary strength properties of materials, such as ultimate strength, endurance limit, and impact value. Such information must necessarily form a basis for model testing, and is also of prime importance to designers and engineers concerned with specification of materials and standardization of tests.

The Tension Test

Under this category are considered all tests made at slow speed in the manner of the ordinary tensile test as performed in material-testing laboratories. The tensile-test specimens that have been standardized in various countries are of constant diameter over a gage length, free from stress-concentration effects. For such specimens the law of similarity was found to apply by Barba[6] and Kick.[7] A plot of some of the data of Barba is shown in Fig. 1. Confirmatory results have been obtained by Bauschinger,[8] Martens,[9] Rudeloff,[10] Moser,[11] and others. Compressive tests made under similar conditions by Kick, Bauschinger,[12] and others show agreement with the law of similarity. It would seem, therefore, that for slow loading of specimens free from stress concentration, the law of similarity holds for ordinary engineering materials.

An exception is apparently found in specimens of very small diameter. Wires are known to have a higher tensile strength than standard test specimens of the same material, but the effect of working is generally present. In considering the size effect, obviously variables due to cold working, quenching, surface finish, etc. must be avoided. However, very small-diameter glass fibers[13] have exhibited unusually high tensile strengths. High values also have been obtained for annealed silver and gold threads.[14] If, however, exceptionally small diameters are excluded and if in metallic specimens a large enough number of grains are present to produce a statistical effect (which conditions are generally fulfilled in engineering design), then the law of similarity may be considered to apply to the slow loading of tensile specimens free from stress-concentration effects.

The effect of size in tensile specimens having stress concentration effects (due to notches or other abrupt changes of contour) has not been thoroughly investigated. Results recently reported by Kuntze[15] indicate that for geometrically similar notched

tensile specimens, small sizes give higher ultimate strengths, as shown in Fig. 2. Kuntze makes use of an idea of Föppl[16] in attributing the phenomenon to an outer layer that acts in a manner different from that of the material inside, somewhat analogous to the phenomenon of capillarity. Kuntze also mentions the possibility of a critical amount of slipping, independent of size, which causes departure from the law of similarity if the number of slip planes is artificially limited, as in a notched specimen. The use of a sharp notch by Kuntze was somewhat unfortunate from the standpoint of geometrical similarity, since actually a microscopic rounding exists at the notch bottom. Recent tests by Dr. Nadai and Mr. MacGregor, of Westinghouse Research Laboratories, indicate no appreciable size effect for steel and aluminum specimens having notches with definite small radii at the notch bottom. It is expected that these data will be published during the forthcoming year.

THE FATIGUE TEST

Data on size effect in fatigue are very meager. Equipment has been developed for making fatigue tests of large specimens[17] up to $3^3/_{16}$ in. in diameter and of small specimens[18] down to 0.050 in. in diameter.

In testing size effect, it is essential that other variables are excluded, and hence the material must be uniform—a require-

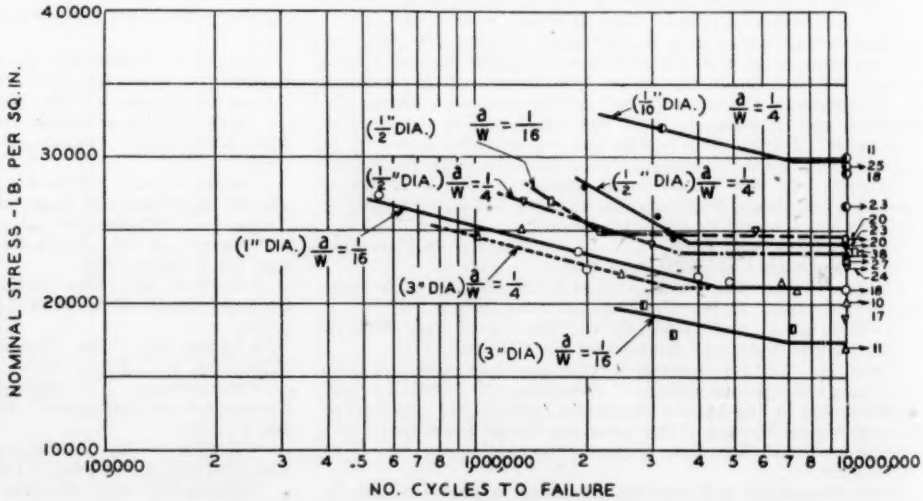

FIG. 4 FATIGUE DATA—SPECIMENS WITH HOLES
(0.45% C steel.)

ment difficult to meet and one that is perhaps of greater importance in dynamic tests. In the investigation of size effect in fatigue it was found necessary that specimens be made according to the following requirements: (1) Material near the outside of a bar or at the center of a bar should not be used as the surface of a test specimen. (2) Small specimens should be taken from the same portion of the bar as that used for the surface of the largest specimen. Thus if a specimen 2 in. in diameter is the largest of a series, the small specimens (say, 0.05 in. in diameter) should be taken from the bar at a radial distance of 1 in. from the center of the bar. (3) All specimens should be taken from the same bar, the ends of the bar not being used. (4) Hardness readings should be made on all specimens.

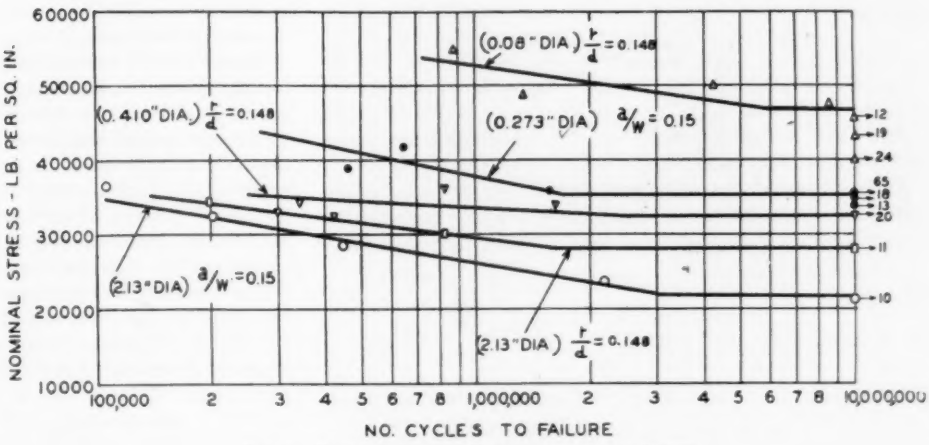

FIG. 6 FATIGUE DATA—FILLET AND HOLE TESTS
(0.57% C steel, heat treated.)

In testing fatigue specimens varying in diameter from 0.05 in. to 2 in., no important size effect was found[18] for the steels tested (carbon contents, 0.20, 0.42, 0.44, 0.57 per cent), as shown in Fig. 3. For cast iron widely scattered results were obtained with very small specimens,[18] which was not surprising, since the cast iron was unusually porous and flaky. Subsequent tests showed no size effect in larger sizes (Fig. 3). Mr. R. L. Templin states[19] that he has found no size effect in fatigue tests of cast aluminum alloys. Prof. H. F. Moore, assisted by Mr. Schorah, made fatigue tests of specimens of two different diameters and found no size effect[19] for medium carbon steel. For steels of low and high carbon contents a size effect was found. Further tests of this kind are necessary.

In the fatigue tests discussed up to this point, smooth contours without stress concentration were tested in each case. It is of practical importance to study the effect of size in fatigue tests where stress-concentration effects are present, since this is practically always the case in machines, due to the presence of fillets, holes, grooves, thread, keyways, notches, etc. The results of the following fatigue tests will be given in terms of stress-concentration factor[20] $k = s_e/s_e' =$ the ordinary endurance limit divided by the endurance limit of specimens having stress concentration.

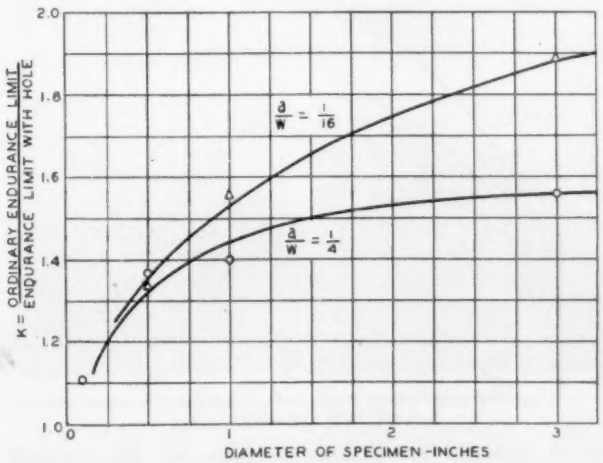

FIG. 5 FATIGUE STRESS CONCENTRATION FOR SPECIMENS WITH HOLES
(0.45% C steel.)

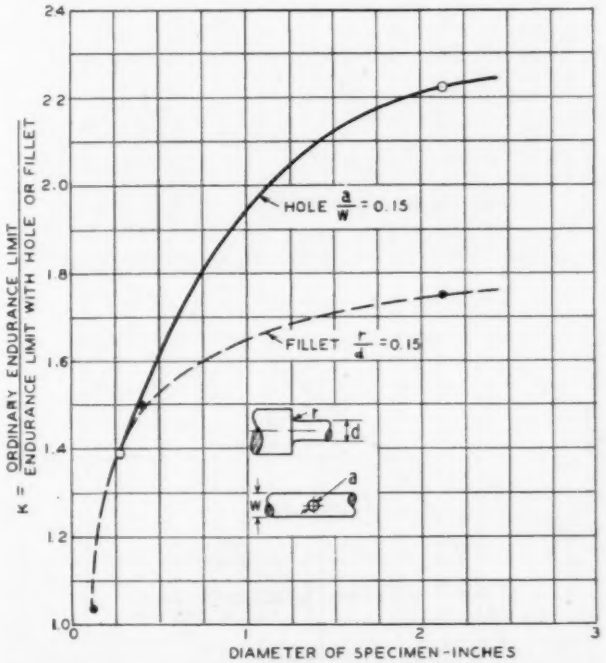

FIG. 7 FATIGUE STRESS CONCENTRATION FACTORS
[Fillet and hole tests (0.57% C steel, heat treated).]

Tests were made of the effect of holes in fatigue specimens of various diameters. The material used was an unusually clean medium carbon steel made under the supervision of Dr. C. H. Herty, Jr. The analysis in per cent: C, 0.45; Mn, 0.79; Si, 0.18; S, 0.032; P, 0.013. Mechanical properties: Yield point (0.2 per cent plastic deformation), 32,500 lb per sq in.; ultimate strength, 76,000 lb per sq in.; elongation (2 in.), 32 per cent; reduction of area, 50 per cent. The endurance limit was found to be 33,000 lb per sq in., the same for large and small specimens (Fig. 3). In investigating the size effect of specimens having holes, it is necessary to keep constant a/w = diameter of hole

[19] Private communication.

[20] Report of Research Committee on Fatigue of Metals (Appendix), "Present-Day Knowledge of Fatigue," Proc. Am. Soc. Test. Matls., vol. 30, Part I (1930), p. 298.

divided by diameter of specimen. This was done for two values $a/w = 1/4$ and $1/16$. In computing nominal stresses for the specimens having holes, the net section was used in the determination of the moment of inertia. From Fig. 4 it is apparent that the endurance limits for small specimens having holes are higher than for large specimens. The corresponding stress-concentrations factors are shown in Fig. 5.

Further test data for specimens having holes are summarized in Figs. 6 and 7, the material being 0.57 per cent carbon steel, heat treated.[18] For the same material, fatigue tests were made

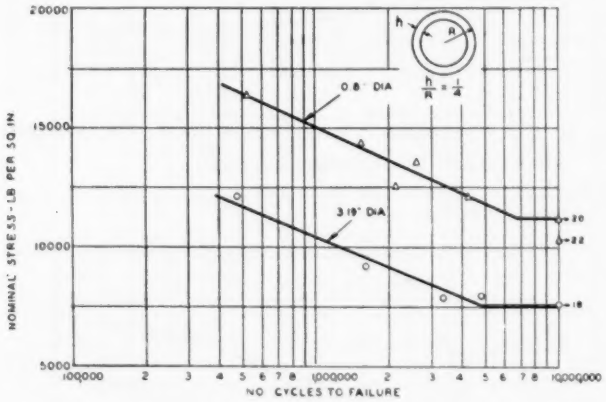

FIG. 8 FATIGUE DATA
[Specimens with circumferential cracks (0.44% C steel).]

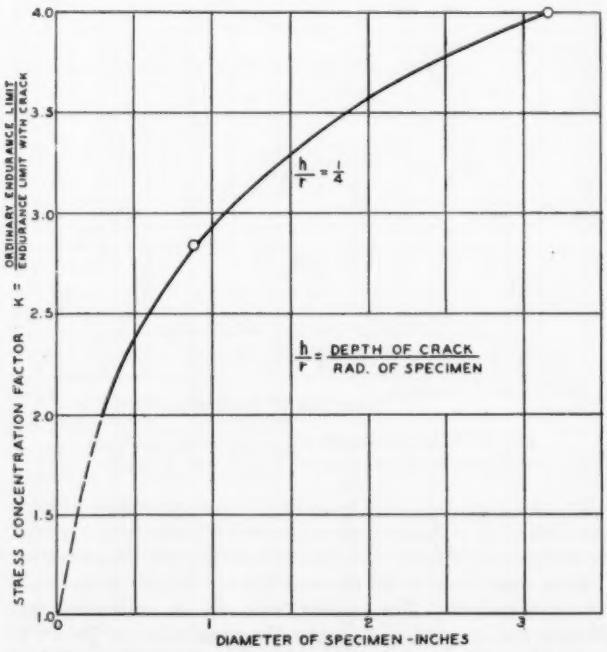

FIG 9 FATIGUE STRESS CONCENTRATION FACTORS FOR SPECIMENS HAVING ARTIFICIAL CRACKS
(0.44% C steel.)

of specimens having fillets with r/d = radius of fillet divided by diameter of specimen = 0.148. The results of the fillet tests are also given in Figs. 6 and 7.

The reason for the apparent size effect is not altogether clear. Different degrees of cold work due to the machining of different sized discontinuities may be an important variable affecting the results, particularly in the case of small discontinuities. Further possible reasons for departure from the law of similarity will be discussed in the closing section of the paper.

In order to test a severe case of stress concentration, specimens having artificial cracks were produced, the method being suggested by Mr. P. G. McVetty. A very narrow V-bottomed groove was turned in a round bar, which was heated and compressed axially to close the groove. The bar was subsequently annealed and machined into a test piece having a circumferential crack. Two series of such specimens were tested, 0.8 in. and $3^3/_{16}$ in. in diameter, with h/r = depth of crack divided by radius = $1/4$. The material was 0.44 per cent carbon steel.[18] The nominal stresses were computed using a moment of inertia based on the following assumptions: (1) Linear stress distribution, (2) crack carries compression, but not tension. The final results are summarized in Figs. 8 and 9. It is intended to present more details of these tests in a future publication, since in this paper only data bearing on size effect are given.

The size-effect tests of specimens having cracks may throw some light on corrosion-fatigue results with different diameter specimens reported by McAdam.[21] The corrosion-fatigue graph for large specimens 1.7 to 2.3 in. in diameter (250 to 400 rpm) was lower than the graph for small specimens $1/2$ in. in diameter (250 to 400 rpm), which in turn was lower than the graph for $1/2$-in. specimens (1450 rpm). Corrosion fatigue involves "notching," and consequently some similarity with crack tests might be expected. Evidence on hand indicates that deeper cracks have higher stress-concentration factors, in some such manner as shown in Fig. 10. If corrosion penetration does not depend on size, h/r would be different for the large and small specimens at slow speed (Fig. 10). The small specimen at high speed would have a lower stress-concentration factor because of reduced time for corrosive action. The results of McAdam line up in the same order as indicated in Fig. 10. The foregoing analysis would be more applicable in the case of prior-corrosion-fatigue tests, but may also have some bearing in corrosion-fatigue tests.

It is apparent from Figs. 5–10 that the stress-concentration

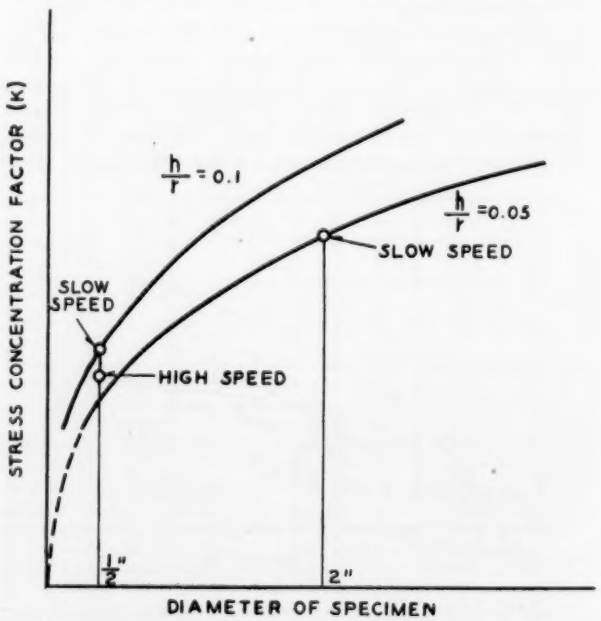

FIG. 10 POSSIBLE EXPLANATION OF CORROSION FATIGUE SIZE EFFECT

[21] McAdam, D. J., "Some Factors Involved in Corrosion and Corrosion Fatigue of Metals," Proc. Am. Soc. Test. Matls., vol. 28, Part II (1928), p. 117.

effect is less for small specimens (higher endurance strength). It is also of interest that in some cases the fatigue-stress-concentration factors for large specimens approach theoretical stress-concentration factors derived from the theory of elasticity.

The foregoing results have an important bearing on the interpretation of tests of models where fatigue is involved. This statement should not be interpreted as discouraging model tests. In many cases it is impractical to test an actual structure. A model properly made indicates the weakest section, reveals the type of fracture, and if properly interpreted gives an indication of the strength of the actual structure. In Fig. 11 is shown a torsional-fatigue model[22] of a crankshaft of an airplane engine. A fatigue model[23] of a turbo-generator rotor is shown in Fig. 12. Since the stress-concentration curves (Figs. 5, 7, 9) have a tendency to flatten out, it is important to make the models as large as the testing equipment permits.

The Impact Test

Of the common tests of materials, the impact test is perhaps the least understood from a fundamental point of view. Until the impact test can be correctly interpreted qualitatively, one cannot draw definite conclusions of a quantitative nature.

A study of impact tests of tensile specimens without notches was made by Körber and Sack,[24] who concluded that the law of similarity was applicable for tests of this type. The specimens were 5 mm and 10 mm in diameter and were made of steels varying in carbon content from 0.08 to 0.86 per cent. The weight of the hammer was 37.8 kg and the drop height 2.67 m. The striking velocity was 7.25 m per sec; a velocity of half this amount did not change the result appreciably.

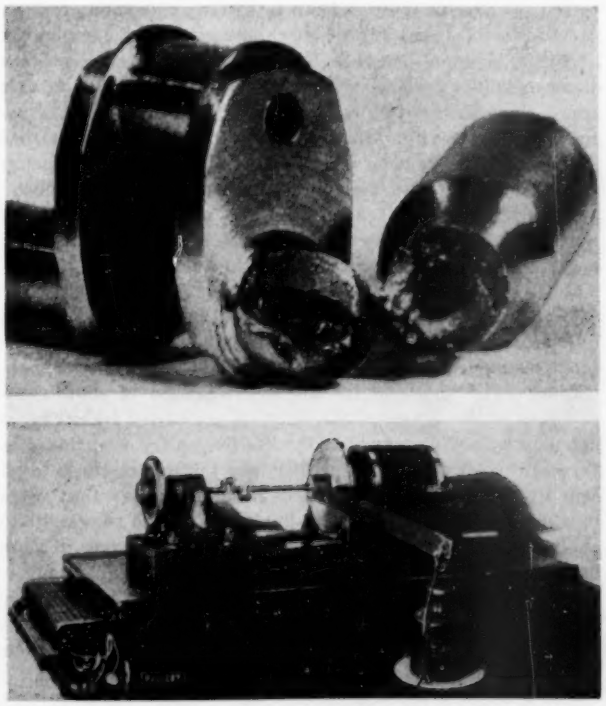

Fig. 11 Crankshaft Torsional Fatigue Model

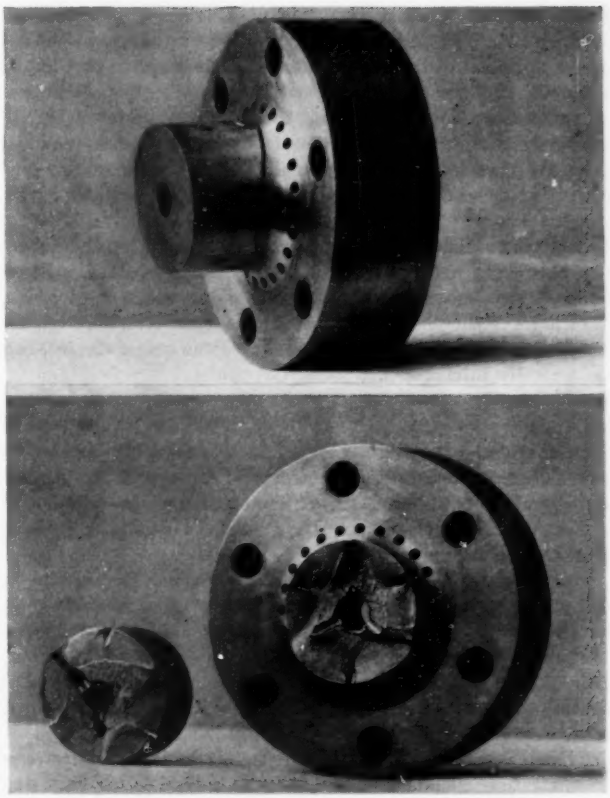

Fig. 12 Turbo-Generator Fatigue Model

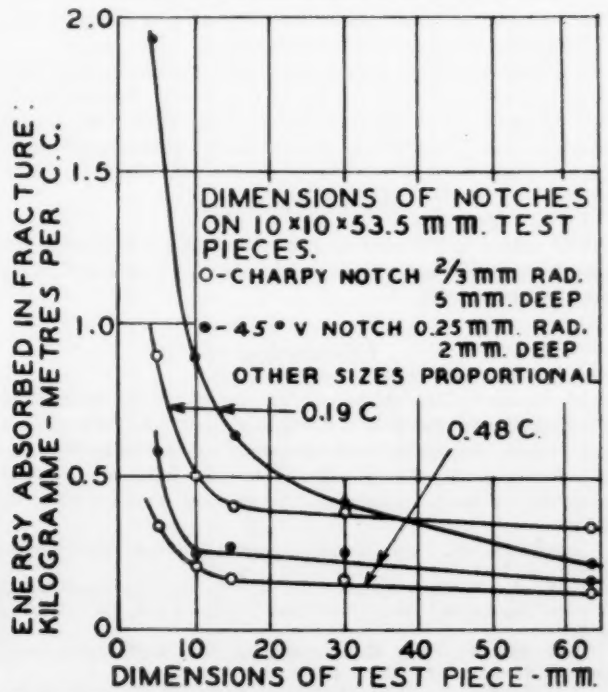

Fig. 13 Notched-Bar Tests on Similar Pieces (Stanton and Batson)

The impact tests as ordinarily performed makes use of notched-bar specimens of Charpy (simple-beam) or Izod (cantilever-beam) type. The notch introduces very marked stress concentration, which changes considerably the phenomena occurring in

[22] Matthaes, K., "Kurbelwellenbrüche und Werkstoffragen," *Luftfahrtforschung*, vol. 8 (1930), p. 91.

[24] Körber, F., and Sack, R. H., "Vergleichende statische und dynamische Zugversuche," Mitt. Kaiser Wilhelm Inst. für Eisenforschung, vol. 4 (1922), p. 11.

the impact test. It has been shown by Stribeck,[25] Stanton and Batson,[26] Moser,[11] and others that the law of similarity does not apply to notched-bar impact tests. The curves of Fig. 13 (Stanton and Batson) illustrate the wide variation of impact value with specimens of different size. The ordinates of Fig. 13 are work per unit volume, whereas if work per unit cross-sectional area is used as ordinates (as is usually done), the curves rise with increasing size of specimen. In either case, the law of similarity is not followed.

Moser[27] concluded that the work done should be divided by the plastically deformed volume. The work of Moser, Mailänder,[28] and other investigators has done much to increase knowledge of the phenomena taking place in notched-bar impact tests, but further research work must be done before the test can be correctly interpreted.

Conclusion

In considering the data covered in this paper it seems that where stress concentration is not present the results are in most cases independent of size. An extension of the law of similarity of Barba and Kick can apparently be made to include other fields than tension testing.

However, with stress concentration present, the results of dynamic tests are quite different. Smaller specimens tend in general to give higher values. The phenomenon has not been adequately explained. It was previously suggested that different degrees of cold work due to the machining of different sized discontinuities may be an important variable affecting the results, particularly in the case of small discontinuities.

There is some evidence that materials having small stress-concentration effect in fatigue are also materials having large internal damping,[29] and vice versa. This may have some bearing on the size-effect problem, since damping capacity is a volume phenomenon, and fracture is a plane phenomenon. The relation between these phenomena varies with size.

The effect of time[30] as reflected in the speed of testing is perhaps important where stress concentration is present. Two extremely slow fatigue tests of specimens having holes were started some time ago, but a long time is required before definite conclusions can be made.

Acknowledgments

The author is indebted to Drs. Nadai and Timoshenko for their interest and suggestions and to Mr. F. Cassel for carrying out the fatigue tests.

Discussion

M. Stone.[31] The subject of the use of models in fracture determinations in the field of strength of materials is of profound importance, because our test specimens are always models, the opportunity rarely being afforded to test full-size structural elements. If we consider what the designer relies on when he analyzes a structure to withstand certain loadings, we recognize two major categories of information: (1) Elastic analysis of stresses produced by forces. (2) Interpretation of stresses in terms of failure.

The first category has received by far the major attention, the work of several decades having investigated multitudinous types of stress loadings. The second category of information remains to a large extent unexplored, the reason being that it needs must be entirely experimental, which experiments are very laborious and costly. Suffice it to recall that simple tension tests for a long time remained the basis of material application, until the phenomena of fatigue was appreciated. Then this latter test was studied thoroughly as to complete variation in stress, and gradually supplemented by superposition of variable on steady stresses. But to extend the experimental information available for such cases to actual stress conditions requires a large jump that is now bridged by resorting to analysis, based on simple elastic theory. (See "Factor of Safety and Working Stresses," by C. R. Soderberg, Trans. A.S.M.E., 1930, APM-52-2.) That this type of information will be replaced by actual experimental information as it becomes crystallized is to be expected, but now our attention is drawn to the validity of the test information itself—the translation of tests on small models to the larger actual structures.

It is evident from the paper that laws governing size effect, in all but the simplest case of tension testing, have not been definitely established. But the writer should like to emphasize the value of the paper in forcing the attention of engineers to the problem. Much work can be and has been done in the experimental investigation of failure under given stress conditions without regard to size of test specimen, and hence is of doubtful value. One particular relation is being recognized now, and that is that stress concentration factors are larger as the specimen is larger. This is in some respects disappointing, since to be certain of the results, the specimens should be as large as possible, approaching the actual size of the structure in question. However, further research will have to be done to determine how the effect increases with size and where an ostensibly constant value is obtained. In the field of weld testing, the size effect is proving itself important, and as this is an active field of investigation, the writer should like to have the author supplement his forward-looking paper with reference to welding.

Dr.-Ing. A. Nadai.[32] The various questions and points raised concerning the model-testing methods as applied to the problems of strength of materials are quite important for many reasons. The analogies for the representation of solutions of problems of the theory of elasticity are considered by engineers, not only as useful means to visualize frequently occurring solutions of certain problems, but they may serve as methods to obtain by experiment numerical information in practical cases, in which it would be difficult or impossible to find the results by analytical methods. Further attempts to work out in more detail the conditions under which mechanical similarity may be attained, either in a test or by using a model, will be of great practical interest, and particularly also the cases will have to be discussed where a given model subjected to a test cannot well represent completely the behavior of the construction element for which it was suggested.

As far as the elastic-plastic equilibrium of metallic pieces is concerned and if fracture is first excluded, a few further remarks may perhaps be in order. If two bodies of the same material and of geometrically similar shape are subjected to the action of similar systems of external loads acting solely in the surface,

the condition of similarity of the two internal states of stress is simple. If the material was deformed in certain regions plastically, while the strains in the remaining parts of the two bodies are still purely elastic strains, the condition is simply that at corresponding points (that is, in points the coordinates of which are in the proportion $x : y : z = x' : y' : z'$) the components of stress or of unit strain must be equal in corresponding sections and directions. From this it follows that the resultant external loads acting on the two bodies must be proportional to the square of the ratio of the dimensions of the two bodies. Another very useful expression of the same fact facilitating comparison is that in the case of mechanical similarity the two pictures of the lines of principal stress must consist of two geometrically similar triple families of curves. Thus the elastic-plastic states of stress produced by compressing a set of hard, rigid balls having diameters d_1, d_2, d_3. . ., into a soft metal will be similar if the forces will be chosen according to $P_1 : P_2 : P_3 : \ldots = d_1^2 : d_2^2 : d_3^2 : \ldots$. This is the law of similarity of Barba-Kick. This rule may easily be generalized to include also the effect of speed of deformation or of rate of flow. It is known that the stresses under which a metal yields to some extent depend on the rate of flow. If rate of flow is an essential further new variable, on which the stress required to produce a given plastic strain would depend, then the necessary and sufficient condition under which again mechanical similarity of the plastic equilibria in two geometrically similar bodies, loaded similarly, would result, would be to change the forces (with time t) so that the unit strains produced by them per unit time in both bodies would be the same.

As the forces which are required to produce the same unit strains in two bodies must be in the proportion of the squares of the linear dimensions of these bodies, the test has to be conducted so that any force $P = P'(l^2/l'^2)$, where P' is the corresponding load acting on the second body and now P or P' are functions of the time t. Two similar hardness tests with a large and with a small ball have to be conducted so that if $P' = f(t)$, $P = P'(d^2/d'^2)$. If, for example, $d = 2d'$, then at equal times the load P on the large ball must be equal four times the load P acting on the small ball.

This, however, is only true in the case of comparatively slow plastic flow. If the forces increase more rapidly with time due to the acceleration of the body masses, additional inertia forces must be produced in the mass elements of the stressed bodies. This is of great importance for all questions referring to impact stresses. The case of impact of bodies needs further variables (inertia forces, mass forces), and the condition of similarity will have also to include the effect of body forces hitherto not considered.

The various observations mentioned in the report referring to fracture and particularly to fatigue strength and fracture, including also the effect of stress concentrations, are highly interesting as they seem to indicate that the conditions of similarity in fatigue tests probably depend on further mechanical or other factors not yet found or established, and it will be an interesting task in the future to search for these unknown variables or effects which seem to influence fatigue failures.

Author's Closure

Dr. Nadai mentions the time variable (rate of deformation) as a possible factor in size effect. A few comparative fatigue tests at widely different rates have not shown a marked effect to date. It is quite clear that much work remains to be done in the fatigue field before the question of size effect can be cleared up, particularly for the stress-concentration cases.

Mr. Stone suggested that some remarks be made about size effect in fatigue of welds. For welds made with bare electrodes, larger sizes gave lower endurance limits, similar to the results herein reported for specimens having holes. Since bare electrode welds contain tiny holes,[33] one might expect some similarity of results. This work is not completed as yet.

Applications of Creep Tests

By GLEASON H. MacCULLOUGH,[1] WORCESTER, MASS.

Analytical solutions of problems which involve creep phenomena and which are of practical interest are at present very limited in number. This paper discusses four specific problems for which solutions have been presented: namely, the problem of the flanged and bolted pipe joint under creep conditions, and the three problems of stress distribution and creep in thick-walled cylinders under internal pressure, in a beam subjected to pure bending, and in a solid circular shaft under torsion. These solutions will illustrate the kind of creep data which the designer desires the experimenter to furnish.

1—The Phenomenon of Creep

CREEP may be defined as the comparatively slow deformation of a material which occurs with lapse of time under the action of an externally applied stress. The exact nature of creep will not be discussed here, other than to say that it undoubtedly is due to shear. This phenomenon of creep is most pronounced at elevated temperatures. A stress which is a fraction of that required to produce failure in a few minutes as in the ordinary static test may ultimately cause failure if allowed sufficient time. Then again, while there may be stresses so small that they will not cause failure of a structural part by creep in a very long period of time, nevertheless such stresses may be harmful because of the structural distortion which they may ultimately set up. Examples of such distortion are the loosening of flanged joints caused by creep in the bolts, and the changes in clearance of turbine blading.

2—Creep Tests—The Long-Time Test

Entering into the usual creep tests of metals, there are four variables: namely, stress, deformation, time, and temperature (1).[2] Such tests may be variously classified as tension or shear (torsion) tests, as long-duration or short-duration tests, and as regards the method employed in testing. Nearly all of the tests so far made have been tensile tests, though a few torsional tests have been made by R. W. Bailey (2) and Dr. F. L. Everett (3). For a rough correlation between the results of tension and torsion tests, see Appendix No. 2.

The most valuable creep tests are those extending over months. Perhaps the most common of these tests are those where strain measurements are taken with respect to time, the stress and temperature being held constant during any one test. In this way, a family of curves like that in Fig. 1 may be obtained. From such curves (or curves where temperature is the parameter and the stress is constant), various derived curves may be obtained such as "time rate of creep vs. time," "stress vs. minimum rate of creep," "stress vs. logarithm of minimum rate of creep," "stress vs. duration to fracture," etc.

Most of the creep-time curves are characterized by an inflection point or by a linear middle portion at which a minimum rate of creep occurs. The slope of the tangent at this inflection point or along this straight portion gives the minimum rate of creep. Along this linear portion, of course, steady creep conditions prevail. In the problems of Arts. 5–8 where the effects of creep upon redistribution of stress and upon permissible deformations are considered, such a steady state of creep is assumed and plots of stress vs. minimum rate of creep consequently form the experimental basis for the solution of such problems.

Another physical property selected from creep data which is sometimes useful, is the concept of a limiting creep stress. H. J. Tapsell (4) defines this limiting creep stress as "the load per unit of the original area which will just not break the bar when allowed to remain on for a long time." Such a stress, reduced slightly by a proper factor of safety, may be used as the safe working stress in design using the ordinary formulas based on the elastic theory. This method may prove unsatisfactory, however, for although the material may not actually fail under such a limiting creep stress, there is a possibility that it will deform so much as to be unsuitable in actual practice. As to permissible tensile strain rates, K. Baumann (5) has suggested the following rates for different parts of a steam plant which seem to have gained wide acceptance:

	Inches per inch per hour
Turbine disks pressed on shafts	10^{-9}
Bolted flanges, turbine cylinders	10^{-8}
Steam piping, welded joints, boiler tubes	10^{-7}
Superheater tubes	10^{-7}

Another method of tensile creep test might be termed the "relaxation" test. This consists of a tension specimen having two turned-down portions and which is mounted between rigid supports. Provision is made for applying an initial tension to the specimen. One of the portions is surrounded by the usual electric heating element and the other portion serves as a calibration bar for measuring the force in the bar, Fig. 2. Knowing the strain in the gaged length of this second section, the corresponding stress can be found from the results of a previous calibration. So indirectly by means of these strain gages it is possible to measure the relaxation in stress due to the yielding or creep of the reduced portion within the furnace. Usually it is not convenient to measure the actual creep of the specimen within the furnace. Curves plotted from data obtained thus appear as shown in Fig. 3.

3—Short-Time or Accelerated Creep Tests

The creep tests already described have the disadvantage of requiring a long time for their performance. Much work is going on in an endeavor to develop new forms of "accelerated" creep tests which will produce in a short time the same indica-

tions regarding the fitness of a material as must occupy very long periods when tests are made by the more fundamental long-duration method.

Three of the proposals made for such accelerated tests aim to obtain a satisfactory working stress or limiting creep stress. One of the best-known methods is that devised by W. H. Hatfield (6) where he obtains a value called the "time-yield." This investigator proposed a comparatively short method of arriving at a particular creep limit, which he stated was, at high temperatures, a value comparable with the yield point at ordinary temperatures. His creep limit, or time-yield, was defined as the maximum stress which would not produce an extension exceeding 0.5 per cent

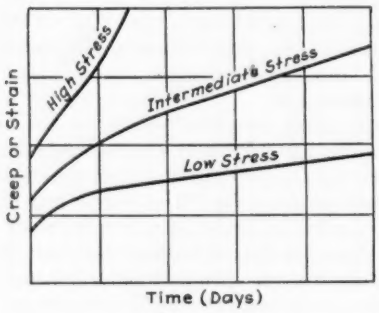

FIG. 1

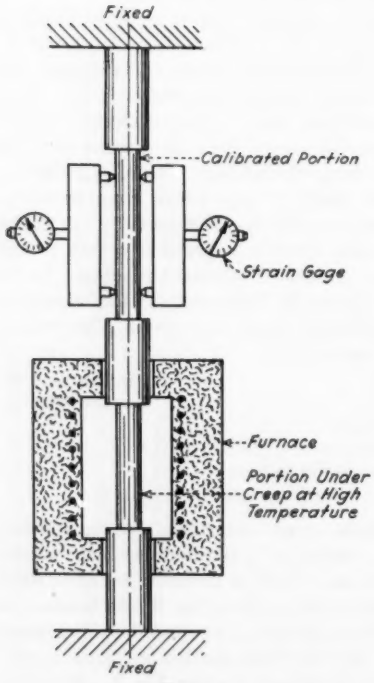

FIG. 2

in the first 24 hr, nor greater than 0.005 per cent in the next 48 hr. To determine this limit requires the making of two or three tests in the vicinity of the predicted creep limit, its actual value being found by interpolation. Such a method for the estimation of the time-yield at a particular temperature was considered to require tests occupying a total period of about one week. As a safe stress, Dr. Hatfield recommends a stress about two-thirds of this time-yield.

Another method, aiming at securing a limiting creep stress within a period of the order of 48 hr, has been devised by Messrs. W. Barr and W. E. Bardgett (7). This method makes use of the so-called "relaxation" test and consists of plotting a curve (Fig. 4) showing the relation between the decrease in stress over a 48-hr period against varying initial stresses. By extrapolation of the straight line obtained, the initial stress corresponding to a zero decrease in stress is found. This initial stress is the limiting creep stress.

For a third suggested method, the reader is referred to H. J. Tapsell's "Creep of Metals," p. 121 (1). Still another method is advocated by A. Pomp and Walter Enders (7a).

Studies have also been made looking toward reducing somewhat the time required for the usual long-time test instead of devising new tests like those already described. It is found that an initial temperature, some 50 to 100 C above the temperature for which the required result is desired, maintained through the first stages of the test and then dropped to the required temperature, shortens the time required and does not materially affect the minimum rate of creep or the limiting creep stress eventually obtained (8). Or the initial stress may be temporarily raised and later reduced to the desired value with the same results (9).

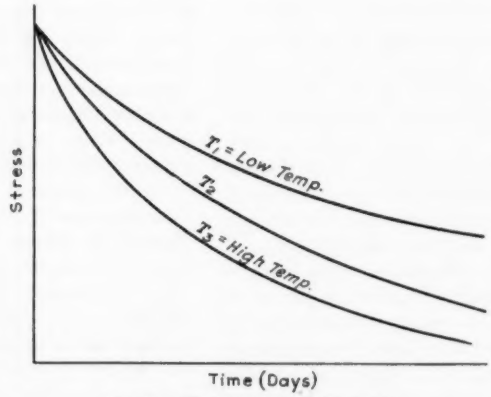

FIG. 3 "RELAXATION" CURVES

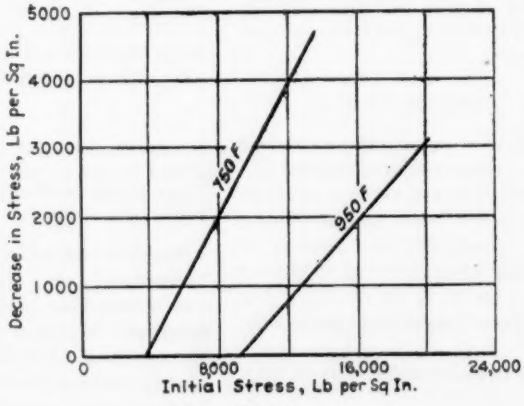

FIG. 4

4—SOME GENERAL CONSIDERATIONS AFFECTING DESIGN

In the general case of design, the most frequent problem facing engineers is that of designing a part for operation at a particular temperature for which experience exists at lower temperatures. If the material is unaltered, it is usual to base design upon existing practice by reducing the working stress in the ratio suggested by creep tests at the two temperatures.

For example, in the case of a steam power plant, considerable experience exists for an initial temperature of 750 F. In the case of design for 850 F, creep tests indicate that for the same carbon steel and the same creep rate, the stress is approximately 60 per cent of that for 750 F. The working stress for elastic design is accordingly reduced in this ratio.

This method of design takes no account of the redistribution of the stress due to creep in the cases of bending and torsion and in thick-walled cylinders. This redistribution is favorable, for it reduces the maximum intensity of stress found by the elastic theory. Neither does this practice take into direct account the permissible deformations. An elaboration of this method is discussed by Messrs. Bailey and Roberts in the article already referred to (8).

When the deformations caused by creep and their effect upon the stress distribution are taken into account, design problems acquire considerable complexity. A few problems have yielded to a rather reliable analytic treatment, among which are those dealing with parts of cylindrical shape so common in pressure vessels. In what follows, four of these solutions are presented.

5—THE PROBLEM OF THE FLANGED PIPE JOINT

This solution is essentially that presented by K. Baumann (10) in the English periodical *Engineering*.

Given a flanged joint (Fig. 5) with flanges as well as bolts subjected to creep and with the elastic flexibility of both taken into account, to find an expression for the time required for the initial stress in the bolt to fall to a given value due to creep, or, conversely, to find the stress in the bolts after an elapsed time; to show also that for any ratio

$$n = \frac{\text{flexibility of flange}}{\text{flexibility of bolt}}$$

and for any ratio

$$p = \frac{\text{creep rate of flange}}{\text{creep rate of bolt}}$$

the time required for the stress to fall from one given value to another is $q = (1 + n)/(1 + p)$ times that given by the curve of Fig. 6. This curve is a plot of the stress in the bolt against time in hours for the case of rigid flanges, $q = 1$, and is what one might call a "relaxation" curve.

The following notation will be adopted:

- L_f = flange span or distance between flanges before the bolts are tightened
- L_b = length that stressed portion of bolt would assume if relieved of load before any creep has occurred
- k_b = total bolt extension due to creep
- k_f = total diminution of flange span due to creep
- δ_b = total elastic extension of bolt
- δ_f = total elastic diminution of flange span
- σ = stress in bolt at any time
- σ_0 = initial stress in bolt before any creep has occurred
- c = creep rate of bolt material (unit strain due to creep per unit of time) taken as following the law $\sigma = a + b \log_e c$, where a and b are empirical constants, for any given temperature. For, in the case of steels at temperatures up to, say, 500 C and stresses of working magnitude, a linear relation between stress and log rate of creep expresses fairly well the results of experiment.

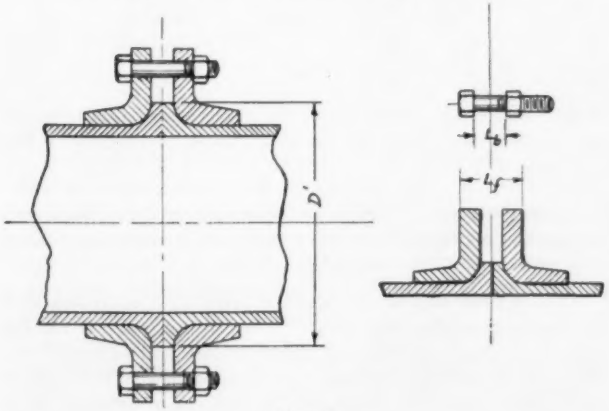

FIG. 5

After the bolt and flange are assembled and creep is taking place, the effective length of the bolt must always equal the span of the flanges. Hence

$$L_b + \delta_b + k_b = L_f - \delta_f - k_f \quad [1]$$

Let

$$s = L_f - L_b \quad [2]$$

= amount nut is screwed up with respect to the unstressed bolt
= lead × turns of nut

$$n = \frac{\text{elastic displacement of flange at bolt circle caused by any given force}}{\text{elastic stretch of bolt caused by the same force}} = \frac{\delta_f}{\delta_b} \quad [3]$$

and

$$p = \frac{\text{creep displacement of flanges at bolt circle caused by a given force}}{\text{creep stretch of bolt caused by the same force}} = \frac{k_f}{k_b} \quad [4]$$

Substituting from [2], [3], and [4] in [1],

$$s = \delta_b(1 + n) + k_b(1 + p) \quad [5]$$

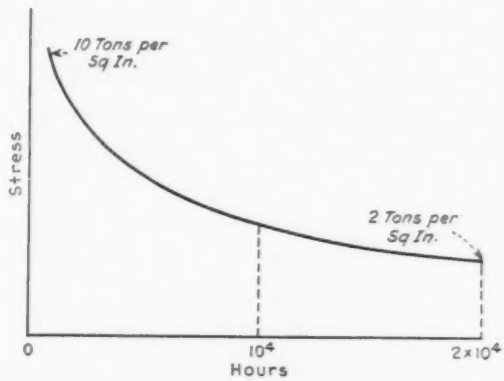

FIG. 6

No matter whether creep has occurred or not, we shall assume that the elastic properties of the bolt remain unchanged. The application of Hooke's law to the bolt, therefore, gives

$$\delta_b = \frac{\sigma L_b}{E} \quad [6]$$

where E is the modulus of elasticity of the bolt material. Substituting [6] in [5] and differentiating with respect to time,

$$0 = (1 + p)\frac{dk_b}{dt} + \frac{1 + n}{E} L_b \frac{d\sigma}{dt} \quad [7]$$

The creep rate per unit of length is

$$c = \frac{d(k_b/L_b)}{dt} = \frac{1}{L_b}\frac{dk_b}{dt} \quad [8]$$

From the assumed creep law,

$$c = e^{\frac{\sigma - a}{b}} \quad [9]$$

Eliminating c between [8] and [9] and substituting the value of dk_b/dt thus found into [7],

$$e^{\frac{\sigma - a}{b}} + \frac{q}{E}\frac{d\sigma}{dt} = 0 \quad [10]$$

where $q = (1 + n)/(1 + p)$.
The solution of the differential Equation [10] is

$$t = \frac{bq}{E}\left[e^{\frac{a - \sigma}{b}} + C\right]$$

Now at time $t = 0$, let the stress $\sigma = \sigma_0$ and hence $C = -e^{\frac{a-\sigma_0}{b}}$

$$t = \frac{bq}{E}\left[e^{\frac{a-\sigma}{b}} - e^{\frac{a-\sigma_0}{b}}\right] \quad \ldots\ldots\ldots\ldots [11]$$

Equation [11] gives the time required for the stress to fall from its initial value σ_0 to a final value σ. Since a, b, and E depend only on the bolt material and temperature and not on the dimensions, when these quantities are fixed, the time required for the stress in the bolts to fall from one given value to another is then proportional to q. It can be shown that this statement is true regardless of what the creep-stress law may be (see

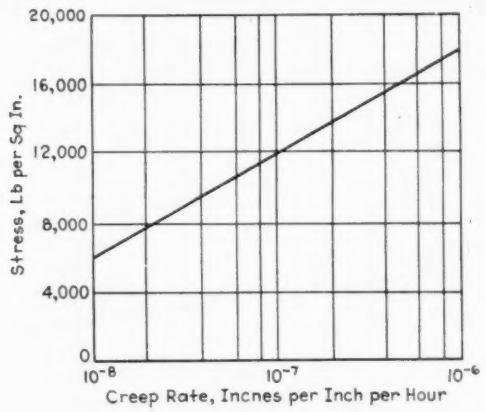

FIG. 7

Appendix No. 1). Since $q = (1 + n)/(1 + p)$, in order that the joint may remain tight for a long time, it is desirable that the flanges be very flexible, provided that this additional flexibility does not involve a proportionate increase in the creep rate of the structure.

From [11], one can obtain an expression for the stress at the end of any given time t.

$$\sigma = a - b \log_e\left[\frac{Et}{bq} + e^{\frac{a-\sigma_0}{b}}\right] \quad \ldots\ldots\ldots [12]$$

As a numerical example of the use of Equation [11], consider a 6-in. flanged pipe joint bolted together with twelve 1-in.-diam. bolts. Diameter of outside of contact surface, $D' = 8^1/_2$ in. The working steam pressure is 600 lb per sq in. For the bolt material, $E = 25{,}000{,}000$ lb per sq in., and the plot of stress against the logarithm of the minimum rate of creep is shown in Fig. 7, assumed for a temperature of 750 F.

The constants a and b in the equation of this plot $\sigma = a + b \log_e c$ are found by substituting two pairs of corresponding values of σ and c, obtained from the curve, in the above equation. Note that

$$\log_e c = 2.3026 \log_{10} c$$
$$6000 = a + 2.3026\, b \log_{10} 10^{-8}$$
$$18{,}000 = a + 2.3026\, b \log_{10} 10^{-6}$$

Solving simultaneously, $a = 54{,}000$

$$b = 2600$$

We shall make the further assumptions that for the joint, $n = 3$, $p = 1$, and that the bolts should always have a tension twice that caused by the steam pressure in order to insure tightness of joint. In calculating this tension in the bolts, it is recommended that the steam pressure be considered as acting upon an area circumscribed by the periphery of the outside of the contact surface. The area in this case is $(\pi/4)\ (8^1/_2)^2 = 56.75$ sq in., and the total steam pressure is $600 \times 56.75 = 34{,}050$ lb. The stress set up in each bolt, when doubled to insure tightness, is 7230 lb per sq in.

Since the bolts may be given an initial tension of 20,000 lb per sq in. and since the tension ought not to fall below the value of $\sigma = 7230$ lb per sq in., the time t necessary for the bolt stress to drop to the latter value is found from Equation [11]. $q = (1 + n)/(1 + p) = 2$.

$$t = \frac{2600 \times 2}{25{,}000{,}000}\left[e^{\frac{54{,}000 - 7230}{2600}} - e^{\frac{54{,}000 - 20{,}000}{2600}}\right]$$
$$= 13{,}600 \text{ hr} = 81 \text{ weeks}.$$

If this is too short a period for the life of the joint, a different bolt material may be used having greater resistance to creep, or the flexibility of the flanges may be increased, thus increasing q.

As an example of the use of Equation [12], suppose one wishes to know the stress in the bolts of the above joint at the end of 2 years or 17,520 hr. Substituting in [12], there results

$$\sigma = 54{,}000 - 2600(2.3026) \log_{10}\left[\frac{25{,}000{,}000 \times 17{,}520}{6070 \times 2} + e^{\frac{54{,}000 - 20{,}000}{2600}}\right] = 8720 \text{ lb per sq in.}$$

It is to be noted in these calculations that increasing the initial tension within safe limits will have but little effect on the life

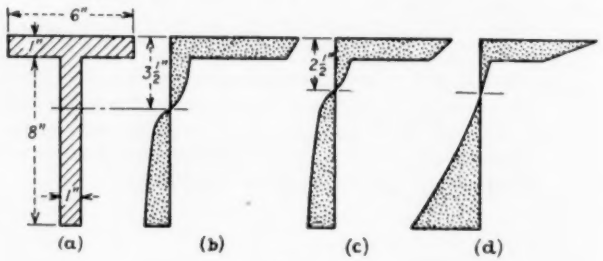

FIG. 8

of the joint. For a more complete discussion of this problem, the reader is referred to the previously mentioned article by Mr. Baumann (5).

6—The Problem of Stress Distribution and Resisting Moment for a Beam Subjected to Pure Bending and Creep Conditions (11)

This solution utilizes the results of creep tests in tension with the assumption that the rates of creep in compression are the same as in tension under the same stresses and temperatures. The general method of attack is this: Knowing the creep rate at the outside fiber of the beam and the manner of deformation of the cross-sections, we can find the creep rates for various fibers within the beam. If it is considered that the stresses producing these creep rates are equal to the stresses that would cause the same minimum rate of creep in tension or compression, then from a plot of "stress vs. minimum rate of creep in tension," the corresponding stresses in bending can be determined. Knowing the stress distribution for a few points in the cross-section of the beam, it is an easy matter to compute the moment of resistance or the bending moment acting on the beam.

The method will be illustrated by considering a numerical problem.

The T-section shown in Fig. 8 will be chosen since the method

of solution is more general than in the case of the simpler rectangular cross-section. Let us endeavor to calculate the bending moment which may act on the beam and still not cause an increase in deflection due to creep at the center of a 48-in. length greater than 0.01 in. in two years, for an assumed temperature of 750 F. A Cr-Ni-Mo alloy steel will be used, for which the plot of stress vs. logarithm of the minimum rate of creep is shown in Fig. 9.

From the fact that the sag, dy, due to creep in two years may be 0.01 in., one can find the rate of angular creep $d\theta/dt$ between plane sections 1 in. apart from the relation

$$\frac{d\theta}{dt} = \frac{8}{l^2}\frac{dy}{dt}$$

which is valid for flat circular arcs.

$$\frac{d\theta}{dt} = \frac{8}{(48)^2} \times \frac{0.01}{2(365)(24)} = 1.98 \times 10^{-9} \text{ radians per hour}$$

Let us start by assuming the neutral axis, or axis of rotation for the plane sections, to pass through the centroid of the cross-section which is $3^1/_2$ in. below the top. Then the rate of creep of any fiber equals the product of its distance from the assumed neutral axis and $d\theta/dt$. The corresponding stress causing this rate of creep can be read from the curve of Fig. 9. The distribution of stress thus found is given in the first three columns of Table 1. This stress distribution, when multiplied by the width of the cross-section at each point, is shown plotted in Fig. 8(b).

TABLE 1

Distance below top	Neutral Axis $3^1/_2$" below top — Rate of creep	Corresponding stress	Neutral Axis $2^1/_2$" below top — Rate of creep	Corresponding stress	Stress × width × xy
0	6.93×10^{-6}	18,000	4.95×10^{-9}	16,000	240,000
$^1/_2$	...	....	3.96	15,000	180,000
1	4.95	16,000	2.97	13,300	120,000
1	...	....	...	13,300	20,000
2	2.97	13,300	0.99	9,000	4,500
$2^1/_2$	...	....	0.0	0	0
3	0.99	9,000	0.99	9,000	4,500
$3^1/_2$	0.0	0	...	....	.....
4	0.99	9,000	2.97	13,300	20,000
5	2.97	13,300	4.95	16,000	40,000
6	4.95	16,000	6.93	18,000	63,000
7	6.93	18,000	8.91	19,300	86,800
8	8.91	19,300	10.9	20,300	112,000
9	10.9	20,300	12.9	21,300	138,000

If the neutral axis has been correctly chosen, the total force above the neutral axis must equal that below. This is equivalent to equating the areas above and below the neutral axis in Fig. 8(b). A rough determination shows these two areas not to be equal but rather in the ratio of about 52 to 31. It is readily seen that raising the neutral axis will reduce the upper area and increase the lower one.

Assuming the neutral axis now to be $2^1/_2$ in. below the top, a calculation similar to the above is repeated with the results shown in the 4th and 5th columns of Table 1 and the plot is shown in Fig. 8(c). The area of the portion above now works out to be about 101,500 lb and that below, 104,500 lb. This indicates that the neutral axis is but little below the $2^1/_2$-in. position assumed, and we shall consider this as satisfactory.

To calculate the moment of resistance, let y be the distance from the neutral axis to any fiber where the stress is σ and where the width of the section is b. There the total moment is expressed by

$$M = \int(\sigma b dy)(y) = \int(\sigma b y)dy$$

Therefore if the horizontal intercepts σb in Fig. 8(c) be multiplied by their respective distances from the neutral axis and a new curve plotted as in Fig. 8(d), the total shaded area represents the moment of resistance. This area gives the required moment and is found to be M = 586,000 in-lb.

If the resisting moment for this beam is figured by the usual elastic theory with the same maximum fiber stress of 21,300 lb per sq in., it is found to be but 330,000 in-lb. The effect of redistribution of stress due to creep is plainly evident. Or for the same moment of 586,000 in-lb as with creep, a maximum stress of 38,000 lb per sq in. would be necessary if the stresses were distributed according to the elastic linear law.

For a beam symmetrical with respect to the middle horizontal

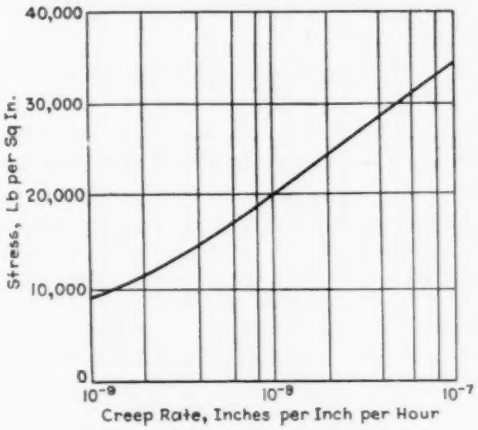

FIG. 9

axis and with like creep characteristics in tension and compression, the procedure is the same excepting that the neutral axis is known to lie at the center and need not be determined by trial. This simplifies the calculations for rectangular or circular cross-sections and for I-beams.

While the method illustrated is strictly applicable only to the case of pure bending by couples applied at the ends, it is felt that the deflection can be considered as due solely to tensile and compressive strains in the longitudinal fibers even when bending is produced by transverse loads, and the method can be used with but slight error as the basis for determining deflections. The limitation must be imposed that the ratio of the length of the beam to its depth is such that the shearing stresses are not greater than one-fourth or one-third of the flexure stresses. For the case of transverse loads, a suggested method of attack consists of subdividing the length of the beam into shorter lengths, and assuming each length to be in pure bending with a moment acting which is equal to the average moment in that length. Each of these lengths will be bent approximately into a circular arc, and the various lengths can then be "pieced together" to ascertain the total deflection at the center of the beam.

7—The Problem of Stress Distribution and Creep in Solid Circular Shafts (12)

But one example will be worked in this connection: that where the torsional stress τ is related to the minimum creep rate in shear ϕ by the relation $\tau = a + b \log_e \phi$ for any particular temperature, and where a and b are empirical constants. Other cases can be worked out similarly, either for hollow circular shafts or where different stress-creep-rate relations than the above exist.

These solutions, however, are based on a tentative hypothesis which really needs further verification experimentally. This hypothesis is stated in the following quotation from R. W. Bailey:

> The author's tests upon thin tubes in torsion indicate that a solid cylindrical test piece should behave as if composed of a number of

elementary concentric tubes undergoing rates of creep in shear proportional to their radii.

In other words, the assumption to be made is analogous to that in bending: that radial lines straight before angular creep remain straight after angular creep. Hence the analytical method to be employed in this solution is also applicable to problems in bending based on a similar assumption regarding cross-sections.

By virtue of this assumption, the shear creep rate ϕ at any point of the solid shaft of Fig. 10 is related to the shear creep rate ϕ_0 at the outside by the relation $\phi = (r/r_0)\phi_0$.

The torsional moment is given by

$$M_t = \int_0^{r_0} \tau r dA = \int_0^{r_0} (a + b \log_e \phi) r \times 2\pi r dr$$

Substituting $\phi = (r/r_0)\phi_0$ into the above and noting that $a + b \log_e \phi_0 = \tau_0$ (τ_0 being the outside shear stress), one gets

$$M_t = 2\pi \int_0^{r_0} (\tau_0 + b \log_e r - b \log_e r_0) r^2 dr$$

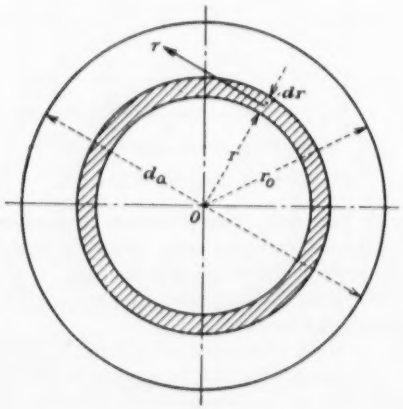

FIG. 10

Upon integration, this becomes

$$M_t = \frac{\pi d_0^3}{12}\left(\tau_0 - \frac{b}{3}\right) \quad \text{.....[I]}$$

where d_0 is the outside diameter. Knowing the external moment, τ_0 can be calculated from the above.

The stress distribution for points not near the center is

$$\tau = a + b \log_e \phi$$

$$= a + b \log_e \left(\frac{r}{r_0}\phi_0\right)$$

$$= a + b \log_e \phi_0 + b \log_e \frac{r}{r_0}$$

$$= \tau_0 - b \log_e \frac{r_0}{r} \quad \text{.....[II]}$$

The creep rate in shear ϕ_0 at the outer surface can be obtained from

$$\tau_0 = a + b \log_e \phi_0$$

or

$$\phi_0 = e^{\frac{\tau_0 - a}{b}}$$

The relation of the angular creep rate α to the shear creep rate ϕ is expressed by $\phi = r\alpha$.

Hence the rate of twist in the shaft is $\alpha = 2\phi_0/d_0$, α being in radians per hour per unit length of the shaft.

As an example of the use of the foregoing equations, let us find the moment or torque which will cause a twist due to creep of 1 deg in one year for a 1-ft length of 10-in.-diameter shaft made of 0.34 per cent carbon steel. The temperature is 400 C. The relation for this material and temperature between stress and minimum rate of creep is expressed by

$$t = 42{,}500 + 2420 \log_e \phi$$

in which $a = 42{,}500$ and $b = 2420$.

The first step is to find the shear creep rate ϕ_0 at the outside in radians per inch per hour, using the relation

$$\phi_0 = \frac{d_0 \alpha}{2}$$

$$= \frac{(10)(\pi/180)}{2(365 \times 24)(12)} = 0.83 \times 10^{-6}$$

The stress producing this creep ϕ_0 is found from the creep law above (or directly from the experimental curve) to be $t_0 = 42{,}500 + 2420(2.303) \log_{10} 0.83 \times 10^{-6} = 8600$ lb per sq in. Substituting this value in [I] gives the torque

$$M_t = \frac{\pi(10)^3}{12}\left(8600 - \frac{2420}{3}\right) = 2{,}040{,}000 \text{ in-lb}$$

Based on elastic theory and with the same maximum stress of 8600 lb per sq in., the torque is found to be 1,690,000 in-lb. The increase with creep is due to the different distribution of stress which is defined by Equation [II].

For the case where the creep law is expressible by $\log \tau = a + b \log_e \phi$, which is more nearly valid for low stresses and low creep rates than the one used above, see R. W. Bailey's paper already referred to (2).

8—The Problem of Stress Distribution and Creep in Thick-Walled Cylinders Under Internal Pressure

The solution of this problem is due to R. W. Bailey (13). It may be a little surprising that the experimental data required for its solution concern creep rates in torsion rather than in tension or compression. To show how these quantities are introduced, a portion of Mr. Bailey's analysis is summarized in Appendixes Nos. 2 and 3.

The following solution is restricted to the case where the creep rate has become constant and where the relation between the shearing stress τ and the minimum rate of creep in shear ϕ is

$$\tau = a + b \log_e \phi = a + 2.303b \log_{10} \phi$$

For cases where the creep law is given by $\log_e \tau = a + b \log_e \phi$ and where there is heat transmission through the wall, see Mr. Bailey's paper.

Let

r_1 = inside radius of cylinder
r_2 = outside radius of cylinder
r = radius to any point in cylinder wall
p = intensity of internal fluid pressure
$\sigma_r, \sigma_\theta, \sigma_z$ = normal stresses in the radial, tangential, and axial directions, respectively, at any point in the wall
b = constant appearing in the assumed creep law.

The magnitudes of the three normal stresses are given by

$$\sigma_r = -p\frac{\log_e \frac{r_2}{r}}{\log_e \frac{r_2}{r_1}} - 2b\log_e\frac{r}{r_1}\log_e\frac{r}{r_2} \quad \text{.....[IV]}$$

$$\sigma_\theta = p\frac{1-\log_e\frac{r_2}{r}}{\log_e\frac{r_2}{r_1}} - 2b\log_e\frac{r}{r_1}\log_e\frac{r}{r_2} + 4b\log_e\frac{r_1}{r} + 2b\log_e\frac{r_2}{r_1}$$

.....[V]

$$\sigma_s = \frac{p}{2}\frac{1-2\log_e\frac{r_2}{r}}{\log_e\frac{r_2}{r_1}} - 2b\log_e\frac{r}{r_1}\log_e\frac{r}{r_2} + 2b\log_e\frac{r_1}{r} + b\log_e\frac{r_2}{r_1}$$

.....[VI]

Since the creep rate is related to $\sigma_\theta - \sigma_r$, we shall deduce now the value of this useful term.

$$\sigma_\theta - \sigma_r = \frac{p}{\log_e\frac{r_2}{r_1}} + 4b\log_e\frac{r_1}{r} + 2b\log_e\frac{r_2}{r_1} \quad \text{...[VII]}$$

If, from the results of torsional creep tests, b is known, then Equations [IV], [V], and [VI] will enable one to calculate the stress distribution throughout the cylinder wall. It is significant that the stresses and creep rates set up depend only on the ratios r_2/r_1, r/r_1, etc. and not on the absolute values of r, r_1, etc.

A study of the stress distribution given by the formulas mentioned shows that the distribution of tangential stress under these creep conditions is relatively uniform across the thickness, which is in contrast with that given by the Lamé formula for purely elastic conditions. These formulas, by the way, can be used for thin-walled tubes also.

If it is desired to find the diametral creep rate of the outside diameter, Equation [VII] with r set equal to r_2 gives the value of $\sigma_\theta - \sigma_r$ at the outside. This can be substituted back into Equation [a] (Appendix No. 3) to get the shear creep rate or its equivalent $2c$, twice the diametral creep rate; that is,

$$\log_e \phi = \log_e 2c = \frac{\sigma_\theta - \sigma_r}{2b} - \frac{a}{b}$$

The inverse of this problem is of practical interest; namely, given the permissible rate of diametral creep, to determine the ratio of r_2/r_1. We have seen that the system of stress represented in Fig. 17 (Appendix No. 3) is equivalent to a pure shear with the shearing stress $\tau = (\sigma_\theta - \sigma_r)/2$. For the outside of the tube wall where $r = r_2$, [VII] reduces to

$$2\tau_2 = \frac{p}{\log_e\frac{r_2}{r_1}} - 2b\log_e\frac{r_2}{r_1}$$

where $2\tau_2$ is the value of $\sigma_\theta - \sigma_r$ at the outside.

This is a quadratic equation in terms of $\log_e (r_2/r_1)$ and its solution is

$$\log_e\frac{r_2}{r_1} = \sqrt{\frac{p}{2b} + \left(\frac{\tau_2}{2b}\right)^2} - \frac{\tau_2}{2b} \quad \text{.....[VIII]}$$

As an application, consider the case of a superheater tube, 2 in. in inside diameter, under a pressure of 1500 lb per sq in. so that the diametral creep rate shall not exceed 10^{-7} in. per in. per hr. The steel used is 0.34 per cent C steel and the temperature is 400 C. The plot of shear stress τ against the minimum rate of creep in shear for this material and temperature is expressed by the relation $\tau = a + b\log_e \phi$, where $a = 42{,}500$ and $b = 2420$.

τ_2 [or $(\sigma_\theta - \sigma_r)/2$ at the outside] for a creep rate $\phi = 2c = 2 \times 10^{-7}$ is

$$\tau_2 = a + b\log_e\phi = 42{,}500 + 2.303(2420)\log_{10}(2\times10^{-7}) = 5200 \text{ lb per sq in.}$$

Substituting in Equation [VIII],

$$\log_e\frac{r_2}{r_1} = \sqrt{\frac{1500}{2(2420)} + \left(\frac{5200}{4840}\right)^2} - \frac{5200}{4840}$$

$$2.303\log_{10}\frac{r_2}{r_1} = 0.136$$

$$\frac{r_2}{r_1} = 1.146$$

The outside diameter should therefore be 2.29 in. It is to be noted that this wall thickness of 0.146 in., based solely on creep characteristics, is less than one-half of the wall thickness of 0.312 in. recommended by the A.S.T.M. tentative specifications[1] for 1350 lb pressure, and therefore the A.S.T.M. recommended pipe will have much more creep resistance than specified in our problem.

Appendix No. 1

SHOWING THAT THE TIME REQUIRED FOR THE STRESS IN THE BOLTS OF A FLANGED JOINT TO FALL FROM ONE GIVEN VALUE TO ANOTHER IS PROPORTIONAL TO q, REGARDLESS OF WHAT THE CREEP LAW MAY BE

The various algebraic quantities are as defined in Art. 5, with the addition that

t_r = time for the stress in a bolt gripping perfectly rigid flanges to fall from one value to another, and

t = time taken for the stress in the bolt to fall through the same range when it grips flanges whose flexibility is n times, and whose linear rate of creep is p times, that of the bolts.

Let us first consider a case where the fall of stress $d\sigma$ is so small that the creep rate c for this interval dt_r may be considered as constant.

In the case of rigid flanges and elastic bolts, from Hooke's law,

$$d\sigma = \frac{E}{L_b}k_b = \frac{E}{L_b}c\,dt_r \quad \text{.....[a]}$$

since the change of stress in the bolt must cause a shortening thereof which exactly compensates for the lengthening of the bolt due to creep under tensile stress.

In the case of flexible flanges and an elastic bolt, the lengthening of the bolt relative to the flanges due to creep is nullified by the relative shortening due to fall of stress. The relative lengthening of the bolt due to creep is

$$k = k_b + k_f = (1+p)k_b$$

since $k_f = pk_b$. The relative shortening of the bolt due to fall of stress is

$$\delta = \delta_b + \delta_f = (1+n)\delta_b$$

since $\delta_f = n\delta_b$. Also

$$d\sigma = \frac{E\delta_b}{L_b} = \frac{E}{L_b}\frac{\delta}{1+n}$$

[1] See "Marks' Handbook," Third Edition, p. 1016.

elementary concentric tubes undergoing rates of creep in shear proportional to their radii.

In other words, the assumption to be made is analogous to that in bending: that radial lines straight before angular creep remain straight after angular creep. Hence the analytical method to be employed in this solution is also applicable to problems in bending based on a similar assumption regarding cross-sections.

By virtue of this assumption, the shear creep rate ϕ at any point of the solid shaft of Fig. 10 is related to the shear creep rate ϕ_0 at the outside by the relation $\phi = (r/r_0)\phi_0$.

The torsional moment is given by

$$M_t = \int_0^{r_0} \tau r dA = \int_0^{r_0} (a + b \log_e \phi) r \times 2\pi r dr$$

Substituting $\phi = (r/r_0)\phi_0$ into the above and noting that $a + b \log_e \phi_0 = \tau_0$ (τ_0 being the outside shear stress), one gets

$$M_t = 2\pi \int_0^{r_0} (\tau_0 + b \log_e r - b \log_e r_0) r^2 dr$$

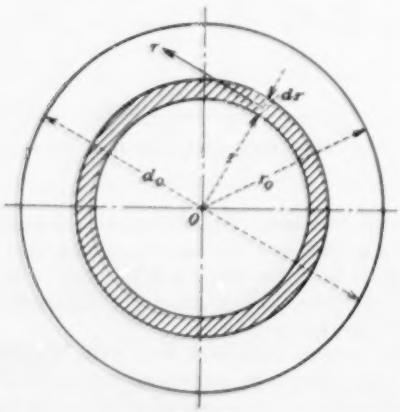

FIG. 10

Upon integration, this becomes

$$M_t = \frac{\pi d_0^3}{12}\left(\tau_0 - \frac{b}{3}\right) \quad \text{[I]}$$

where d_0 is the outside diameter. Knowing the external moment, τ_0 can be calculated from the above.

The stress distribution for points not near the center is

$$\tau = a + b \log_e \phi$$

$$= a + b \log_e \left(\frac{r}{r_0}\phi_0\right)$$

$$= a + b \log_e \phi_0 + b \log_e \frac{r}{r_0}$$

$$= \tau_0 - b \log_e \frac{r_0}{r} \quad \text{[II]}$$

The creep rate in shear ϕ_0 at the outer surface can be obtained from

$$\tau_0 = a + b \log_e \phi_0$$

or

$$\phi_0 = e^{\frac{\tau_0 - a}{b}}$$

The relation of the angular creep rate α to the shear creep rate ϕ is expressed by $\phi = r\alpha$.

Hence the rate of twist in the shaft is $\alpha = 2\phi_0/d_0$, α being in radians per hour per unit length of the shaft.

As an example of the use of the foregoing equations, let us find the moment or torque which will cause a twist due to creep of 1 deg in one year for a 1-ft length of 10-in.-diameter shaft made of 0.34 per cent carbon steel. The temperature is 400 C. The relation for this material and temperature between stress and minimum rate of creep is expressed by

$$t = 42{,}500 + 2420 \log_e \phi$$

in which $a = 42{,}500$ and $b = 2420$.

The first step is to find the shear creep rate ϕ_0 at the outside in radians per inch per hour, using the relation

$$\phi_0 = \frac{d_0 \alpha}{2}$$

$$= \frac{(10)(\pi/180)}{2(365 \times 24)(12)} = 0.83 \times 10^{-6}$$

The stress producing this creep ϕ_0 is found from the creep law above (or directly from the experimental curve) to be $t_0 = 42{,}500 + 2420(2.303) \log_{10} 0.83 \times 10^{-6} = 8600$ lb per sq in. Substituting this value in [I] gives the torque

$$M_t = \frac{\pi(10)^3}{12}\left(8600 - \frac{2420}{3}\right) = 2{,}040{,}000 \text{ in-lb}$$

Based on elastic theory and with the same maximum stress of 8600 lb per sq in., the torque is found to be 1,690,000 in-lb. The increase with creep is due to the different distribution of stress which is defined by Equation [II].

For the case where the creep law is expressible by $\log \tau = a + b \log_e \phi$, which is more nearly valid for low stresses and low creep rates than the one used above, see R. W. Bailey's paper already referred to (2).

8—The Problem of Stress Distribution and Creep in Thick-Walled Cylinders Under Internal Pressure

The solution of this problem is due to R. W. Bailey (13). It may be a little surprising that the experimental data required for its solution concern creep rates in torsion rather than in tension or compression. To show how these quantities are introduced, a portion of Mr. Bailey's analysis is summarized in Appendixes Nos. 2 and 3.

The following solution is restricted to the case where the creep rate has become constant and where the relation between the shearing stress τ and the minimum rate of creep in shear ϕ is

$$\tau = a + b \log_e \phi = a + 2.303b \log_{10} \phi$$

For cases where the creep law is given by $\log_e \tau = a + b \log_e \phi$ and where there is heat transmission through the wall, see Mr. Bailey's paper.

Let

r_1 = inside radius of cylinder
r_2 = outside radius of cylinder
r = radius to any point in cylinder wall
p = intensity of internal fluid pressure
$\sigma_r, \sigma_\theta, \sigma_z$ = normal stresses in the radial, tangential, and axial directions, respectively, at any point in the wall
b = constant appearing in the assumed creep law.

The magnitudes of the three normal stresses are given by

$$\sigma_r = -p\frac{\log_e \frac{r_2}{r}}{\log_e \frac{r_2}{r_1}} - 2b\log_e\frac{r}{r_1}\log_e\frac{r}{r_2} \quad \text{.....[IV]}$$

$$\sigma_\theta = p\frac{1 - \log_e \frac{r_2}{r}}{\log_e \frac{r_2}{r_1}} - 2b\log_e\frac{r}{r_1}\log_e\frac{r}{r_2} + 4b\log_e\frac{r_1}{r} + 2b\log_e\frac{r_2}{r_1}$$

.....[V]

$$\sigma_z = \frac{p}{2}\frac{1 - 2\log_e \frac{r_2}{r}}{\log_e \frac{r_2}{r_1}} - 2b\log_e\frac{r}{r_1}\log_e\frac{r}{r_2} + 2b\log_e\frac{r_1}{r} + b\log_e\frac{r_2}{r_1}$$

.....[VI]

Since the creep rate is related to $\sigma_\theta - \sigma_r$, we shall deduce now the value of this useful term.

$$\sigma_\theta - \sigma_r = \frac{p}{\log_e \frac{r_2}{r_1}} + 4b\log_e\frac{r_1}{r} + 2b\log_e\frac{r_2}{r_1} \quad \text{...[VII]}$$

If, from the results of torsional creep tests, b is known, then Equations [IV], [V], and [VI] will enable one to calculate the stress distribution throughout the cylinder wall. It is significant that the stresses and creep rates set up depend only on the ratios r_2/r_1, r/r_1, etc. and not on the absolute values of r, r_1, etc.

A study of the stress distribution given by the formulas mentioned shows that the distribution of tangential stress under these creep conditions is relatively uniform across the thickness, which is in contrast with that given by the Lamé formula for purely elastic conditions. These formulas, by the way, can be used for thin-walled tubes also.

If it is desired to find the diametral creep rate of the outside diameter, Equation [VII] with r set equal to r_2 gives the value of $\sigma_\theta - \sigma_r$ at the outside. This can be substituted back into Equation [a] (Appendix No. 3) to get the shear creep rate or its equivalent $2c$, twice the diametral creep rate; that is,

$$\log_e \phi = \log_e 2c = \frac{\sigma_\theta - \sigma_r}{2b} = \frac{a}{b}$$

The inverse of this problem is of practical interest; namely, given the permissible rate of diametral creep, to determine the ratio of r_2/r_1. We have seen that the system of stress represented in Fig. 17 (Appendix No. 3) is equivalent to a pure shear with the shearing stress $\tau = (\sigma_\theta - \sigma_r)/2$. For the outside of the tube wall where $r = r_2$, [VII] reduces to

$$2r_2 = \frac{p}{\log_e \frac{r_2}{r_1}} - 2b\log_e\frac{r_2}{r_1}$$

where $2r_2$ is the value of $\sigma_\theta - \sigma_r$ at the outside.

This is a quadratic equation in terms of $\log_e (r_2/r_1)$ and its solution is

$$\log_e\frac{r_2}{r_1} = \sqrt{\frac{p}{2b} + \left(\frac{r_2}{2b}\right)^2} - \frac{r_2}{2b} \quad \text{.....[VIII]}$$

As an application, consider the case of a superheater tube, 2 in. in inside diameter, under a pressure of 1500 lb per sq in. so that the diametral creep rate shall not exceed 10^{-7} in. per in. per hr. The steel used is 0.34 per cent C steel and the temperature is 400 C. The plot of shear stress τ against the minimum rate of creep in shear for this material and temperature is expressed by the relation $\tau = a + b\log_e \phi$, where $a = 42{,}500$ and $b = 2420$.

r_2 [or $(\sigma_\theta - \sigma_r)/2$ at the outside] for a creep rate $\phi = 2c = 2 \times 10^{-7}$ is

$$r_2 = a + b\log_e \phi = 42{,}500 + 2.303(2420)\log_{10}(2 \times 10^{-7}) = 5200 \text{ lb per sq in.}$$

Substituting in Equation [VIII],

$$\log_e\frac{r_2}{r_1} = \sqrt{\frac{1500}{2(2420)} + \left(\frac{5200}{4840}\right)^2} - \frac{5200}{4840}$$

$$2.303\log_{10}\frac{r_2}{r_1} = 0.136$$

$$\frac{r_2}{r_1} = 1.146$$

The outside diameter should therefore be 2.29 in. It is to be noted that this wall thickness of 0.146 in., based solely on creep characteristics, is less than one-half of the wall thickness of 0.312 in. recommended by the A.S.T.M. tentative specifications[1] for 1350 lb pressure, and therefore the A.S.T.M. recommended pipe will have much more creep resistance than specified in our problem.

Appendix No. 1

SHOWING THAT THE TIME REQUIRED FOR THE STRESS IN THE BOLTS OF A FLANGED JOINT TO FALL FROM ONE GIVEN VALUE TO ANOTHER IS PROPORTIONAL TO q, REGARDLESS OF WHAT THE CREEP LAW MAY BE

The various algebraic quantities are as defined in Art. 5, with the addition that

t_r = time for the stress in a bolt gripping perfectly rigid flanges to fall from one value to another, and

t = time taken for the stress in the bolt to fall through the same range when it grips flanges whose flexibility is n times, and whose linear rate of creep is p times, that of the bolts.

Let us first consider a case where the fall of stress $d\sigma$ is so small that the creep rate c for this interval dt_r may be considered as constant.

In the case of rigid flanges and elastic bolts, from Hooke's law,

$$d\sigma = \frac{E}{L_b}k_b = \frac{E}{L_b}cdt_r \quad \text{.....[a]}$$

since the change of stress in the bolt must cause a shortening thereof which exactly compensates for the lengthening of the bolt due to creep under tensile stress.

In the case of flexible flanges and an elastic bolt, the lengthening of the bolt relative to the flanges due to creep is nullified by the relative shortening due to fall of stress. The relative lengthening of the bolt due to creep is

$$k = k_b + k_f = (1 + p)k_b$$

since $k_f = pk_b$. The relative shortening of the bolt due to fall of stress is

$$\delta' = \delta_b + \delta_f = (1 + n)\delta_b$$

since $\delta_f = n\delta_b$. Also

$$d\sigma = \frac{E\delta_b}{L_b} = \frac{E}{L_b}\frac{\delta}{1 + n}$$

[1] See "Marks' Handbook," Third Edition, p. 1016.

Now $\delta = k = (1 + p)k_b$, and hence

$$d\sigma = \frac{E}{L_b}\frac{1+p}{1+n}k_b = \frac{E}{L_b}\frac{1+p}{1+n}cdt \ldots\ldots\ldots\ldots [b]$$

Equating $d\sigma$ between [a] and, [b] there results

$$dt = \frac{1+n}{1+p}dt_r = qdt_r$$

For any number of these intervals, $\Sigma dt = q\Sigma dt_r$ or

$$t = qt_r$$

which was to be proved. It will be observed that no assumptions have been made concerning the creep law.

If n or p is determined either experimentally or analytically so that q is known, and if a plot or data are given showing the relation between the stress in the bolts and the time for rigid flanges, the time required for the bolt stress in the flexible flange to drop a certain amount is q times that found for rigid flanges.

Appendix No. 2

RELATIONS BETWEEN SHEAR CREEP, TORSIONAL CREEP, AND TENSILE CREEP. APPROXIMATIONS FOR SHEAR-CREEP DATA OBTAINED FROM TENSILE-CREEP TESTS

Let

- r = mean radius of tube of Fig. 11 in inches
- α = angular creep rate per unit length of tube in radians per inch per hour
- ϕ = creep rate in shear in radians per hour
- c = circumferential and also diametral creep rate in inches per inch per hour. That these two creep rates are equal is evident because the circumference is proportional to the diameter. That this diagonal creep in shear is the circumferential creep of the tube under internal pressure, see R. W. Bailey's article, reference 12.

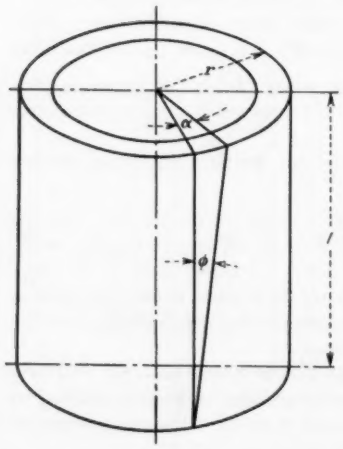

FIG. 11

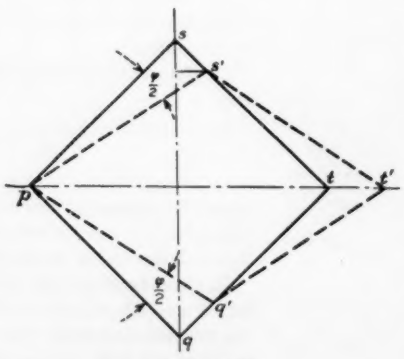

FIG. 12

The relation between α and ϕ is self-evident from Fig. 11.

$$\phi = r\alpha$$

To get the tensile-creep rate c, find how much point t (Fig. 12) moves for a shear strain θ. From the geometry of Fig. 12, the unit tensile strain over the distance pt is

$$\frac{a\theta \cos 45^\circ}{2a \cos 45^\circ} = \frac{\theta}{2}$$

where a = length of side of cube. Introducing the time element

$$c = \frac{\phi}{2}$$

Attempts have been made to connect up the experimental creep rates found in tension and torsion tests so that, from the results of tensile-creep tests, the creep rates in shear may be predicted. Messrs. Bailey, Dickenson (14), and others suggest the following procedure as giving roughly approximate results.

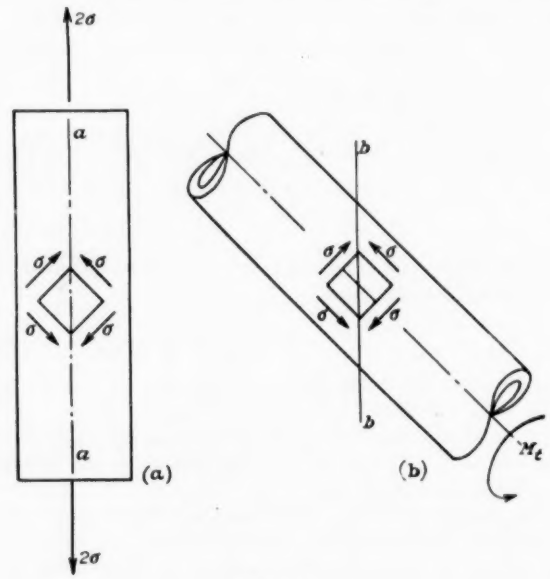

FIG. 13

According to the theory of combined stresses, a tensile stress of intensity 2σ acting on a tension specimen [Fig. 13(a)] induces shearing stresses of intensity σ on the faces of the element shown whose faces make 45 deg with the axis of the specimen. There are also normal stresses set up but, as pointed out later in Appendix No. 3, these have no effect upon the rate of creep. Let there also be a torsion specimen so stressed that the element shown, Fig. 13(b), is in pure shear with shearing stresses of intensity σ.

We have seen that the creep C' along the diagonal bb is $C' = \phi/2$. Also let the creep rate along aa be denoted by c. Now Mr. Bailey has found experimentally that c = 2 to 3 times C' = 1 to 1½ times ϕ, or, roughly $c = \phi$. Likewise a tensile stress 2σ sets up shear-stress components of magnitude σ as shown. This suggests, then, that a plot of shearing stress versus rate of creep may be obtained from tensile-creep results by halving the tensile stress to get the shear stress and by taking the value of ϕ for creep in shear equal to c as found for tension.

Appendix No. 3

MATHEMATICAL SOLUTION FOR THE PROBLEM OF STRESS DISTRIBUTION AND CREEP IN THICK-WALLED CYLINDERS UNDER INTERNAL PRESSURE

Some careful experimental work carried out by Mr. Bailey on thin-walled steel tubes and lead pipes has led to the following

conclusions which form the bases for his solution of the above problem. Since he detected no creep in the axial direction in the case of tubes undergoing creep due to torsion, he concludes that the normal stress acting on any plane has negligible influence upon the creep due to shear at that plane. Consequently, a hydrostatic system of tensile or compressive stresses may be superimposed upon any system of stress without altering the creep due to the latter. This artifice is extremely useful in converting a three-dimensional system of stress into a two-dimensional one equivalent so far as creep is concerned.

By means of this artifice, it is shown that the creep of a thin-walled tube under torsion is equivalent to that of a tube under internal fluid pressure. The application of this theory, as well as experiment, shows that there is also no axial creep in such

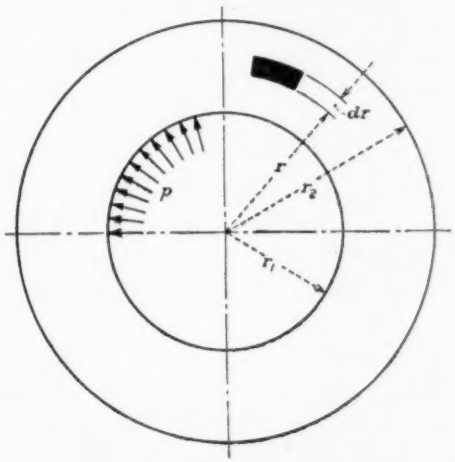

FIG. 14

thin-walled tubes subjected to internal pressure only. Interpreted in terms of stress, an absence of axial creep means that the stress condition set up is like that in thin-walled tubes under internal pressure: namely, that the circumferential stress is double the axial stress.

With the above conclusions and the relations of Appendix No. 2 at our disposal, we can now proceed to the main *problem:* to find the stress distribution and creep in thick-walled cylinders under internal fluid pressure and at a uniform temperature throughout.

Given the thick cylinder with inside radius r_1 and outside radius r_2 subjected to an internal fluid pressure of uniform intensity p as shown in Fig. 14.

Let Fig. 15 represent a curved element cut from the wall of the cylinder and located a variable distance r from the origin at the center of the cylinder. Let dr be the thickness of the element, $d\theta$ the included angle between its radial faces, and let its length in the axial direction be unity.

Let this element be acted upon by three sets of tensile or normal stress, σ_r, σ_θ, σ_z, as shown. Because of symmetry, there can be no shear stress on the surfaces of the element which are normal to σ_z and σ_θ. The absence of shear stresses on the two cylindrical surfaces is discussed later.

In order to solve for the three unknowns, σ_r, σ_θ, and σ_z, three condition equations must be set up. These conditions are:

1 There must be equilibrium of forces in the radial direction

2 There is no axial creep of the thick cylinder found experimentally

3 There is no volume change in creep phenomenon.

Several assumptions are being made either explicitly or implicitly:

1 That the relation between minimum rate of creep in shear, ϕ, and the shear stress, τ, is

$$\tau = a + b \log_e \phi$$

(A solution is also obtained by Mr. Bailey (15) on the assumption that $\log_e \tau = a' + b' \log_e \phi$.)

2 That the artifice can be employed that the addition of a hydrostatic stress does not influence creep.

3 That the stress components σ_θ and σ_z are independent of θ and z. This reduces the number of equations of equilibrium to one, that in the radial direction.

4 That plane transverse sections remain plane and parallel.

5 It is further assumed in this problem that the creep rate has become steady and has attained its minimum value.

EQUATION I. The condition for radial equilibrium of forces is

$$(\sigma_r + d\sigma_r)(r + dr)\, d\theta - \sigma_r r d\theta - 2\left(\sigma_\theta dr \cdot 1 \sin \frac{d\theta}{2}\right) = 0$$

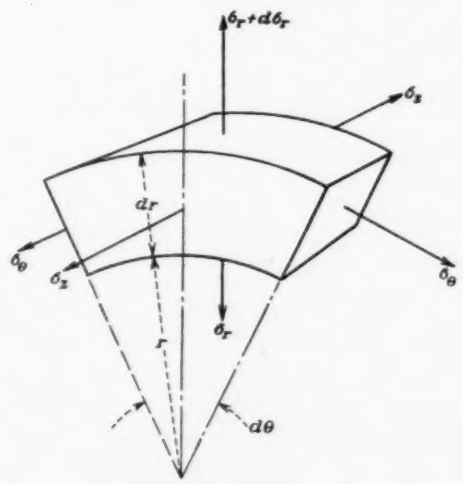

FIG. 15

Neglecting products of differentials and noting that $\sin \frac{d\theta}{2} = \frac{d\theta}{2}$, approximately, for small angles, the above equation reduces to

$$\sigma_r - \sigma_\theta + r \frac{d\sigma_r}{dr} = 0 \quad \text{..... [I]}$$

EQUATION II is based on the condition that there is found by experiment to be no axial creep in the thick cylinder. Let us first add a hydrostatic compressive stress of arbitrary magnitude $-\sigma_r$ to all faces by virtue of assumption 2; then the resulting system of stress is that pictured in Fig. 16.

On the basis of assumption 4, we are justified in dividing the thick tube up into thin tubes, the axial deformation of every one being the same, and also equal to zero, with no shear forces between the cylindrical surfaces. We can therefore imagine that Fig. 16 represents an element from a thin-walled tube subjected to an internal pressure $d\sigma_r$. The condition that there be no axial deformation or creep in this or any thin-walled tube is that the circumferential stress be twice the axial stress. Consequently,

$$\sigma_\theta - \sigma_r = 2(\sigma_z - \sigma_r) \quad \text{..... [II]}$$

EQUATION III is based on the condition that there be no volume change. Since there is no axial deformation of the cylinder,

the cross-sectional area included between any two circles must remain constant before and after creep.

Let

c_1 = circumferential or diametral creep rate at inside of cylinder in inches per inch per hour
c_2 = same at outside of cylinder
c = same at any radius r.

Between any two circles, the area after creep = area before creep.

$$\pi[(1 + c)r]^2 - \pi[(1 + c_1)r_1]^2 = \pi r^2 - \pi r_1^2$$

Neglecting the squares of the creep rates, c^2 and c_1^2,

$$c = c_1\left(\frac{r_1}{r}\right)^2$$

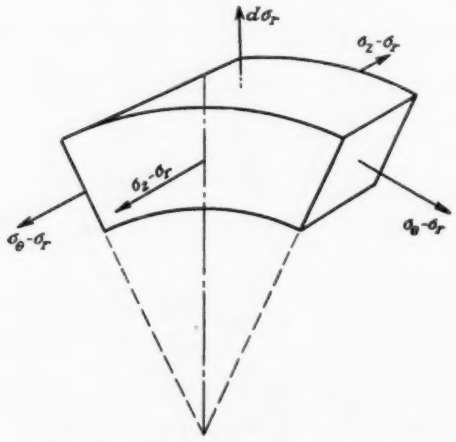

FIG. 16

This can be extended similarly to read

$$c = c_1\left(\frac{r_1}{r}\right)^2 = c_2\left(\frac{r_2}{r}\right)^2 \quad \text{[III]}$$

This equation can be expressed in terms of the creep rate in shear by substituting

$$c = \frac{\phi}{2},\ c_1 = \frac{\phi_1}{2},\ c_2 = \frac{\phi_2}{2}$$

There results

$$\phi = \phi_1\left(\frac{r_1}{r}\right)^2 = \phi_2\left(\frac{r_2}{r}\right)^2 \quad \text{[IIIa]}$$

The reason for introducing shear into this problem is because the term $\sigma_\theta - \sigma_r$ can be expressed directly in terms of the rate of creep in shear as found from experiment.

To see this, suppose, to the system of stress represented in Fig. 16, with the additional condition of Equation [II] that

$$\frac{\sigma_\theta - \sigma_r}{2} = \sigma_s - \sigma_r$$

and neglecting $d\sigma_r$ for the time being, we add a hydrostatic pressure of intensity $(\sigma_\theta - \sigma_r)/2$, we then get the system of Fig. 17. But from a preceding argument, we see this is a stress distribution resulting from pure shear. Experimentally by means of torsion tests a relationship can be established between the rate of creep in shear, ϕ, and the shear stress, $\tau = (\sigma_\theta - \sigma_r)/2$. This relationship, we are assuming as per assumption 1, is $\tau = a + b \log_e \phi$, or

$$\log_e \phi = \frac{\sigma_\theta - \sigma_r}{2b} - \frac{a}{b} \quad [a]$$

Reducing Equation [IIIa] to the logarithmic form, we have

$$\log_e \phi - \log_e \phi_1 = 2 \log_e \frac{r_1}{r}$$

$$(\sigma_\theta - \sigma_r) - (\sigma_{\theta'} - \sigma_{r'}) = 4b \log_e \frac{r_1}{r}$$

where $\sigma_{\theta'}$ and $\sigma_{r'}$ are the transverse and radial stresses at the inner surface. But at this surface, $\sigma_{r'} = -p$. Then

$$(\sigma_\theta - \sigma_r) - (\sigma_{\theta'} + p) = 4b \log_e \frac{r_1}{r} \quad \text{[IIIb]}$$

The problem now consists in solving for σ_θ, σ_r, and σ_s in terms of r by the use of Equations [I], [II], [IIIb], and the proper boundary conditions. The results are those stated by Equations [IV], [V], and [VI].

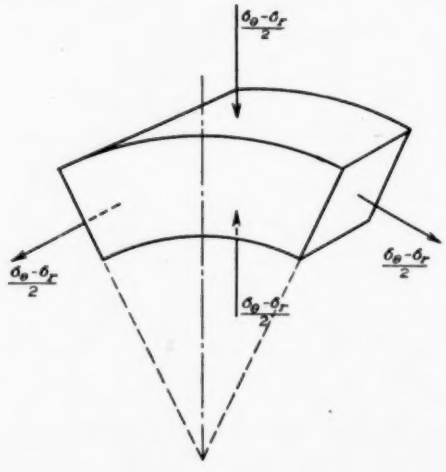

FIG. 17

BIBLIOGRAPHY AND REFERENCES

In compiling this Bibliography, no attempt has been made to give a complete list of the literature on creep of metals, a major portion of which is concerned with the experimental side, but rather to mention principally those articles of recent date which pertain to applications of creep data in design problems. A rather complete bibliography is contained in the symposium referred to in Item (14) below.

For the sake of brevity, the first fifteen items are the references appearing in parentheses in the text; a few of them refer to specific pages in an article or book mentioned.

Both of the above writings of Dr. Nadai contain references to the literature of creep not mentioned here.
Allen, R. C., "Strength of Turbine Materials for High Temperatures," paper in symposium mentioned in Item 14. Discusses on p. 30 the design of bolts.
Lea, F. C., and Parker, C. F., "The Effect of Temperature on Some of the Physical Properties of Metals," *Engineering*, Jan., 1932, vol. 133, pp. 23, 54. Presents some recent experimental work, including certain experiments where torsion was employed.

Discussion

P. G. McVetty.[4] A survey of the literature on creep of metals reveals a considerable amount of experimental data on the creep of steels under stress at elevated temperatures. Up to the present time, however, relatively little has been published to show the application of creep data to specific cases of high-temperature design. Such applications require necessarily the extrapolation of creep curves and various assumptions as to the laws governing creep. The author has rendered a real service in bringing together the methods proposed by Baumann and Bailey in addition to the results of his own work. These analyses indicate methods of attack which may be applied to other problems which arise in practice.

It seems desirable to emphasize one point of great importance relative to the temperature which is assumed to represent service conditions. Experiment shows that the creep rate is particularly sensitive to temperature changes. If, for example, the temperature rises to 875 F when a value of 850 F has been assumed, we may expect an increase in the creep rate of as much as 6 to 1. This should be kept in mind in any application of creep data so that sufficient allowance is made for possible temperature fluctuations. On this account, designs are usually based on maximum rather than on average service temperatures.

In reference to the permissible creep rates suggested by Baumann for various parts of a steam plant, a distinction must be made between average and minimum creep rates. A study of Baumann's paper shows that these rates are obtained by dividing the total permissible deformation by the time in service. The resulting average rate may be quite different from the minimum rate used in the flanged joint problem. In this connection, Baumann mentions the test of a particular bolt material in which the creep in the first 200 hours is as great as that during 5000 hours at the minimum rate. He also suggests a preliminary treatment for bolts to carry them through the first stage of creep prior to their use in flanges. This has an important bearing on the relaxation problem, since the rapid initial creep causes a more rapid lowering of stress than is obtained from the assumption of a minimum creep rate. This distinction is necessary also in applying published creep rates from various sources, since the term may refer either to an average or a minimum value.

In the flanged-joint problem, the statement is made that the life of the joint may be prolonged by increasing the flexibility of the flange relative to that of the bolts above the assumed value of $q = 2$. This is true only if the change can be made without increasing the creep of the flange. Otherwise a rapid decrease of joint life may result from increased flange flexibility. Further study of the behavior of such joints at high temperature with special reference to flange creep would be of great help in the quantitative analysis of this problem.

The author makes use of the formula, $\sigma = a + b \log_e c$, to express the relation between stress and minimum creep rate at a given temperature. Perhaps it should be mentioned that this relation is only true over a limited range of creep rate. The accurate measurement of such rates below 10^{-7} in. per in. per hr is extremely difficult, and it would be interesting to know the extent of extrapolation involved in Figs. 7 and 9. It might be mentioned that Professor Norton and others have found a linear relation between logarithm of creep rate and logarithm of stress.

This lack of agreement among investigators suggests a critical attitude toward the extrapolation of curves representing such mathematical expressions. The only definite conclusion possible at the present time is that any assumed relation between stress and creep rate must be considered as tentative and subject to revision as our knowledge increases. This applies not only to the fundamental laws governing creep of metals, but also to the proof that such laws apply to commercial alloys.

T. H. Swisher.[5] The writer wishes to call attention to the fact that the value of the modulus of elasticity of steels at elevated temperatures is subject to considerable variation, depending upon the rate of loading.[6] Recently, in our laboratory, a test was made which is of interest in this connection.

A bar of chrome-molybdenum-silicon steel had been under a flow-rate test for 2300 hr at 550 C (1022 F). It had a plastic flow of 1.1 mils per inch, and with a stress of 4300 lb per sq in. was flowing at the rate of 2 per cent in 100,000 hr.

The stress was dropped to 1000 lb per sq in. and the bar immediately shortened 0.13 mil per inch, giving a modulus of

$$(4300 - 1000) \times \frac{1000}{0.13} = 25{,}400{,}000$$

Seventeen hours later the bar had shortened a total of 0.27 mil per inch, giving a modulus of 12,200,000. At the end of 180 hr the bar had shortened a total of 0.34 mil per inch, giving a modulus of 9,700,000.

From this it may be concluded that our information on the modulus of elasticity at elevated temperatures is still somewhat meager. This situation adds further complication to the calculation of flow problems.

Author's Closure

Mr. McVetty very well summarizes the purpose of the paper when he says, "These analyses indicate methods of attack which may be applied to other problems which arise in practice."

[4] Westinghouse Research Laboratories, East Pittsburgh, Pa. Mem. A.S.M.E.

[5] Research Engineer, General Electric Co., Schenectady, N. Y. Jun. A.S.M.E.

[6] "The Modulus of Elasticity of Steel at High Temperatures," by Dr. E. Honegger, *Brown-Boveri Review*, July-August, 1932.

With this as a primary purpose, some of the practical details of creep applications were underemphasized or slighted by the author. Mr. McVetty's comments therefore furnish a valuable supplement to the paper. Before applying the formulas developed, the designer should become thoroughly familiar with such limitations as suggested by the discusser and also by others to be found in many of the references cited in the footnotes and bibliography.

Mr. Swisher presents information concerning the effect of the rate of loading upon the modulus of elasticity. This has a pertinent bearing on the choice of modulus of elasticity to be used in such problems as discussed in the paper.

APM-55-13

Factors Affecting Choice of Working Stresses for High-Temperature Service

By P. G. McVETTY,[1] EAST PITTSBURGH, PA.

This paper discusses the various methods which have been proposed to determine safe working stresses for high-temperature service. The question of the stability of alloys during the test and in subsequent service is considered, with particular emphasis upon probable changes in creep characteristics during long exposure to stress and temperature. It is shown that published data in general do not admit of extrapolation, and that attempts to estimate total creep in service from such data are not usually satisfactory. The author stresses the need for more fundamental study of the laws governing creep rather than creep tests of many different materials.

IT WAS just ten years ago that a paper[2] was presented before this Society which did much to awaken interest in the advantages to be derived from the use of higher temperatures in the steam power plant. At that time it was shown that progress in power-plant design was seriously hindered by lack of reliable information regarding the properties of metals at elevated temperatures. In other fields a similar condition existed, particularly in the oil-refining and chemical industries, and attention was focused upon the tests intended to furnish the desired information. Within two years a symposium[3] was held at a joint meeting of the A.S.T.M. and the A.S.M.E. at which available information on metals and test methods was presented and discussed. The need for a definite program of research was so apparent that the two societies cooperated in the establishment of a Joint Research Committee on the Effect of Temperature Upon the Properties of Metals. Since that time many papers have been published giving the results of an immense amount of work here and abroad. Reference may be made to bibliographies published by this Society in 1928 and 1931, to the second symposium and additional bibliography also in 1931, and to the abstracts published monthly in *Metals and Alloys*.

Two books[4] on creep have helped to summarize the state of our knowledge of this subject. The latest contributions to the literature,[5] together with the extensive discussion which they brought out, are worthy of the most careful study.

It is to these sources of information that the designer naturally turns for guidance in solving the practical problems relating to choice of materials and working stresses for high-temperature applications. After all the work which has been done, he feels justified in expecting to find standardized test methods and a continually increasing fund of reliable, correlated data suitable for design purposes. Unfortunately, this expectation has not been fully realized because of the large number of variables which influence the properties of metals under service conditions, and the time required to investigate the effects of these variables.

A study of the literature for the purpose of collecting and correlating all available information soon reveals the difficulty of the task. Testing methods have not been standardized and the data from different investigators are rarely comparable. The demand for useful information has been so insistent as to stimulate tests of promising materials under prescribed conditions rather than studies of the fundamental laws governing the problem.

Some work of the latter type has been done, but the complexity of the variables has necessitated assumptions which may not be tenable in many cases. It is the purpose of this paper to discuss the validity of some of these assumptions and to show that the use of creep data requires a clear understanding of the effects of test and service conditions and methods of interpretation.

I—Methods of Estimating Safe Working Stresses

Of the many tests which have been proposed, it is now generally agreed that the long-time or "creep" test is the most reliable basis for estimates of working stresses. Whether this be made to determine the effects of stress in tension, shear, or otherwise, we have fundamentally a measurement of strain in the direction of the applied stress while the stress itself and the temperature are kept essentially constant. Up to the present time most work has been done in tension, although creep is generally considered to result from slip along shear planes. Fig. 1 shows a family of tension creep curves for various stresses at the same temperature.

A similar set of curves may be obtained from tests at the same stress and a series of temperatures. Each test requires a different test specimen, all of which must be as nearly alike as possible in order to preserve the proper relations among the several tests.

At the higher stresses or temperatures represented by curves *d* and *e*, a transition point is found, beyond which the rate of creep increases. Experience indicates that a continuation of test *c* leads to a similar transition after a considerable time. It is reasonable to expect then that curves *a* and *b* will do the same if the test is sufficiently prolonged. Since the selection of the working stress usually depends upon keeping the deformation within a fixed limit during the expected life of the material, it is necessary either to extend the tests to times as great as 20 years or to resort to some method of extrapolation. In general, the latter is the only practicable course, and it is here that the designer must exercise great care. A test extending over a few thousand hours at most is often extrapolated to 100,000 hr or more. The term "creep rate" may mean the minimum rate at the inflection point, the minimum rate measured during the test, or the average rate from the beginning of the test. In any case, the implied constant rate is not realized in practice and a statement that the creep is 0.001 per cent in 1000 hr cannot be interpreted to mean 0.1 per cent in 100,000 hr. These facts are well known, but they are often neglected in the application of charts similar to Fig. 2 which put creep information into a form convenient for design use,

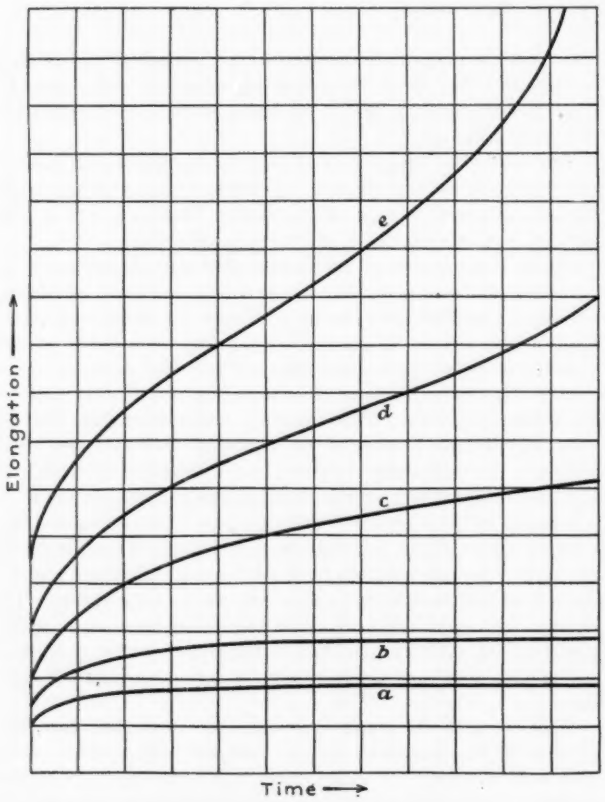

FIG. 1 CREEP CURVES FOR VARIOUS STRESSES AT SAME TEMPERATURES

When this chart is considered by itself, the inference that a definite rate of creep is associated with each combination of stress and temperatures is unmistakable. The designer is tempted to divide his total allowable deformation by the expected life to obtain an average rate similar to those represented by the curves. Whether the chart was originally based upon average or minimum creep rates, this method of extrapolation is not justified by the form of curve shown in Fig. 1.

An additional problem is presented in many applications in which the allowable creep is less than that indicated by the curves. Reference to the original data in the form of creep curves fails to show a rational basis for extrapolation which is generally applicable. By making certain assumptions, it is possible in any particular case to extrapolate into the field of smaller creep. However, the validity of each assumption is questionable and an attempt to add curves for smaller creeps to Fig. 2 requires careful consideration of the possible errors involved.

One common assumption is that a straight-line relation exists between the logarithm of the creep rate and the logarithm of the stress in tests at any one temperature. Many curves plotted in this way appear to confirm this linear relation. Other investigators plot the logarithm of the creep rate against the stress itself and again find a linear relation. In either case, extrapolation of the straight line to extremely small creep rates gives what appears to be an easy method for extension of the range of Fig. 2. Obviously the two methods cannot agree, and the error lies in the assumption that a certain creep rate is associated with a given combination of stress and temperature. Furthermore, it is evident from Fig. 1 that total creep at the end of a given time is not obtainable directly from any measured creep rate.

Since simple methods of extrapolation are not applicable to the general case, it appears necessary, in the present state of our knowledge, to go back to a study of the original creep curves in order to estimate the total creep which may be expected in any particular case. A consideration of these fundamental curves does much to explain the difficulty of correlating existing data.

II—THE CREEP TEST

Fig. 3 shows a family of creep curves similar to those in Fig. 1. These indicate the general nature of creep at the same temperature and six different stresses. The portion of the curves to the left of line *M–N* represents the relations revealed by actual tests, while that to the right represents what may happen in service in times greater than the duration of any test. At the higher stresses, transition points such as *a*, *b*, and *c* are frequently found. The measured minimum creep rates at these points are sometimes used in extrapolating to lower rates at lower stresses, as in the construction of charts similar to Fig. 2. All experimental evidence indicates that similar transitions such as *d* and *e* would be found if the tests were sufficiently prolonged. The same reasoning leads to a statement that any creep curve such as *F* or *G* will have a creep rate gradually decreasing to a minimum, beyond

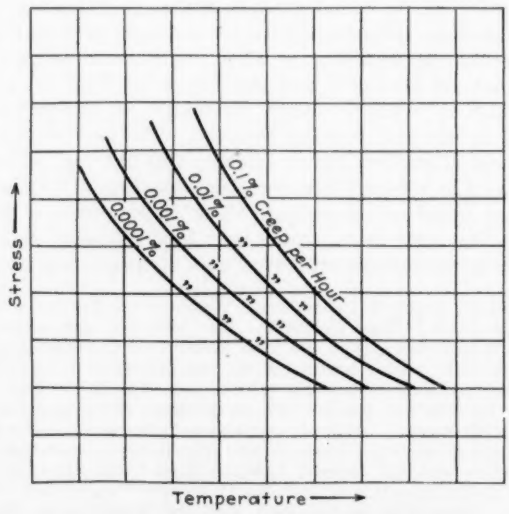

FIG. 2 CURVES OF CONSTANT CREEP RATES

which the rate will increase. If service conditions are such that this transition point is not reached within the life of the material, the estimated total creep from the curves will be on the safe side. This places considerable importance upon the location of the curve R–S joining the several transition points. On account of the time required to locate transitions at the lower stresses, very little is known about this curve. It is evident that any estimate of total creep at the end of ten to twenty years based upon creep curves extending over a few thousand hours requires consideration of such transition points.

The form of the known curves A and B in Fig. 3 indicates the action of two opposing forces, one diminishing and the other increasing in magnitude as time goes on. The transition points a and b represent a temporary balance of the two forces. In the simplest case we may assume that the adjustment of stress over the cross-section causes relatively large deformation of a few crystals in the first stage of creep. The resulting strain hardening reduces the rate of deformation toward what appears to be a constant creep rate when the stress has been uniformly distributed. As time goes on the cumulative effect of time and temperature relieves this strain hardening and causes a gradually increasing creep rate. Applying the same reasoning to curves representing lower stresses, we may conclude that curves F and G, Fig. 3, will act similarly if exposed to stress and temperature for a sufficient length of time. Under these conditions it is difficult to see how any so-called "creep rates" taken from relatively short creep tests can offer a rational method of extrapolation to times representing the service life of the material. If working stress must be based upon allowable deformation, due consideration should be given also to the first and third stages of creep.

III—Stability of Alloys in Service

It has been shown by Bailey and Roberts[6] that plain carbon steels undergo a change in the carbide from the lamellar to the spheroidized form during long exposure to elevated temperature. Their experiments show a considerable increase in the creep rate after this change has taken place. From this we may expect an increase in creep rate of such materials at the end of a time which may be greater than that represented by any ordinary creep test unless precautions are taken to stabilize the material prior to its use. Much further investigation is necessary to determine the extent of this structural change in service.

Complex alloy steels of the type usually recommended for high-temperature service are particularly subject to internal changes. Age hardening in service is a familiar example. A gradually increasing strength would tend to decrease the creep rate. An investigation of this phenomenon has shown that the hardening effect proceeds to a maximum value, after which it decreases toward a stable condition. The time required to reach the maximum may be short or long, depending upon the temperature. If the maximum is not reached during the creep test, we have an effect opposing the normal creep during the test, but tending to add to the creep effect in subsequent service. A creep rate measured under these conditions is decidedly misleading.

Another possibility is an actual volume change under the action of stress and temperature. Several investigators have found what appeared to be negative creep rates. This cannot be due to age hardening, and it must be explained by actual shrinkage of the material. When such shrinkage exceeds the creep, the negative readings serve as a warning, but when slightly less than the creep, a dangerous interpretation of the resulting low creep rate may result.

[6] R. W. Bailey and A. M. Roberts, "Testing of Materials for Service in High-Temperature Steam Plant," Proc. Inst. M.E., vol. 122 (1932), p. 209.

These disturbing influences cannot be ignored in the interpretation of creep tests. When the test is conducted at constant stress and temperature while deformation is measured as a function of time, conclusions must be based on the assumption that no other uncontrolled variables are operating. If the creep test is to have rational interpretation, the same care in controlling other variables must be used as is now employed to control temperature.

Any attempt to add high-temperature strength which makes the alloy unstable under service conditions is undesirable. This statement applies to cold work, age hardening, or other processing

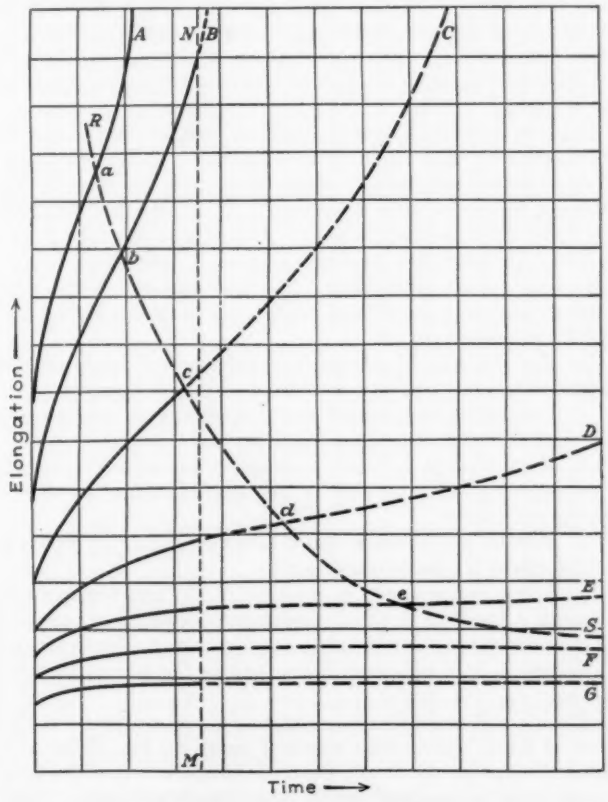

Fig. 3 Extrapolated Creep Curves

of the material. Unless great care is used, these treatments may impart a temporary creep resistance which is not maintained in service.

IV—Need for Fundamental Research

The difficulties inherent in the conduct and interpretation of creep tests have been mentioned primarily to emphasize the importance of investigating the fundamental laws involved. For example, Tapsell[7] states that "anything like a correct estimation of the total deformation in, say, 50,000 hr based on a 1000-hr test would appear to be a matter of chance." In their recent paper Bailey and Roberts[8] attack the wide use of minimum creep rates in the following statement: "It will be clear that at temperatures of interest in connection with steam power plant and in cases where small creep only is permissible, no practical extrapolation of minimum creep-rate data of the kind plotted in Fig. 40 (temperature versus logarithm of minimum creep rate,

[7] H. J. Tapsell, "Creep of Metals," p. 171.

[8] R. W. Bailey and A. M. Roberts, "Testing of Materials for Service in High-Temperature Steam Plant," Proc. Inst. M.E., vol. 122 (1932), p. 264.

curves of constant stress), or plotted against stress, or logarithm of stress, the temperature being constant, is likely to lead to satisfactory working values of stress and temperature. Such extrapolation will result in stresses and temperatures too high for safety." Statements of this kind from recognized authorities cannot fail to warn the designer against acceptance of test data without careful consideration of the methods used. They serve a further useful purpose in stimulating interest in the more fundamental aspects of the problem.

Before making extensive creep tests, it seems desirable to study the factors affecting the stability of the material not only during the test, but also in subsequent service. This is primarily a metallurgical problem involving the equilibrium of the alloy constituents under conditions existing in service. This phase of creep testing deserves much more attention than it has received in the past.

Another promising method of attack requires creep tests at temperatures higher than those of service. It is conceivable that a testing temperature might be selected at which all the changes associated with a service life of many years might be crowded into a period of 1000 hr. This suggests a study of the relation between time and temperature in producing definite amounts of total deformation. The establishment of this relation would lead to a rational accelerated creep test having the following advantages:

1 The stress and resulting total deformation would be the same in the short test as is considered allowable in service.

2 The higher temperature would accelerate all the internal changes which affect deformation in service.

3 Results would be based upon the attainment of a definite increase in length rather than on the measurement of extremely small rates of flow.

4 Tests at higher temperatures would furnish direct evidence of the effects of overheating in service.

5 Extrapolation would be confined to the time-temperature relation. As means of initial stabilization become better known, this would lead to the establishment of laws applicable to groups of materials, with the possibility of finding the general laws involved.

There is still much that is speculative in our conception of the laws of creep. The recent excellent paper by Dr. Nadai[9] has done much to express clearly the fundamental nature of the laws involved and to point the way for further analytical study. This type of study of reliable test data from carefully prepared test specimens appears to offer great promise of useful results. One of the most important phases in this field is the study of combined stresses. This includes not only the usual combinations of tension, compression, and shear, but also the effects of vibration and impact upon creep. Some work has been done on high-temperature fatigue tests, but much study is still required of the case in which the stress varies in intensity but not in direction. Another field of investigation would determine the effects of various surrounding atmospheres such as superheated steam or flue gas. A methodical study of these problems may well be considered as desirable fundamental research.

V—Conclusions and Recommendations

The growing needs of the designer furnish ample incentive for further study of the laws of creep. It is only in this way that we may cope with the problems of the future. However, an immediate pressing need confronts us in the selection of working stresses to be used in present designs. It is impossible to wait for further tests, and we have but to consider the advances in design of the past ten years to be convinced that there is real value in the data available. In attempts to summarize and correlate all these data, a few precautions may serve as a guide toward rational conclusions.

In general, the original creep curve offers the most reliable basis for estimating deformation in service. From it, allowance may be made for initial creep, together with provision for the probable effects of test and service conditions. The actual procedure involves extrapolation of the final tangent of the creep curve to the deformation corresponding with the expected service life. The possibility of a transition in the creep curve must be carefully considered in connection with the occurrence of such transitions at higher stresses and temperatures. The factor of safety must include the large effect of even slight overheating in service.

Many of the published data give creep rates such as 1 per cent in 100,000 hr. These rates appear to represent a certain stress and temperature, and their relative value depends on uniformity in the method of extrapolation. In general, they are more useful for comparing materials than for assigning working stresses. In any case, the method of measuring creep rate must be known before comparing data from different sources.

In the use of test data, preference must be given to those representing maximum care in the conduct of the test. The necessary refinement of test methods is directly related to the permissible deformation, and it is obviously wrong to accept data not suited to the particular application.

With these precautions in mind, it is possible to select from the literature the data most suitable to the problem at hand. When due regard is paid to the variables involved, extrapolation loses much of its uncertainty. For some time to come it is probable that design will err on the safe side. The prospect for increased working stresses will depend upon the extent of study of the laws involved and their application to practical problems.

VI—Acknowledgment

The author wishes to acknowledge his indebtedness to Dr. A. Nadai and Mr. R. E. Peterson for their unfailing interest and many helpful suggestions and criticisms.

Discussion

Pierre de Bethune.[10] The writer would like to emphasize the point made by the author that the creep curves indicate "the action of two opposing forces," and to present a more accurate analysis than that given in the paper, because it is his belief that the solution of the creep problem lies in a critical examination of the form of the creep curves.

Referring to Fig. 4, the fact of two opposing forces may be expressed by decomposing the curve of creep into two components, curves 1 and 2. The form of curve 1 suggests the elastic after-effect. If this were true we could apply the author's statement that "the adjustment of stress over the cross-section causes relatively large deformation of a few crystals in the first stages of creep." Of course the movement ends not only on account of the strain hardening of those grains, but also because their overstressing has simultaneously been reduced.

The writer would not consider curve 1 as due only to an elastic after-effect, because in this case the deformation is mostly elastic, only a few grains being deformed plastically, and therefore the amount d of the deformation should be small. He would more likely consider that the plastic deformation reaches every grain in the metal. In this case the discontinuance of the deformation is due only to strain hardening, this effect becoming more and more important as time progresses and reducing relatively the speed of deformation.

[9] A. Nadai, "The Creep of Metals," A.S.M.E. New Haven Meeting, June, 1932.

[10] Louvain, Belgium.

Curve 2 represents what should really be the creep of the metal. This has been drawn with an increasing rate of creep, but the changes suggested in section III of the paper, Stability of Alloys in Service, will introduce irregularities into the form of the curve.

The deformation in this case can be ascribed to an intergranular or an intragranular mechanism. The author believes that "the creep is generally considered to result from slip along shear planes," which means intragranular deformation. The writer is

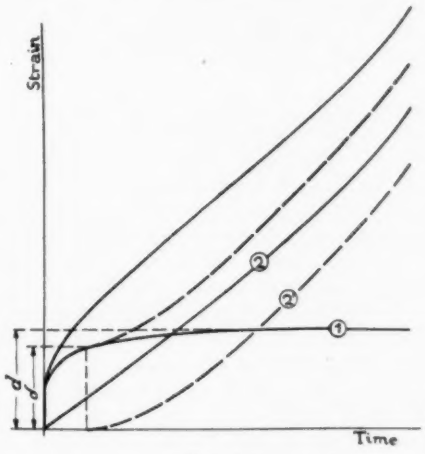

FIG. 4

much inclined toward this latter hypothesis, but would not underestimate a priori the possibility of the former.

However, in this latter hypothesis, as the author points out, the creep requires the relief of strain hardening. Since his introduction of time and temperature may seem in certain respects arbitrary, the writer will call attention to a number of facts set forth by many metallographers which seem to afford a physical explanation of this phenomenon.

The strain hardening is due mostly to the cessation of the slipping along each slip plane. The movement then continues along another slip plane, and so on up to the point where the slip lamellae become sufficiently thin. The manifestation of further slipping requires a raising of the stress. This cessation of slipping along individual slip planes has not as yet been explained satisfactorily, but it is undoubtedly related to the lattice distortion near the slip plane shown by the experiments of Joffé,[11] Dehlinger,[12] Sinkiti Sekito[13] and others.

Next to this study of cold working of metals, attention must be called to the relation existing between recrystallization and the amount of cold working. The work of many metallographers has shown that in the case of cold-worked metals the recrystallization brought about by raising the temperature begins at temperatures even lower than the general transition points.

It is thought, therefore, that this recrystallization may obliterate the distortion of the lattice due to the slipping. The crystal lattice will be restored in an unstrained state, thus allowing for further movement without increase of the stress.

This would explain curve 2,[14] the rate of creep depending on the speed of plastic deformation and of recrystallization.

No definite proof of these views has yet been given, and no relation has yet been shown to exist between creep and recrystallization limits, but the writer believes that research based on them as a working hypothesis should lead to interesting results.

D. S. JACOBUS.[15] The author points out the difficulty of interpreting data secured from creep tests and states that the growing needs of the designer furnish ample incentive for the further study of the laws of creep. There is certainly a broad field yet to be covered; in the meantime the designer is forced to proceed on the basis of our present knowledge.

Four or five years ago published results for the stress to produce creep at higher temperatures caused apprehension in regard to stresses that were in use. This led to a paper entitled "Working Stresses for Steel at High Temperatures," which the writer presented at the Annual Meeting, December, 1929. In this paper the stresses were based on the results secured in practice and the results of creep tests were used to set the stresses for higher temperatures than those for which actual operating data were available, so as to give a set of working stresses for plain carbon steel up to temperature of 950 F for drums of boilers and pressure vessels and for superheater headers.

The stresses were based on what had been found suitable through long use in boiler and superheater practice and on data secured from oil stills, the first of which was constructed about 10 years before the time of writing the paper. The superheater and oil-still data established a working stress of 8000 lb per sq in. at 800 F for steel having a minimum tensile strength of 55,000 lb per sq in.

An abstract of the paper giving the proposed working stresses was published in *The Metallurgist* (supplement to *The Engineer*, London), March 28, 1930.

The working stresses specified in the A.S.M.E. Boiler Code for plain carbon steels at high temperatures are in substantial agreement with those given in the writer's paper for the same grades of steel, and for other grades they are in line on the basis of creep-test values.

Table 1 is a copy of Tables P-6 and U-3 of the A.S.M.E. Boiler Code. Opinions regarding the correctness of the values given in this table would be appreciated.

TABLE 1 WORKING STRESSES FOR DRUMS OF BOILERS AND PRESSURE VESSELS AND FOR SUPERHEATER HEADERS CONSTRUCTED OF PLAIN CARBON STEEL

Max. temp., deg F	Minimum of specified range of the tensile strength of the material, lb per sq in.				
	45,000	50,000	55,000	60,000	75,000
700	9,000	10,000	11,000	12,000	15,000
750	8,220	9,110	10,000	11,200	13,000
800	6,550	7,330	8,000	9,000	10,200
850	5,440	6,05	6,750	7,400	8,300
900	4,330	4,830	5,500	5,600	6,000
950	3,200	3,600	4,000	4,000	4,000

It should be borne in mind, as brought out in the paper referred to, that the working stresses which are given are for the constructions specified and that they are not universally applicable. In certain types of apparatus where the life is less than in a boiler, higher stresses may be used to advantage, whereas in other types the working stress should be lower.

F. N. SPELLER.[16] The author brings out clearly the need for more fundamental research on the factors affecting the creep values of metals at high temperatures; particularly is this necessary in connection with the changes that occur in the properties

[14] It seems to result from certain experiments that the recrystallization requires some strain, irrespective of the stress responsible for that strain. This is represented by shifting of curve 2 to curve 2', creep beginning only when the deformation along curve 1 has reached the critical value δ.

of steel at elevated temperatures with time. In this connection, it is quite important to know how to put the metal in the most stable condition in a relatively short time so that no material change affecting its physical properties will occur during the period of the creep test or the life of the metal in service.

It seems highly desirable before undertaking a more extensive creep-test program for all concerned to agree upon a tentative standard of procedure. With this in mind the American Petroleum Institute recently appointed a small committee with powers to cooperate and act with the Joint Committee on Effect of Temperature on the Properties of Metals and the tube manufacturers, with a view to arriving at a definite specification as to the procedure. While this perhaps cannot be completely accomplished at present, it will nevertheless be a forward step. With a better understanding of the factors that are now known to affect creep, refinement of equipment, and methods of controlling and measuring temperatures and elongation, much more reliable results may be expected.

In this connection it may be stated that the Metallurgical Advisory Board of Pittsburgh expect to be able to continue next year their cooperative investigations of the effect of inclusions on the physical properties of steel. The results obtained on control of non-metallic inclusions in steel and their influence on the properties of the metal may prove of interest in connection with high-temperature testing, although the work was originally undertaken to obtain closer control of the physical properties of steel in the lower range of temperature. Samples of carbon steels with various amounts and kinds of inclusions are available for creep investigation. The creep of metals is an ideal subject for cooperative research on account of economy, efficiency of operation, and general application of results. When the procedure has been standardized and a program of tests carefully prepared in detail, there should be no trouble in getting the necessary funds from those interested to carry on work to obtain reliable data on this important subject.

Author's Closure

The author is quite in agreement with Mr. de Bethune's statement that the solution of the creep problem lies in a critical examination of the form of the creep curves. So long as practical considerations make it necessary to extrapolate such curves over intervals as great as one hundred times the length of the usual creep test, it is necessary to analyze the various factors which may influence the relations among the four variables of strain, time, stress, and temperature. The results of considerable work in this direction will be given in a later paper.

The statement that curve 2 in Fig. 4 represents the real creep curve in which velocity increases with increasing time may be somewhat disturbing to the designer. For applications in which elongation is limited, the stresses are relatively low, and the creep curve may be represented by curve *G* in Fig. 3. It is probable that a very long time would elapse before the intersection of curve *G* with curve *R-S* and a greater time before an appreciable increase in velocity. This slow approach toward a minimum velocity at low stresses helps to justify the assumption that the creep curve may be replaced by a straight line in the neighborhood of the transition point. At higher stresses, the transition occurs within shorter periods of time, but the corresponding elongation is usually greater than would be permissible in practice.

In reference to the relation between recrystallization and the amount of cold working, this depends not only on temperature, but also on the time of exposure to the temperature. This might account for the increasing creep rate shown in curve 2 in Fig. 4. Unless precautions are taken to keep unit stress instead of total load constant, a similar effect would result from the decrease in cross-section which accompanies any increase in length of the test specimen.

Dr. Jacobus rightfully emphasizes the importance of utilizing to the fullest possible extent our present knowledge of creep properties of metals. The values given in his 1929 paper and in the A.S.M.E. Boiler Code have been most useful in boiler and superheater design, but they do not provide a means of estimating the deformation which may be expected to result from the use of the suggested working stresses. The author has considered primarily those applications in which allowable deformation is the criterion of safety. Bailey[17] has discussed this problem and has found for medium-carbon steels an approximate relation among the variables, tensile stress, temperature, and creep rate. In the same paper he gives a curve which allows extrapolation from 750 F to 1000 F where reliable data are available at 750 F. The approximate agreement with the values given in Table 1 is probably less important than the fact that Boiler Code values have been found satisfactory in practice.

Dr. Speller has mentioned the desirability of adopting some standard procedure for creep tests. Agreement on testing procedure requires compromises, since one application may allow 3 per cent creep in one year while another is limited to 0.2 per cent in 20 years. To cover such a wide range, several methods of measuring creep rate, controlling temperature, etc. may be necessary, and this adds difficulty to the problem of securing agreement on a single procedure. A tentative code has been prepared and is now being discussed by the Joint Research Committee. It is expected that this will be published in the near future.

The author has followed with great interest the work of the Metallurgical Advisory Board, of Pittsburgh, in connection with the influence of non-metallic inclusions on the properties of metals. The extension of this investigation to problems involving the use of metals at high temperatures opens a field of great practical importance. Up to the present time most high-temperature tests have been confined to very uniform material, on account of the necessity of restricting the variable factors to a minimum. As our knowledge of fundamental creep phenomena increases, the importance of other metallurgical factors such as the amount and kind of non-metallic inclusions must be recognized. Exploration of this promising field may account for some of the occasional peculiar test results which cannot now be explained.

APM-55-14

Notched-Bar Tests[1]

By MAX MOSER,[2] ESSEN, GERMANY

In the present paper the author discusses the influence of such factors as temperature, width, and geometrical similarity in dimensions of specimens on the impact values as obtained by means of the notched-bar test. Various shapes of specimens for notched-bar tests are compared and their impact values determined.

DURING the last few decades the notched-bar test has found application to a rapidly growing extent as one of the procedures for the mechanical testing of materials. In connection therewith, valuable research work has been performed by various investigators and this work has enabled the author of the present paper[3] to determine the relationship existing between the test results and the various conditions under which the tests have been made.

In so far as the evaluation of the results obtained from notched-bar tests is concerned, several difficulties are still being encountered, and it seems that they can be overcome only by adopting certain standards for conducting the tests. The nature of these difficulties will first be analyzed, after which will follow a description of the attempts that are being made in Germany to introduce a set of standards covering the notched-bar test, and to promote the reaching of an international agreement concerning the establishment of such standards.

The Present Situation and the Requirements to Be Met

When steel rods of different dimensions are subjected to a tensile test, the results will be the same for all specimens, provided that the latter have the same proportions. For instance, the specimens *a* and *b*, see Fig. 1 and Table 1, have the same ratio of 10 to 1 between gage length and diameter. But the tensile test offers still broader possibilities. The dimensions of the specimen *c*, Fig. 1, are not proportional to those of the specimens *a* and *b*. Specimen *c* has the same cross-section as specimen *a*, but its ratio between gage length and diameter is different, i.e., 5 to 1. Nevertheless the anticipated, comparable values are actually obtained.

TABLE 1 RESULTS OF TENSILE TEST FOR THE SPECIMENS *a*, *b*, *c* OF FIG. 1

	Specimen		
	a	*b*	*c*
Yield stress, σ_s, kg per sq mm	36	36	36
Ultimate strength, σ_B, kg per sq mm	64	64	64
Elongation, δ, per cent	$\delta_{10} = 22$	$\delta_{10} = 22$	$\delta_5 = 26$*
Contraction, ψ, per cent	47	47	47

* $\delta_5 = 1.2\delta_{10}$.

Conditions are different, however, for the notched-bar test. Each pair of notched-bar specimens in Fig. 2, either at the left or the right, has the same proportions between the dimensions of the two specimens. Nevertheless the results of the notched-bar tests obtained for the two specimens of each pair are far from being identical for the small and for the large specimen. This would not be objectionable if the impact values for the large and for the small specimens bore at least a definite ratio to each other. However, the quoted values indicate that even this is by no means the case. In consequence no conclusions can be drawn from the results of one notched-bar test that will be of any assistance in predicting the values to be obtained from another, not even when the specimens have proportional dimensions. (Compare the impact values given in Table 2 for the specimens shown in Fig. 2.) For the same reason it is not possible either to compare the results of tests made with different specimens. And this in spite of the fact that every governmental commission, every association, and every manufacturing company has its own particular type of specimen.

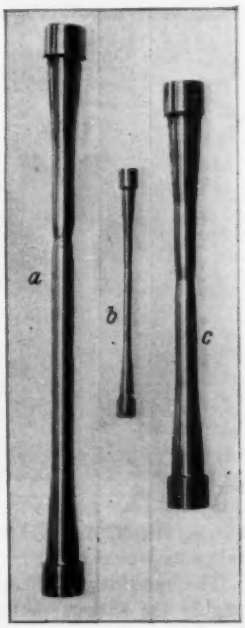

FIG. 1 LARGE AND SMALL TENSION TEST SPECIMENS (For test values see Table 1.)

A standardized method of dealing with problems relating to the strength of notched specimens is still lacking, not only in international testing procedure but also in that of the various countries.

What now is the significance of the present situation as set forth in the previous paragraphs?

It is true that when a higher or lower figure for the impact value is found, this is not a reason for reinforcing or weakening our machine or structural parts, nor does it constitute a criterion for judging the strength of those parts, because impact values are not a basis for designs. In other words, the notched-bar test does not give any practical design information. Nevertheless it is of value, because it makes possible, for instance, a comparison of the ductilities (toughnesses) of various grades of steel, and more

---

[1] Although questions concerning standardization of methods in testing materials do not strictly belong to the subjects of this symposium, it was felt that the present excellent review of some of the main factors which have a pronounced influence on the impact values as determined by notched-bar tests, kindly prepared by Dr.-Ing. Moser, an authority on the impact testing in Germany, should be brought before the American engineer. The Applied Mechanics Division is particularly calling attention of the engineers of this country to this subject because of the extended use the impact test has found in Europe as a quick method for controlling certain treatments of materials.

[2] Head of the Testing Laboratory (Probieranstalt) and the Material Acceptance Department of the Fried. Krupp Aktiengesellschaft, Gussstahlfabrik, Essen. Dr.-Ing. Moser was born at Brumath, Alsace, in 1873; he studied at the Universities of Strasbourg, Stuttgart, and Berlin, was graduated as a mechanical engineer, became assistant at the laboratories for testing materials at Stuttgart and Neubabelsberg, and later entered the service of Fried. Krupp at Essen, where he has remained ever since. He has published a great number of scientific papers on important problems, such as those concerning strength and rupture of materials, and is one of the first authorities on standardization of testing methods in Europe. He has particularly investigated the conditions determining the yield point of steel and the impact test. He is a co-author of the German Handbook on the rolling process, and is chairman of the committee on impact tests which presented a report before the International Association for Testing Materials at Zurich in 1931.

[3] Translated from the German by A. van Niekerk, Pittsburgh, Pa.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Dec. 5 to 9, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

particularly of steels at low temperatures. Further, being a typical aging test, it leads to certain conclusions concerning the metallurgical characteristics of steels. And finally, it affords the possibility of making a technological check test for the purpose of determining whether the material, especially steel, actually has the structure which it was assumed to have when it was selected for a certain machine or structural part.

TABLE 2 IMPACT VALUES (WORK PER UNIT OF AREA OF CROSS-SECTION) FOR THE NOTCHED-BAR TEST SPECIMENS *a*, *b*, *c*, *d* OF FIG. 2

Specimen	Impact value, kg per sq mm	Ratio
a	22.3	*a*:*b* = 2.1
b	10.6	
c	0.6	*c*:*d* = 0.75
d	0.8	

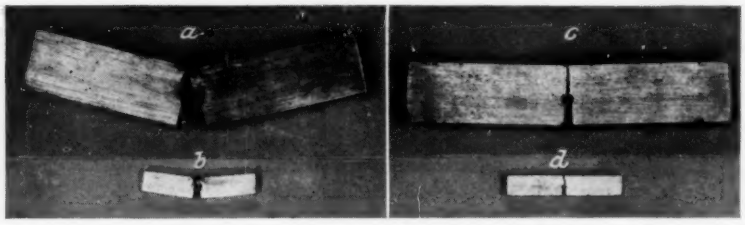

FIG. 2 LARGE AND SMALL NOTCHED-BAR TEST SPECIMENS
(For impact values of specimens see Table 2.)

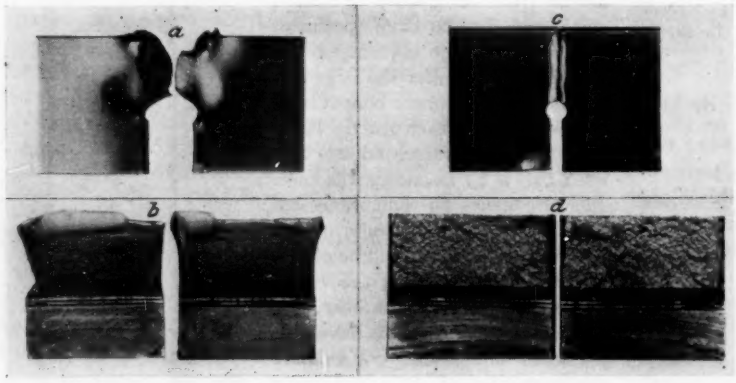

FIG. 3 SLIDING FAILURE (*a*, *b*) AND SEPARATION FAILURE (*c*, *d*)

The tendency, noticeable everywhere, to investigate thoroughly the characteristics and behavior of materials from the standpoint of impact testing, has its origin in the recognition that the notched-bar test is of decided value in connection with our attempts to make our designs perfectly safe.[4]

But the results of the research work carried out by individual investigators cannot be of general benefit, and their discussion cannot be of any value, unless the regrettable situation prevailing at present, as pointed out in the foregoing, is improved to such an extent that we shall be able to express all proceedings relating to notched-bar testing in a *uniform* language that will be readily understood by all those concerned, and will not leave the slightest doubt as to the true meaning of the terms and designations employed.

This means that all reports publishing test results, all comparisons, and all conclusions must be made on the basis of a definite, generally accepted, and uniform testing procedure; or, expressed in other words, we must *standardize* the impact or notched-bar test.

[4] See F. Rötscher and M. Fink, "The Notched-Bar Impact Values of High-Grade Construction Steels," *Z.V.D.I.*, vol. 76 (1932), no. 8, p. 173.

The adoption of a local standard for each individual country will be satisfactory when the organizations of cooperating interests do not expand beyond the frontiers of those countries. However, the iron and steel business is international in extent. For this reason it is quite interesting to note that the New International Association for Testing Materials, which held its First International Congress at Zurich in September, 1931, has designated the problem of standardizing the notched-bar test as one of the first problems that should be studied.[5]

It is well known that we have a specimen, the so-called Charpy specimen, which has been more or less considered as an international standard specimen. This Charpy specimen was very satisfactory from a testing standpoint, but on account of its size its use has fallen off. With the development of the use of high-grade steels to the present stage, it has become of increasing importance to utilize specimens that can be taken even from forgings of very small size, or from portions of large forgings where the designer anticipates that the stress conditions will be the most dangerous. And finally, when it is necessary to examine broken parts, it is desirable to take specimens exactly from those points where the failure has occurred. None of these things is possible, however, when specimens having the size of a Charpy specimen must be procured; and this explains why there is everywhere a search being made for suitable standardized specimens of small size.[6]

Committees have also been organized in Germany by the German Association for Testing Materials as well as by the German Institute of Steel Engineers (Verein Deutscher Eisenhüttenleute), which have for years been attempting to solve the problem of determining the best type of small specimen for notched-bar tests. As a result, we were able to present to the Congress at Zurich a unanimous German proposal which apparently satisfies all the requirements that must be met by a small-size standard specimen. This proposal was intended, first, to provide a tentative standard for use in Germany, and, in addition, to serve as a basis for seeking an international agreement.

FACTS AND POSSIBILITIES

In order to be able to present a proposal having the highest possible degree of perfection, it was first necessary to make a final check of all available knowledge concerning the factors which influence the results of a notched-bar test, and to fill in the remaining gaps in this knowledge. We finally succeeded in putting our knowledge of the fundamentals in a satisfactory and fairly complete shape, and an attempt will now be made to describe briefly the principal facts; a more elaborate description, including a bibliography of recent researches relating to the subject, was presented to the Congress at Zurich in the form of a report, to which reference has already been made.

To begin with, a structure can be occasionally overloaded

[5] The author was requested by the German Association for Testing Materials to report on the situation of the problems relating to notched-bar testing. The report was written with the cooperation of Dr. Fettweis and Dr. Mailänder, and has been published in the "First Series of Communications of the First International Congress held by the New International Association for Testing Materials at Zurich, Group A, Zurich, 1931." An abstract, not explicitly mentioning the source, can be found in *Z.V.D.I.*, vol. 75 (1931), p. 1401, in an article by E. Lehr on the testing of materials.

[6] See: Fr. F. Fischer, "How Must a Small Standard Specimen for Notched-Bar Tests Be Selected?" *Kruppsche Monatshefte*, vol. 9 (1928), p. 53. See also *Stahl u. Eisen*, vol. 48 (1928), p. 541.

without any harm, even by impact loads, when its design or the properties of its material are such that the overloading will be reduced automatically by a yielding of the structure, that is, by a deformation of a comparatively large part of it. However, such overloads can be extremely dangerous when the deformation remains restricted to a small part of the structure. The occasional overloading that the structure is able to withstand will be much higher in the first case, and an examination of a broken part will reveal the fact that the fracture did not occur until the susceptibility of the material to deform under stresses had reached the limit; in this case the designation "sliding failure" (*Verformungsbruch*) is used.[7] But in the second case, failure will have been caused by a comparatively small overload, and the evidence exhibited by the broken parts of having been deformed considerably will not be very pronounced. In this case we have the so-called "separation failure" or "cohesion failure" (*Trennungsbruch*); due to the absence of any stress-reducing reaction, the increased stress has been able to overcome rapidly the resistance offered by the material against separation, thus causing the abrupt destruction of the structure.[8]

In the author's opinion, the notched-bar test is important from a test standpoint mainly because, by performing this test, we are able to force the material to disclose its resistance against failure due to separation when it is subjected to impact loads. In order to have the material reveal this fact, we compel it to remain in a condition of restricted stress equalization, by providing the notch with adjoining stiff walls. Fig. 3 shows specimens of a steel that was available in two forms with different structures, after they had been subjected to notched-bar tests. In its first form (see *a* and *b*) the steel does not show a great tendency toward separation failure, whereas in its second form (see *c* and *d*) this tendency is strongly pronounced; the test conditions were the same for

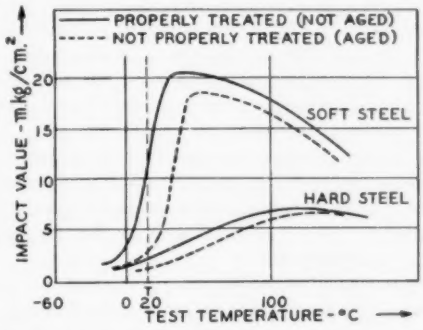

FIG. 4 HIGH AND LOW IMPACT VALUES AT VARIOUS TEST TEMPERATURES (MAILÄNDER)

(Impact value = work per unit of area of cross-section.)

both specimens. Notwithstanding the condition of restricted stress equalization during the notched-bar test, the steel in its first form shows a "sliding failure;" in its second form it shows a "separation failure." The measured impact values (the work per unit of area of the cross-section along which the test pieces break) are high in the first case and low in the second. In this connection the designations *high* impact value and *low* impact value (computed per unit of area of the cross-section along which the rupture occurred) will be used.

The state of stress or the strained condition enforced upon the steel during the notched-bar test can be influenced and, incidentally, if desired, can be intensified in three different ways:

1 By changing the temperature prevailing during the test

2 By changing the ratio between height and width of the cross-section subjected to the impact

3 By changing the shape of the notch, i.e., its sharpness and depth.

A further possibility of exerting the influence just mentioned consists in changing the working speed of the impact testing machine; this possibility hardly needs to be mentioned, since it does not find application in practice.

1 Fig. 4, taken from a paper prepared by Dr. Mailänder,[9]

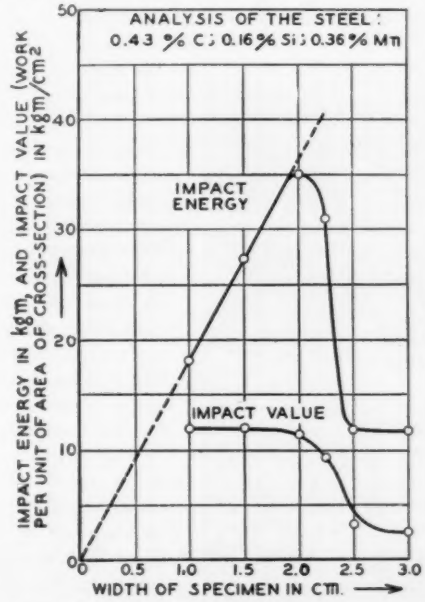

FIG. 5 IMPACT ENERGY AND IMPACT VALUES FOR VARIOUS WIDTHS OF SPECIMEN (MOSER)

(Material, medium-soft steel. Up to the point of critical specimen width, the impact energy increases proportionately with the width; thereafter the impact energy and impact values suddenly start to drop.)

clearly reveals the influence of the temperature prevailing during the test. At higher temperatures the impact values, as defined above, are high. When the temperature drops, the impact values decrease. The temperature at which the impact values start to decrease is different for the various structural conditions of a steel. As a consequence, the curve of impact value plotted against temperature will disclose whether the material, in so far as its structure is concerned, is in the most favorable or in a less desirable condition. In the latter case, the drop to low impact values will have already started at a higher temperature. Comparisons between different materials can be made in a similar manner by using this curve.

Evidently the statement just made applies only under the assumption that the two other factors which influence the strained condition of the material remain unchanged, that is, the shapes of the specimens and of the notches must remain the same in all cases. It should be emphasized that the influences of the three factors mentioned, i.e., test temperature, shape of specimen, and shape of notch, are not independent of one another; as a matter of fact, the influence of any one of these factors will be modified by the other two. For instance, in the temperature diagram, the temperature at which the drop in impact value occurs will also depend on the shape of specimen and notch. It will be shown later how this fact has been utilized in establishing a tentative standard specimen. The existence of such a relationship between

[7] W. Schwinning, "The Notched-Bar Test as a Criterion for the Properties of Materials," *Z.V.D.I.*, vol. 73 (1929), p. 321.

[8] F. László, "The Notched Bar," *Z.V.D.I.*, vol. 72 (1928), p. 851.

[9] R. Mailänder, "The Influence of Temperature, Shape of Specimen, and Test Speed on the Notched-Bar Impact Values of Iron and Steel," *Die Wärme*, vol. 48 (1925), p. 283.

the three influencing factors forces us to recognize that standardization of the notched-bar test is also badly needed from the standpoint of scientific research.

2 In Fig. 5 have been plotted the results of a series of tests made with specimens which had been given different values for the ratio between height and width of cross-section by changing the width of the specimens in steps, the height remaining unchanged.[10] The upper curve shows the relationship between the amount of energy absorbed during impact and the width of the specimen, and the lower curve the impact values or the work per unit of cross-section, calculated from the impact energy by dividing it by the area of the smallest cross-section of the bar. When the width of the specimen exceeds a certain critical value, the impact values suddenly start to decrease, exactly as in the case of the temperature curve. And here again the point at which the drop in impact value starts is different and characteristic for the various conditions of the structure as well as for various materials.

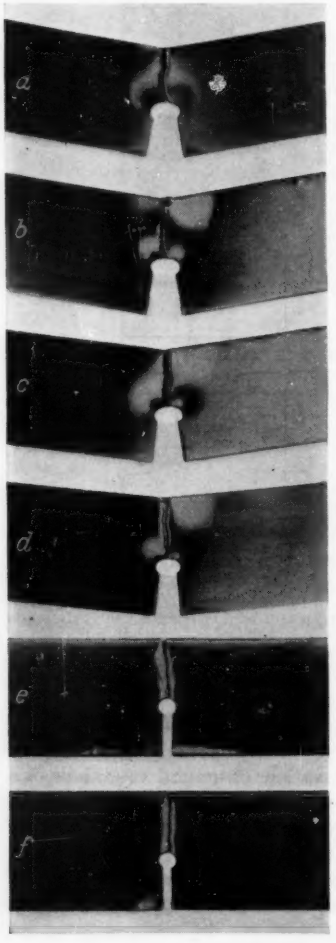

FIG. 6 DISAPPEARANCE OF THE REGION IN WHICH A PLASTIC FLOW OCCURS. CHANGE INTO A SEPARATION FAILURE
(Width of specimens in centimeters: *a*, 1; *b*, 1.5; *c*, 2; *d*, 2.25; *e*, 2.5; *f*, 3.)

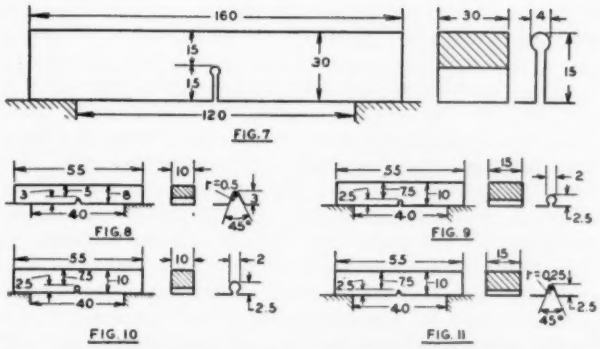
The drop in impact value must be demonstrated by the appearance of the fracture of specimens that have been subjected to the impact test, i.e., the fracture must appear in the form of a transition from a sliding failure to a separation failure. This transition is very clearly shown by the polished specimens of Fig. 6; for this particular steel the transition occurred at a critical width of the specimen equal to 2.25 cm.

3 When polished specimens are used and the extent of the region in which plastic flow occurs is considered, it will be found that the deformation of a specimen under the influence of stresses will decrease up to the point where finally a separation failure is unavoidable, when the radius of the notch is made smaller and smaller, that is, when the sharpness of the notch is increased, all other test conditions remaining unchanged.[10]

VARIOUS DESIGNS OF SPECIMENS—TENTATIVE STANDARDS

It is recommended that the complete set of characteristic curves be determined, when materials must be tested for which the notched-bar characteristics are still unknown or when the influences of changing conditions must be investigated. The impact temperature curve, Fig. 4, is undoubtedly one of the most instructive curves of this set. But for the particular purpose that we are attempting to achieve by establishing a standard test, the procedure involved in determining the complete curves would require too much time and material. It should be possible to meet the specification of a practical notched-bar test by making tests at but one temperature, and it should not be necessary to determine the entire series of temperature curves in each individual case.

It appears logical to choose for this purpose exactly that temperature at which the material is still able to maintain its high impact value when its structure has the desired qualities, because in this case the impact value will immediately drop to its low point as soon as the qualities of the structure are impaired in any respect whatever. From a practical standpoint it would be most desirable if the temperature thus defined could be invariably the same for all grades of steel that will ever have to be subjected to this test, and the same as the room temperature. For it hardly needs to be emphasized that, in practice, difficulties and legal tangles can be avoided only if tests are made at room temperature.



It was realized that it should be possible, by properly choosing the dimensional ratio of the cross-section of the specimen, and by giving the notch a suitable shape, to shift the almost vertically dropping parts of the temperature curves to such an extent that the drop in impact value would occur at practically room temperature. That this possibility exists is evidenced by what was stated in a previous paragraph regarding the existence of a relationship between the three factors influencing the strained condition of the specimen. However, it was recognized at the same time that in case the characteristics of the various grades of steel to be covered by the test should widely differ, it would hardly be possible to have the drop in impact value for all grades occur at room temperature by shifting all temperature curves in the same manner, that is, by using one standard specimen for all grades. For this reason it was thought that, although a single standard specimen would be sufficient for the majority of grades of steel to be covered by the test, it would eventually be necessary to adopt additional specimens for other grades not included in this majority. Nevertheless the standard specimen would have to be designed in such a manner as to make its field of application as broad as possible.

Finally, the problem to be dealt with by the committees took the following practical form:

A small standard specimen must be developed, on the basis of our present knowledge of this particular subject which has been described in the foregoing; and the shape of this specimen and the form of its notch must be such that, at room temperature, it will be possible to distinguish the various grades of steel and their structures in a satisfactory manner. When the adoption of subsidiary specimens should be necessary, their number should be restricted to a minimum.

The most important specimens that have been designed and tested by the two German committees in line with the foregoing considerations are listed in Table 3. The ratio between width and height of the cross-section was varied systematically, and both sharp and round notches were tried. Several series of tests were made with these specimens, employing all the various grades of steel and their different structures that are to be covered by this particular test, and it was found that several of the specimens could be eliminated from further consideration. The remaining designs are shown in Figs. 7–11, from which a comparison of their dimensions with those of the Charpy specimen, Fig. 7, can be readily made. The efficacy of the various specimens in producing the desired test results was determined by using the former standard specimen, i.e., the Charpy specimen with the dimensions 160 × 30 × 30 mm, as a basis of comparison. In

[10] M. Moser, "The Laws of the Notched-Bar Test," *Kruppsche Monatshefte*, vol. 2 (1921), p. 225.

(All dimensions in millimeters.)

other words, all grades of steel and their various structures had also to be tested with the Charpy specimen.

11	15	10	55	2	3	15 × 7	40
12	10	8	55	1	3	10 × 5	40

The question now was, Which of these specimens will best serve to positively identify the various grades of steel and their different structures in practice?

The answer was as follows: It was found that, of all the specimens examined, the Charpy specimen still differentiates most distinctly between the various steel grades and steel structures; at the same time it was found, however, that one of the newly designed specimens, i.e., the 10 × 10-mm specimen with the 2-mm round notch as represented in Fig. 10 (see Table 3, No. 2), was almost as efficient as the Charpy specimen. This may be seen by comparing the results obtained with some of those of a series of tests made by Dr. László (see Fig. 12 and Tables 4–6); these latter data serve at the same time to give an idea of the method of investigation followed by us.

A steel, the analysis of which is indicated in Table 4 (1 per cent nickel steel), had been subjected to eight different heat treatments, and consequently was available in eight different structural conditions. Table 6 gives particulars of the heat treatments. The eight different structures of the steel were subjected to the notched-bar test in the form of the specimens under investigation; details regarding three of these specimens are given in Table 5. Fig. 12 shows that the Charpy specimen and the 10 × 10-mm specimen with the 2-mm round notch (curve 2) of almost the same efficiency, produce a well-nigh perfect separation of the different structural conditions. It is seen that these conditions can be very clearly identified, the absolute values being sufficiently high.

After another very careful check of all factors entering into the problem, the decision was reached that the new specimen just referred to, i.e., No. 2 of Table 3, which had been found to be the best substitute for the Charpy specimen, should be proposed as a tentative German standard. At the same time, however, for several reasons, it was decided to increase the depth of the notch to 3 mm. One reason was that with the original notch depth of 2.5 mm the deformation would occasionally spread to a greater or less extent into regions on both sides of the notch, thus affecting the positiveness of the results. This difficulty was avoided when the depth of the notch was increased to 3 mm. This increase in depth will further lessen the influence of small discrepancies in the notch depth that can always occur when the specimens are made in a commercial shop, and thereby result in smaller discrepancies between the impact values.

However, it was found, as had been anticipated from previous knowledge of the subject, that the positive range of differentiation of this particular specimen does not include the very ductile steel grades. These can be differentiated only when a specimen

with a sharp notch is used. As a consequence, it was found necessary to adopt, in addition to the main specimen with round notch to be proposed as a tentative standard, a subsidiary tentative standard with a sharp notch. In the author's opinion, the adoption of this additional specimen would be sufficient to cover the entire range.

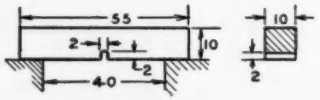

FIG. 17:- MESNAGER SPECIMEN. (FRANCE AND ITALY)

FIGS. 15–17 SPECIMENS FOR THE NOTCHED-BAR TEST USED IN VARIOUS COUNTRIES
(All dimensions in millimeters.)

The new tentative German standard specimen, to be designated as "Small Standard Proposed by the DVM (German Association for Testing Materials)," is shown in Fig. 13. No restrictions are placed on the method of machining the notch, that is, whether it must be drilled, milled, or ground. It is important, however, to avoid any cross-scratches, and when these appear, they must be removed. Fig. 14 shows the subsidiary tentative standard specimen, with the sharp notch, to be designated as "Additional Small Standard Proposed by the DVM." The specified radius of 0.5 mm at the bottom of the notch will facilitate the manufacture of this standard specimen in the shop. It has been found from experiments that the exact form of the notch can no longer be guaranteed when a smaller radius is employed.

It is interesting to note that the dimensions of the Charpy specimen and of the proposed tentative standards are such that the two halves of a Charpy specimen which has been subjected to the impact test, can be used afterward for making small DVM specimens. This means that it is relatively simple to make comparative series of tests with both specimens.

Conclusions

The small specimen, Fig. 13, and its supplementary specimen, Fig. 14, constitute the two tentative standards that will be submitted later to the German producing and consuming interests by the German Association for Testing Materials.

In the future it is intended to have all statements relating to impact values based on this standard and on the subsidiary standard specimen, on the latter in those cases where the toughness of the material to be tested is so great that the round-notch specimen would not lead to conclusive results.

In a few exceptional cases, the standard specimens will not apply—for instance, when the material and the form in which it is delivered are such that the specimens used at present must be retained as special specimens. An example of such a special case is cast steel. Here it will be more desirable to use the old Charpy specimen, because, on account of its larger size, it contains a larger amount of the coarse-crystalline material. And, for similar reasons, when we must test materials which are manufactured in the form of plates, we cannot, at least not at the present time, do without the customary specimens now in use.

But nevertheless, with the introduction of the standard specimens described in the foregoing, a uniform language, which will not leave the slightest doubt as to its true meaning, will become available to those who must deal with scientific and practical problems relating to the properties of materials as revealed by notched-bar tests. And this is certainly an important step forward!

The accomplishments of the Congress at Zurich are such that an international agreement looking toward the establishment of a standard specimen does not seem unlikely.

Several specimens for notched-bar testing, much used in other countries, and differing but slightly from the tentative German standard and subsidiary standard specimens, are reproduced in Figs. 15–17.

APM-55-15

Theories of Strength

By A. NADAI,[1] EAST PITTSBURGH, PA.

The conditions under which yielding starts at lower temperatures in metallic and also in other materials are discussed. Recent tests, particularly those made in England, Germany, Switzerland, and the United States, are compared and the results of a number of new ones concerning the conditions of yielding of steel are reported.

More detailed reference to these tests is made, and conclusions as to the best expressions available at present are drawn from them and utilized in rules for computing working stresses in practical cases. In conclusion, certain suggestions are made as to the conditions of ordinary rupture in a static test.

I—INTRODUCTION

AT THE suggestion of the Applied Mechanics Division, a brief review of the so-called theories of strength is offered in what follows. The discussion will be confined mainly to two principal questions which may be raised in connection with the various possibilities under which failure in general may be observed in engineering materials. No attempt will be made to define the term "failure" with greater accuracy, because of the great variety of factors which would have to be considered if the conditions should be described under which the safety of a given construction member has to be determined. The problems to be discussed in the following may perhaps be reduced to two: (1) What are the mechanical conditions, if any exist, under which engineering materials start to deform permanently, that is, under which they start to yield plastically? And (2) what are the corresponding conditions under which rupture or visible separation of the parts of a construction member occurs? However, before entering into a detailed discussion of the answers which at the present state of our knowledge may be advanced concerning these questions, a few experimental facts about the behavior of materials under stress must be briefly recalled.

If a solid body is subjected to a homogeneous state of stress such as pure tension, compression, or pure shear, the strains produced in the body will be partly elastic and partly plastic. There are materials, such as mild steel, glass, etc., which at a sufficiently low temperature behave perfectly elastically within a certain range of stress. They deform slightly under stress, but the deformations disappear completely if the loads are removed. In other cases, however, no range of stress can be detected within which an initially unstressed material would behave perfectly elastically. If a stress which has been acting for a certain time and has produced the strain ϵ (point A, Fig. 1) is removed, the material will exhibit a certain strain ϵ'' (point B). The portion ϵ' of ϵ may be called the elastic, and the portion ϵ'' the permanent, part of the strain ϵ. The curves $\sigma = f(\epsilon)$ for loading and for unloading will in general not coincide, and if unloading and loading are repeated between the limits of stress σ (point A) and the stress zero (point B), in general a loop of elastic hysteresis will be observed in the corresponding "stress-strain curves," such as the one indicated in Fig. 1 between the curves $A2B$ and $B3A$. If the stresses are increased above the stress σ (branch AC), the curve AC will continue about in the direction of the extension of the first branch OA. These details may be characteristic for the shape of the "stress-strain curves" for initial loading in certain engineering materials. If the initial stress-strain curve is of the shape shown in Fig. 2, with a distinct elastic line OA and with permanent deformations starting quite suddenly as soon as the stress $\sigma = \sigma_0$ is reached (point A), the material has a sharply defined "yield point" or a sharp limit of plasticity σ_0 under which the material starts to deform permanently or plastically (line AB). In this case an elastic

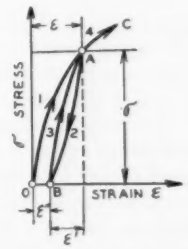

FIG. 1 :- ELASTIC AND PERMANENT STRAIN

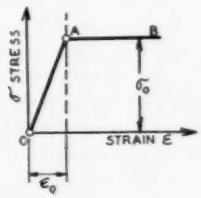

FIG. 2 :- SHARPLY DEFINED YIELD STRESS

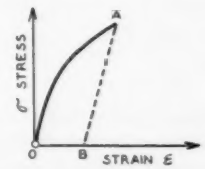

FIG. 3 :- STRESS-STRAIN DIAGRAM WITH GRADUAL TRANSITION CURVE

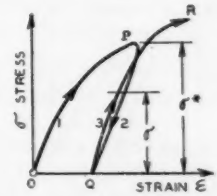

FIG. 4 :- DEFINITION OF YIELD STRESS, ASSUMING STRAINHARDENING

range $0 < \epsilon < \epsilon_0$ of the strains may well be distinguished from the plastic range of strains $\epsilon > \epsilon_0$. In other cases the transition from a purely elastic initial stage into the plastic range is less sharply marked, as, for example, in the case of the stress-strain curve shown in Fig. 3. Is there any justification in speaking of a yield stress also in this case, and if so, what stress, if any, can be called the "yield stress?" The answer will be given by interrupting the test at a point P (Fig. 4). If the material were to be unloaded from the stress σ^* and again loaded in the same manner but to a stress σ not exceeding σ^*, only small elastic changes of the strains would be noticeable, corresponding to the curves $P2Q$ and $Q3P$. If, however, $\sigma \geqq \sigma^*$, then yielding starts along PR again. For this reason σ^* may be called the new "yield stress." In most of the polycrystalline metallic materials, the yield stresses σ^* producing new permanent plastic deformations increase with ϵ (strain hardening). A stable condition of yielding requires always that $d\sigma/d\epsilon > 0$. In materials exhibiting

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

considerable strain hardening, an elastic range of the strains may be distinguished; they behave more or less elastically after the yielding is interrupted and provided that the subsequently applied stresses σ remain smaller than the previous yield stress ($\sigma < \sigma^*$, curve $P2Q$ or $Q3P$ in Fig. 4).

In what follows it will furthermore be useful to distinguish between (*a*) brittle, (*b*) tough, and (*c*) ductile materials. (Fig. 5.) This refers to the shapes of the stress-strain curves of the materials in pure tension. A brittle material will not exhibit much permanent deformation until rupture occurs (glass, cast iron); a tough material will show a considerable increase of stress while it deforms to a few per cent elongation (hard steels), and a ductile material can be stretched 20 to 40 per cent or more before it breaks (soft copper). It is, however, important to note that this distinction is an artificial one, because materials which under ordinary conditions are brittle, under other circumstances may be brought into a tough or even a ductile condition. This can be done by repeating the tensile or the compression test and by applying a heavy hydraulic pressure at the same time on the bounding surfaces of the test piece; and under such circumstances brittle materials such as marble have been deformed considerably in plastic distortion. Another example is the plastic impression obtained in cast iron under a hard steel ball, although cast iron is a brittle material.

For this and other reasons, not explained here, it is perhaps more correct not to speak of brittle or of ductile materials, but rather of the brittle and the plastic states of a given material.

When speaking of the conditions under which yielding as just defined (including strain or work hardening) starts, it is furthermore assumed that the stresses are applied slowly and at normal temperatures. It is known that the speed of deformation has an influence on the magnitude of the yield stress producing a given strain ϵ such that a bar of a ductile metal stretches permanently. Recent tests,[2] in which the speed of stretching was varied in the ratio of 1 to 1,000,000, seem to confirm results obtained earlier by Cassebaum and P. Ludwik that for the ductile metals the yield stress σ which is required to produce a *given* elongation ϵ at normal temperatures increases with the rate of elongation $d\epsilon/dt$ according to a logarithmic expression of the form

$$\sigma = \sigma_1 + \sigma_2 \log \frac{v}{v_0}$$

where σ_1, σ_2, and v_0 are material constants and $v = d\epsilon/dt$. These latter changes will not amount to more than a few per cent under ordinary testing conditions, and the stress conditions discussed below therefore apply to ordinary testing speeds but not to impact or in cases of very rapid plastic stretching. The second and more important restriction to the use of the criteria to be discussed refers, as has already been mentioned, to the temperature. It is assumed that the temperatures are sufficiently low not to cause gradual creep and very slow plastic distortions, which, under continued application of a load, could become appreciable even under comparatively small stresses. All such slow permanent deformations which depend on time, that is, the phenomena of creep or of recrystallization as effected by elevated temperatures, are excluded.

As far as the phenomena of rupture are concerned, only stationary or prolonged cases of loading are assumed, and particularly failure due to fatigue is excluded, this case being treated by another paper of the present symposium. The observations made below refer only to polycrystalline materials. Although single crystals have exhibited some of the phenomena of yielding and rupture in a more perfect way than polycrystalline materials, their low strength properties make it unnecessary to deal with them separately here. Special reference should, however, be made to the extensive experimental work by means of which the mechanical properties of single metal crystals have been established in recent years, and which has contributed so much to a better understanding of the mechanism of yielding, and of rupture also, in the polycrystalline metals.

A homogeneous state of stress is determined by six quantities, for example, the three normal stresses σ_x, σ_y, σ_z, and the three components of shearing stress τ_{xy}, τ_{xy}, τ_{zx} acting in the faces of a small parallelopiped cut out of the stressed material. Instead of using these six components, however, it is more convenient to deal with the principal stresses σ_1, σ_2, σ_3, and to assume that the three mutually perpendicular directions are given in which they act. In a similar way the state of strain may be given either by the unit strains ϵ_x, ϵ_y, ϵ_z, and the unit shears γ_{xy}, γ_{yz}, γ_{zx}, or by the three principal strains ϵ_1, ϵ_2, ϵ_3, and by their directions. When speaking of strains it is assumed that they are small quantities compared with unity and that reference is made only to the permanent strains. It is assumed also that, while the material yields, the directions of the principal stresses do not *rotate* with respect to the body itself. This limits the discussion to certain types of loads or modes of plastic yielding, and makes it possible to neglect the elastic parts of strains at first. A more general discussion of the conditions of yielding, and particularly of the transition curves from an elastic state of strain to a plastic, continuously changing state of strain with both elastic and plastic parts, would require the abandonment of one of the assumptions made implicitly, namely, that both the tensor of the elastic strains and that of the permanent strains during a transition curve are two *coaxial* tensors.

II—EXPERIMENTAL DETERMINATION OF THE CONDITION OF YIELDING

In this section will be described briefly the method which has been used by the author and his collaborator, Dr. W. Lode, in their tests (1925–1928)[3] to find the stress relation which seems to express the condition of yielding in ductile metals.[4] A principal consequence of the assumptions made above is that yielding in the ductile metals may be considered as depending on a relation or expression in which the principal stresses σ_1, σ_2, σ_3 appear only as variables. Previous tests with metallic materials, as well as those made on single metal crystals, have shown that if a system of principal stresses σ_1, σ_2, σ_3 is at a limit of plasticity, by the addition or subtraction of a three-axial uniform tensile stress or of a hydraulic compression σ^*, a system $\sigma_1 - \sigma^*$, $\sigma_2 - \sigma^*$, $\sigma_3 - \sigma^*$ is obtained which is also at the limit of plasticity. Hence yielding can depend only on the principal-stress differences $\sigma_1 - \sigma_2$, $\sigma_2 - \sigma_3$, and $\sigma_3 - \sigma_1$, and, at least under not too large an average or mean pressure $\sigma = (\sigma_1 + \sigma_2 + \sigma_3)/3$, yielding is independent of the mean pressure. Until now this could obviously be established only under comparatively low values of σ; it is true mainly for the ductile metals, while the

Eisen*, Düsseldorf, 1925; and "Versuche über die Fliessgrenze des Eisens," Proc. 2 Intern. Congress for Applied Mechanics, Zurich, 1926. Also, W. Lode: "Versuche über den Einfluss der mittleren Hauptspannung auf das Fliessen der Metalle Eisen, Kupfer und Nickel," *Zeit. für Physik*, Bd. 36, p. 913–939, 1926; and "Der Einfluss der mittleren Hauptspannung auf das Fliessen der Metalle," Forschungsarbeiten des Vereines deutscher Ingenieure, Berlin, Heft 303, 1928.

[4] As a bibliography of the tests made under combined stress previous to these tests, with a critical discussion of their results, is contained in Dr. Lode's second paper mentioned in the previous footnote, further reference to the earlier work on the subject will be omitted here.

yielding of other polycrystalline materials, particularly of those commonly called brittle materials, may depend on σ.

With reference to the transition part of a stress-strain curve from the elastic to a plastic state, particularly when repeated loading and unloading curves are compared, it is worthy of note that in a tensile test with mild steel an almost perfect straight line is obtained as the unloading curve (CD in Fig. 6) and that this will also coincide with the lower portion of the succeeding loading curve if the yielding is suddenly interrupted. If the unloading occurs very slowly on account of some afterflow, the corner at C will be somewhat rounded, but later the unloading curve will still be nearly a perfectly straight line, as CD.

Dr. Lode and G. J. Taylor and H. Quinney[5] have shown that a test piece of a ductile metal, such as copper, aluminum, or iron, which has been stretched in pure tension with frequent interruptions, furnishes a diagram similar to that shown in Fig. 7. Each subsequent loading curve leaves the straight line B_1A_1, B_2A_2, B_3A_3 at a certain point C_1, C_2, C_3, and bends more or less gradually into a new direction which closely coincides with a curve passing through the points A_1, A_2, A_3. The same curve would have been obtained, if the test piece had been stretched continuously and without interruption in a single test.

In test pieces in the form of tubes having not too small or great a wall thickness, distributions of stress may be produced by means of internal pressure and axial loads in which two of the three principal stresses σ_1, σ_2, σ_3 are tensile stresses. As the third principal stress in such a tube is either zero or very nearly equal thereto, distributions of stress can be obtained in which

$$\sigma_1 \geqq \sigma_2 \geqq \sigma_3 = 0$$

Thus the intermediate principal stress σ_2 may be chosen equal to any value between $\sigma_1 \geqq \sigma_2 \geqq 0$, and the influence of the intermediate principal stress σ_2 on the yielding be determined. If such a tube is first tested in pure tension in the axial direction, then, by a combination of internal hydraulic pressure and axial tension, similar curves to those shown in Fig. 7 can be recorded. In obtaining these diagrams it is assumed that the principal stresses in the hollow cylinder increase according to the proportion $\sigma_1 : \sigma_2 = \sigma_1' : \sigma_2'$. The points A_1, A_2, A_3 . . . obtained for a set of consecutive tests made on the same tube under a number of different distributions of stress applicable to the tube may now serve to determine the condition of yielding (Fig. 8). For example, if a hollow cylinder is subjected first to pure (axial) tension σ_1, $\sigma_2 = \sigma_3 = 0$, then unloaded and again stressed by an axial load and in addition by an internal pressure until it yields, and such tests with various loads and pressures are repeated, curves for the axial principal stress σ_1 as a function of the axial principal strain ϵ_1 will be obtained such as those shown in Fig. 8. Each of the subsequent curves C_1A_2, C_2A_3, C_3A_4 . . . will correspond to another principal stress system σ_1, σ_2, σ_3, and the height of the new points A_1, A_2 . . . may now be compared with the ordinates of the projected curve A_1, A_3 . . . shown by the broken line, which line would be the stress-strain curve for pure tension.

In this manner Dr. Lode and the author in their tests have eliminated the influence which the strain hardening of a ductile metal must have on the condition of yielding. Using a number of mild steel, copper, and nickel tubes, all of which in their original condition were annealed, the following test results were obtained:

1 The condition of yielding for the ductile metals can, within errors of about 3 per cent, be expressed by the equation:

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_0^2 = \text{const.} \ldots [1]$$

[5] "The Plastic Distortion of Metals," Phil. Trans. Roy. Soc., London, Series A, vol. 230.

first suggested by R. von Mises[6] and later by H. Hencky.[7] Here σ_0 is the yield stress for pure tension in the strain-hardened condition of the material. This equation, expressing the condition for uniform yielding, was checked within about 10 per cent of the total axial extension and verified, with the exception of the first yielding in the case of mild steel.

It is known that the characteristic phenomenon of the upper and lower yield points for the first yielding in tensile tests of mild steel may be observed on smooth cylinders or tubes which have heads with very gradually changing cross-sections. In such bars or tubes an instability of the static equilibrium develops until the first signs of yielding become visible. The load then drops suddenly, while at the same time yielding starts in a narrow oblique layer, this latter becoming visible as a strain or flow figure on the surface of the bar. As the "upper yield stress" of mild steel is a stress under which the bar is in an unstable equilibrium, such a limit has no greater practical significance as a limit of plasticity. It is therefore important, as far as the behavior of mild steel is concerned, not to include tensile tests in which an upper yield point has been observed in the comparison and which refer to the first yielding. Various discrepancies in the interpretation of the results of former tests made under combined stresses may probably be due to this cause. As soon as the lower yield point is observed or when uniform yielding starts in test pieces of mild steel, Equation [1] is found to agree with the results of the tests.

[6] Mechanik der festen Körper im plastisch deformablen Zustand," *Göttinger Nachrichten*, 1913.

[7] "Zur Theorie plastischer Deformationen, etc.," *Zeit. für angew. Math. u. Mech.*, vol. 4 (1924), p. 323; "Uber das Wesen. der plastischen Verformung," *Z.V.D.I.*, vol. 69 (1925), p. 695. In the discussion of this condition, Equation [1], at the 1st International Congress for Applied Mechanics in Delft (1924) it developed that Prof. M. J. Huber had also independently suggested the same equation as the condition of yielding.

2 For the *infinitesimal* permanent parts of the resulting deformations, the following three laws express the mode of yielding:

a The volume remains constant:

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \quad \ldots\ldots [2]$$

b The axes of the three principal strains coincide with the axes of the three principal stresses σ_1, σ_2, σ_3.

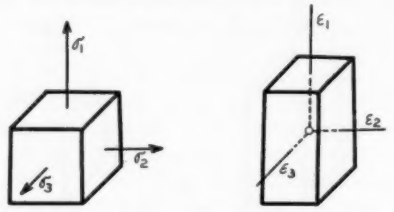

FIG. 9 :- PRINCIPAL STRESSES $\sigma_1, \sigma_2, \sigma_3$ AND PRINCIPAL PLASTIC STRAINS $\epsilon_1 \epsilon_2 \epsilon_3$.

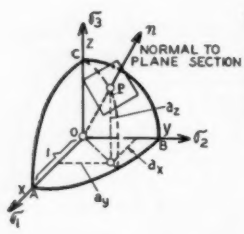

FIG. 10

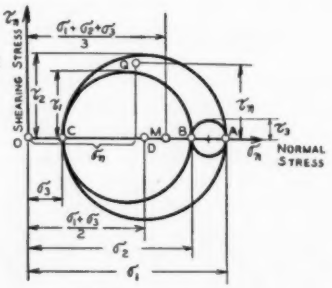

FIG. 11

MOHR'S REPRESENTATION OF STRESS

c Rule of yielding: Although in the tests of Lode certain deviations from the law expressed by Equation [3] were clearly observable, for practical purposes it can be assumed that if the strains ϵ_1, ϵ_2, ϵ_3 change uniformly,

$$\frac{\epsilon_1 - \epsilon_2}{\sigma_1 - \sigma_2} = \frac{\epsilon_2 - \epsilon_3}{\sigma_2 - \sigma_3} = \frac{\epsilon_3 - \epsilon_1}{\sigma_3 - \sigma_1} \quad \ldots\ldots [3]$$

Since

$$\gamma_1 = \epsilon_2 - \epsilon_3, \quad \gamma_2 = \epsilon_3 - \epsilon_1, \quad \gamma_3 = \epsilon_1 - \epsilon_2 \quad \ldots\ldots [4]$$

are the principal shearing strains and

$$\tau_1 = \frac{\sigma_2 - \sigma_3}{2}, \quad \tau_2 = \frac{\sigma_3 - \sigma_1}{2}, \quad \tau_3 = \frac{\sigma_1 - \sigma_2}{2} \quad \ldots\ldots [5]$$

are the principal shearing stresses, Equation [3] is identical with

$$\frac{\gamma_1}{\tau_1} = \frac{\gamma_2}{\tau_2} = \frac{\gamma_3}{\tau_3} \quad \ldots\ldots [6]$$

or, expressed in words, when a metal yields, the principal shears change in proportion to the principal shearing stresses which cause the plastic distortion.

Introducing the principal shearing stresses τ_1, τ_2, τ_3 and the maximum shearing stress $k = \sigma_0/2$ for yielding in pure tension, the condition of plasticity, Equation [1], can be rewritten in the form:

$$\tau_1^2 + \tau_2^2 + \tau_3^2 = 2k^2 = \text{const} \quad \ldots\ldots [7]$$

Another convenient way of expressing the meaning of Equations [2] and [3] suggested by Dr. Lode and the author utilizes Mohr's representation of stress by means of the three principal stress and strain circles. In an octant of a small sphere of material (Fig. 10), the edges x, y, z of which are parallel to the principal stress directions, any point P on the surface represents the position of a plane section in the stressed material. If the radius of the sphere is taken equal to unity, then the direction cosines, a_x, a_y, a_z of the radius OP or of the normal n to the tangent plane of the sphere are the rectangular coordinates of the point P. In Mohr's plane (Fig. 11) a second point Q corresponds to any point P in Fig. 10, the rectangular coordinates of which are equal to the normal stress σ_n and the shearing stress τ_n acting in the plane section with the normal n. The three principal circles in the octant of the sphere, AB, BC, CA in Fig. 10, correspond to the three principal circles of stress indicated by the same letters in Fig. 11. The abscissas of the three points A, B, C in Fig. 11 determine the principal stresses σ_1, σ_2, σ_3, and the radii of these three principal circles determine the principal shearing stresses τ_1, τ_2, τ_3. If now a variable μ is introduced for the ratio of the lengths DB and $AD = DC$, then

$$\mu = \frac{BD}{AD} = \frac{\sigma_2 - \frac{\sigma_1 + \sigma_3}{2}}{\frac{\sigma_1 - \sigma_3}{2}} = \frac{2\sigma_2 - \sigma_1 - \sigma_3}{\sigma_1 - \sigma_3} \quad \ldots\ldots [8]$$

determines the intermediate principal stress σ_2 provided that $\sigma_1 > \sigma_2 > \sigma_3$. The point D is the center of the largest of the three principal-stress circles.

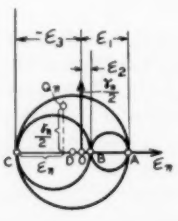

FIG. 12 :- PRINCIPAL STRAIN CIRCLES WHEN $\epsilon_1+\epsilon_2+\epsilon_3=0$

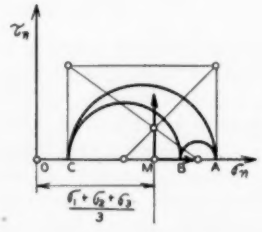

FIG. 13 :- CONSTRUCTION OF ORIGIN M (WHICH IS CENTER OF GRAVITY OF POINTS ABC, ASSUMING EQUAL MASSES)

As yielding in the case of ductile metals does not depend appreciably on the mean pressure $\sigma = (\sigma_1 + \sigma_2 + \sigma_3)/3$, it is frequently convenient to introduce in Fig. 11 a new origin M which is obtained by making $OM = (\sigma_1 + \sigma_2 + \sigma_3)/3 = \sigma$. Obviously M is the center of gravity of the three points A, B, C, assuming equal masses concentrated in them, and can be constructed as indicated in Fig. 13. The principal stresses for this new origin M are then

$$\sigma_1^* = \sigma_1 - \sigma, \quad \sigma_2^* = \sigma_2 - \sigma, \quad \sigma_3^* = \sigma_3 - \sigma$$

In a similar way the state of plastic strain ϵ_x, ϵ_y, ϵ_z, γ_{xy}, γ_{yz}, γ_{zx} may be represented by Mohr's circles. If ϵ_1, ϵ_2, ϵ_3 are the principal strains, then Mohr's circles in Fig. 12 represent the state of strain. As for the state of plastic strain,

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0$$

the origin O of the three principal plastic-strain circles must always coincide with the center of gravity of the points A, B, C on the ϵ-axis. The ordinates in the strain diagram, Fig. 12, are equal to $\gamma_n/2$.

In quite an analogous way a second variable ν referring to the principal strains ϵ_1, ϵ_2, ϵ_3 and determining the mean or intermediate plastic principal strains ϵ_2 may now be introduced by defining ν as

$$\nu = \frac{\epsilon_2 - \frac{\epsilon_1 + \epsilon_3}{2}}{\frac{\epsilon_1 - \epsilon_3}{2}} = \frac{2\epsilon_2 - \epsilon_1 - \epsilon_3}{\epsilon_1 - \epsilon_3} \quad \ldots\ldots [9]$$

The third law of plastic yielding can then be expressed by the equation

$$\mu = \nu \quad \ldots\ldots [10]$$

which indicates that a plastic state of stress produces such strains that the principal-strain circles (Fig. 12) consist of a group of circles similar to the principal-stress circles (Fig. 11 or 13). Both sets of circles are furthermore oriented similarly to their respective origins M (Fig. 11) and O (Fig. 12).

Two points Q and Q_n which are chosen in each of these two figures in a similar position determine by their abscissas and ordinates the normal and shearing stress σ_n, τ, and the unit elongation ϵ_n and half of the shear $\gamma_n/2$, respectively corresponding to the same normal n in Fig. 10. As according to Equation [6] for the principal shears

$$\tau_1 = c\gamma_1, \quad \tau_2 = c\gamma_2, \quad \tau_3 = c\gamma_3 \quad \ldots\ldots [11]$$

then quite generally for any direction of a given n section,

$$\tau_n = c\gamma_n \quad \ldots\ldots [12]$$

This shows that plastic slip or shearing strains occur naturally not only in one, two, or all the three pairs of planes in which the principal shearing stresses τ_1, τ_2, τ_3 act, but *on all planes oblique* to the principal-strain directions. This may be mentioned here, because some authors have been inclined to assume "that slip or gliding occurs in the planes of maximum shear," while others assume that it occurs "in the planes of maximum and minimum shear."[8] As, on the other hand, visible signs of initial plastic distortion can frequently be detected on the surfaces of test pieces of mild steel along thin layers which nearly coincide with a pair of the principal shearing planes, it is evident that here two quite different things are frequently confused in such statements as those just quoted, namely, *simple slip or shear* as one of the six components of a uniform strain or of a tensor—and *the temporary localization of a shear* or of a *plastic strain in a thin layer throughout the body*. In the former sense and according to Equation [12], plastic slip occurs in *all* oblique planes. In the second sense it refers to a temporary infinitesimal tangential movement of a certain part of the body as a rigid whole with respect to the remainder of the body, during which both portions are separated by a thin plastic layer. (Strain or flow figure, Lüders line.)

It is perhaps noteworthy that the first and second invariants of a stress tensor have a significance for the laws of the yielding of perfectly plastic materials. The first invariant,

$$\sigma = \frac{\sigma_1 + \sigma_2 + \sigma_3}{3}$$

determines the origin M for the three principal-stress circles. A second invariant expressing the von Mises-Hencky condition of yielding for the ductile metals may also be interpreted as a certain invariant of a tensor using scalar multiplications.

III—USING OCTAHEDRAL SHEARING STRESS IN PLASTICITY CONDITIONS

If one computes the stress components σ_n and τ_n for a special oblique plane the normal n of which makes equal angles of 54° 44′ with the three principal stress directions and the principal stresses are referred to the origin M [taken as $\sigma_1^* = \sigma_1 - \sigma$, $\sigma_2^* = \sigma_2 - \sigma$, $\sigma_3^* = \sigma_3 - \sigma$, where $\sigma = (\sigma_1 + \sigma_2 + \sigma_3)/3$] so that

$$\sigma_1^* + \sigma_2^* + \sigma_3^* = 0$$

then the normal stress σ_n^* in this oblique plane vanishes. The normal stress σ_n in this plane is accordingly given by $\sigma_n = (\sigma_1 + \sigma_2 + \sigma_3)/3$ for any stress distribution.

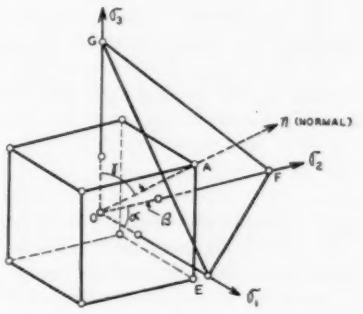

FIG 14.

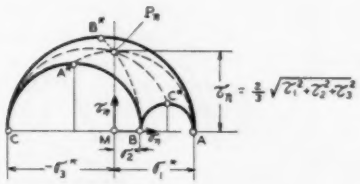

FIG 15 - CONSTRUCTION OF SHEAR STRESS τ_n

If one orients a cube with the faces according to the principal-stress axes, then there are eight planes which have a similar orientation with respect to the cube as the oblique plane, the normal of which bisects the first octant. They round off the eight corners of the cube and are the planes of an octahedron coaxial with the cube. The shearing stress τ_n in the octahedral plane *EFG*, Fig. 14, having for its normal the line *OA* or n, with the direction cosines $\cos\alpha = \cos\beta = \cos\gamma = 1/\sqrt{3}$, is given by

$$\tau_n^2 = \frac{\sigma_1^2 + \sigma_2^2 + \sigma_3^2}{3} - \frac{(\sigma_1 + \sigma_2 + \sigma_3)^2}{9} \quad \ldots\ldots [13]$$

or

$$\tau_n^2 = \frac{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2}{9} \quad \ldots\ldots [13a]$$

This shows that evidently in an octahedral plane (as *EFG*, Fig. 14)

$$\tau_n = \frac{2}{3}\sqrt{\tau_1^2 + \tau_2^2 + \tau_3^2} \quad \ldots\ldots [14]$$

or according to the condition of yielding (Equation [7]) in a plastic state, the shearing stress τ_n in an octahedral plane is

$$\tau_n = \frac{2\sqrt{2}}{3}k = \frac{\sqrt{2}}{3}\sigma_0 = 0.47\sigma_0 = \text{const} \quad \ldots\ldots [15]$$

To have a short designation for the physical facts underlying Equation [15], the author suggests calling Equation [15] the *condition of constant octahedral shearing stress* $\tau_n = const.$ It is

[8] In a paper by M. Ros and A. Eichinger: "Versuche zur Klärung der Frage der Bruchgefahr," Eidgen. Material prüfungsanstalt, Zürich, Sept., 1926, for example, it is said on page 10 (and italicized) that "the permanent deformations occur through slip in slip planes, which coincide with the planes of the maximum and minimum shearing stresses."

seen, therefore, that yielding in a perfectly plastic material according to *the theory of constant octahedral shearing stress* would start when the shearing stress τ_n in any one of the eight octahedral planes reaches a certain value (which, according to Equation [15], is equal to $\sqrt{2} \cdot \sigma_0/3 = 0.47\,\sigma_0$, where σ_0 is the yield stress for pure tension), the octahedron being oriented coaxially with the principal stress directions.

In Mohr's representation of stress a point P_n is easily found which furnishes the shearing stress τ_n. One has only to draw any one of the three bisecting circles AA^*, BB^*, CC^* indicated by broken lines in Fig. 15. Their common intersection or the intersection of one of them with the ordinate axis furnishes the point P_n and the ordinate $MP_n = \tau_n$ determines the shearing stress τ_n acting in one of the eight octahedral planes. The normal stress in the eight planes of the octahedron vanishes, provided

$$\sigma_1^* = \sigma_1 - \sigma, \ldots$$

To determine finally also the direction of the shearing stress τ_n acting in one of the eight octahedron planes it is not necessary to consider the reduced system σ_1^*, σ_2^*, σ_3^*, for we can construct τ_n for any system σ_1, σ_2, σ_3. If only the principal stress σ_2 would act alone (Fig. 16), then this stress σ_2 would produce a resultant stress σ_r in the plane *EFG* indicated in Fig. 16, making equal

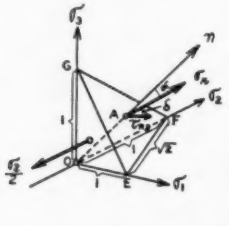

FIG. 16:- THE SHEARING STRESS τ_{n_2} PRODUCED BY σ_2

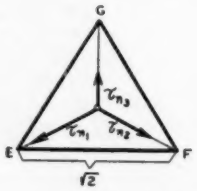

FIG. 17:- CONSTRUCTING OF $\tau_n = \frac{1}{3}\sqrt{\tau_1^2 + \tau_2^2 + \tau_3^2}$ FROM THREE COMPONENTS $\tau_{n_1}, \tau_{n_2}, \tau_{n_3}$

angles with the three directions σ_1, σ_2, σ_3, and which must be equal to $\sigma_2/\sqrt{3}$. (The area of the equilateral triangle *EFG* is $\sqrt{3}/2$ if the lengths of the three edges $OE = OF = OG$ of the tetrahedron *OEFG* are chosen equal to unity.[9]) Thus from equilibrium,

$$\frac{\sigma_2}{2} = \sigma_r \cdot \frac{\sqrt{3}}{2} \quad \text{or} \quad \sigma_r = \frac{\sigma_2}{\sqrt{3}} \ldots\ldots\ldots [16]$$

The stress σ_r must be parallel to σ_2, hence its tangential component or the shearing stress $\tau_{n2} = \sigma_r \times \cos\delta$, where δ is the angle of the σ_r axis with the plane *EFG*. As $\cos\delta = \sin\alpha$ and $\cos\alpha = 1/\sqrt{3}$, $\cos\delta$ becomes $= \sqrt{\frac{2}{3}}$. Thus

$$\tau_{n2} = \frac{\sqrt{2}}{3}\sigma_2 \ldots\ldots\ldots\ldots\ldots [17]$$

and the vector representing τ_{n2} must for reasons of symmetry coincide with the bisecting line of the angle at *F*. Similarly the other two principal stresses σ_1 and σ_3 will produce shearing stress components in the triangle *EFG* equal to

$$\tau_{n1} = \frac{\sqrt{2}}{3}\sigma_1, \quad \tau_{n3} = \frac{\sqrt{2}}{3}\sigma_3 \ldots\ldots\ldots\ldots [18]$$

The three coplanar vectors τ_{n1}, τ_{n2}, τ_{n3} are situated symmetrically as indicated in Fig. 17. Their resultant finally is the octahedral shearing stress τ_n given by Equation [15] and can thus be easily constructed.

As the elastic energy of distortion or the amount of energy required to distort the material purely elastically just to the yield point (the total elastic energy of deformation minus the work done in changing the volume) is equal to

$$A_d = \frac{1}{3G}\left(\tau_1^2 + \tau_2^2 + \tau_3^2\right) \ldots\ldots\ldots [19]$$

and for simple tension $\sigma_1 = \sigma_0$, $\sigma_2 = \sigma_3 = 0$, $\tau_1 = 0$, $\tau_2 = -\frac{\sigma_0}{2}$, $\tau_3 = \frac{\sigma_0}{2}$

$$A_d = \frac{\sigma_0^2}{6G} = \frac{2k^2}{3G} \ldots\ldots\ldots\ldots [20]$$

Equation [1] or [7] may therefore also be expressed by saying that yielding starts as soon as an amount of energy of distortion A_d given by [20] is reached in the material. This is the same amount of distortion energy the material contains in pure tension just when yielding starts.

Summing up the foregoing statements, it can be seen that the conditions of yielding, Equation [1] or [15], may be interpreted physically in several easily expressible ways. Mathematically they are simple and show a close connection with the fundamental variables of tensors, and it may perhaps be of interest to state briefly some additional reasons or facts which might be considered in their favor.

From a mechanical point of view it is hardly conceivable why the intermediate principal stress σ_2 (assuming that algebraically $\sigma_1 > \sigma_2 > \sigma_3$) should in polycrystalline materials have no effect when yielding starts. The conditions of yielding as stated in Equations [1] and [7] indicate that yielding is influenced by σ_2. According to the so-called "maximum-shear theory" and to its generalization by O. Mohr, yielding should not depend on σ_2. The experimental evidence based on more recently made tests, however, is opposed to this. (Cf. discussion of test results given later.) According to the observations which led to the condition $\mu = \nu$, the dimensions of a body which is plastically deformed change in a direction parallel to the direction of the intermediate principal stress σ_2. The only exception is when $\sigma_2 = (\sigma_1 + \sigma_3)/2$. In this case the radii of the two smaller circles in Mohr's representation become equal and the mean stress equal to the intermediate stress: $\sigma = (\sigma_1 + \sigma_2 + \sigma_3)/3 = \sigma_2$. This is the case of a pure shear or a pure shear combined with a pure hydraulic-pressure distribution. According to Mohr's hypothesis or to its special case included in the theory of maximum shear, one should expect, however, that in all other cases of stress or strain the intermediate dimension of a body parallel to ϵ_2 or σ_2 should not change, except only in the case when two of the three principal stresses become equal to each other. This has not been verified by tests.

The condition of yielding as an equation $F(\sigma_1, \sigma_2, \sigma_3) = 0$ containing the three principal stresses σ_1, σ_2, σ_3 may be represented or visualized graphically in space as a surface taking σ_1, σ_2, σ_3 as rectangular coordinates. This representation has been introduced by H. M. Westergaard and B. P. Haigh. The author suggested that this surface might be called the "surface

[9] Ros and Eichinger explain the shearing stress (or the corresponding unit shear γ_n) acting in an octahedral plane as "the resultant shearing stress" (or the "resultant shear") of the given stress or strain distribution. A stress or strain tensor having in general six components cannot be reduced or replaced by one "resultant shearing stress or strain." If the six components of a strain tensor are all finite and one relation is prescribed among them, as is the case above, they can be reduced to not less than five simple shears, but not to a single "resultant shear."

of yielding." The general problem of describing the conditions of yielding would then consist in determining empirically by tests the shapes of the surfaces of yielding $F(\sigma_1, \sigma_2, \sigma_3) = 0$ for the principal materials of construction.[10]

Taking $\sigma_1 > \sigma_2 > \sigma_3$, the maximum-shear theory is expressed by

$$\tau_2 = \frac{\sigma_1 - \sigma_3}{2} = \text{const} \quad \ldots\ldots\ldots\ldots\ldots [21]$$

which is the equation of a plane, and Mohr's theory by

$$\frac{\sigma_1 - \sigma_3}{2} = f\left(\frac{\sigma_1 + \sigma_3}{2}\right) \quad \ldots\ldots\ldots\ldots [22]$$

which is the equation of a cylinder. By interchanging the order of $\sigma_1, \sigma_2, \sigma_3$, six such planes and six such cylinders will be obtained. The shape of the surface of yielding for the various possibilities which may exist for $\sigma_1, \sigma_2, \sigma_3$ is therefore given in the former case by a hexagonal prism, the axis of which bisects the first octant of the principal directions. According to Mohr's theory also, a sort of hexagonal body is obtained having six different curved faces with sharp edges oriented symmetrically around a straight axis. This leads to insurmountable difficulties from a mathematical point of view, if the stresses in a plastic body change from point to point and are functions of the coordinates x, y, z. It would be necessary to introduce inequalities, which would limit the stresses to one or the other of the faces of the surface of yielding. Such difficulties are at once eliminated by introducing the von Mises-Hencky condition of yielding:

$$(\sigma_1 + \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_0^2 = \text{const.} \quad [23]$$

which is a circular cylinder. This cylinder circumscribes the hexagonal prism of the maximum-shear theory, and it is evidently a simpler condition to satisfy that a point may be situated on a circular cylinder than to prescribe that the point may move on six different planes. It is true that in certain cases it may be advantageous to replace parts of this cylindrical surface by a plane, by which the second-order expression (Equation [23]) in the stresses is reduced to a linear equation. In general, however, to introduce a hexagonal cylinder or a body having regular hexagons with changing side lengths as sections, as in Mohr's case, seems too artificial. Certain other objections against Mohr's theory have been recently raised by W. V. Burzynski[11] which make it probable that Mohr's enveloping curve does not envelop truly all the possible limiting largest stress circles which determine the critical states of stress.

IV—TESTS ON THE YIELDING OF DUCTILE METALS UNDER COMBINED STRESS

(a) W. Lode's Recent Tests

Since the tests described in the papers mentioned in footnote No. 3 were made, W. Lode and the author have attempted to control the former experiments with improved apparatus.[12] This was done with two different equipments.

1 *Axial Tension and Internal Pressure.* A 20-ton universal Losenhausen machine for tension and a high-pressure pump designed by A. Amsler, of Schaffhausen, which could produce hydraulic pressures up to 1200 atm where simultaneously used. Hollow cylinders were tested, which were stretched in the axial direction and subjected to internal pressure. Particular care was taken in cutting these cylinders from various steels in the form of solid bars, these being first drilled out for the bore, to avoid the inevitable anisotropy encountered in drawn tubes (such as were used by J. Guest and others and in earlier tests by Dr. Lode). The steel tubes had a gage length of 180 to 200 mm, an internal diameter of 20 to 30 mm, and wall thicknesses of 3 to 3.8 mm. The wall thickness did not vary more than 0.1 mm, this being controlled by a special micrometer apparatus. The bars had heavy heads with gradually changing cross-sections and large fillets.

The tests were conducted so that the high-pressure pump furnished an internal pressure p, which increased in a given proportion simultaneously with the increasing axial load P. To secure this simultaneous proportional increase of the axial and tangential principal stresses in the hollow cylinder, an auxiliary pointer was designed which indicated the pressure p but also moved along the scale on which the axial loads were read. By adjusting the valve of the pump for the high pressure the auxiliary pointer could be moved with such a speed that it would advance simultaneously with the pointer of the load, thus securing strictly proportional increase of both p and P. The pressures of the Amsler pump were measured by a high-pressure pendulum manometer, and the indications for the axial loads of the tensile machine were controlled by a balance beam. The changes of shape of the tubes were carefully measured after each test by micrometers, and during the test by means of a Bauschinger roller apparatus and a lateral extensometer.

From the theory of elasticity the stresses in a tube closed at its ends (r_1, r_2, internal and outer radii) and simultaneously subjected to internal pressure p and an axial load P, are given by

Radial stress: $$\sigma_r = -\frac{pr_1^2}{r_2^2 - r_1^2}\left(\frac{r_2^2}{r^2} - 1\right) \quad \ldots\ldots [I]$$

Tangential stress: $$\sigma_t = \frac{pr_1^2}{r_2^2 - r_1^2}\left(\frac{r_2^2}{r^2} + 1\right) \quad \ldots\ldots [II]$$

Axial stress: $$\sigma_z = \frac{pr_1^2}{r_2^2 - r_1^2} + \frac{P}{\pi(r_2^2 - r_1^2)} \quad \ldots\ldots [III]$$

Taking for r the mean radius

$$r = \frac{r_1 + r_2}{2} \quad \ldots\ldots [IV]$$

and designating the wall thickness by

$$\delta = r_2 - r_1 \quad \ldots\ldots [V]$$

the formulas above may be rewritten, after expanding in powers of δ and neglecting higher powers of δ than the first, as follows:

$$\left.\begin{aligned} \sigma_r &= -\frac{p}{2} \\ \sigma_t &= -\frac{p}{2} + \frac{pr}{\delta} \\ \sigma_z &= -\frac{p}{2} + \frac{pr}{2\delta} + \frac{P}{2\pi r\delta} \end{aligned}\right\} \quad \ldots [VI]$$

The condition of yielding at the mean radius of a hollow tube then takes according to Equation [23] the form

[10] A very instructive discussion of the shapes of this surface for the various theories of strength is given in the paper by H. M. Westergaard, "On the Resistance of Ductile Materials to Combined Stresses," *Jl. Franklin Inst.*, May, 1920, p. 627.

[11] "Über die Anstrengungshypothesen," *Schweiz. Bauzeitung*, Zürich, Bd. 94 (1929), Nov. 23.

[12] After the author left Germany at the end of 1927, Dr. Lode continued his tests until 1929. As the latter has until now also not published the results of his recent tests, a brief résumé of a part of his tests is given above.

$$\left[\frac{P}{2\pi r\delta\sigma_0}\right]^2 + \left[\frac{\sqrt{3}rp}{2\delta\sigma_0}\right]^2 = 1 \ldots\ldots\ldots\ldots [VII]$$

With regard to the terms included in the two brackets and which are taken as variables, this is the equation of a circle having unity for its radius. σ_0 is the yield stress for pure tension. The results

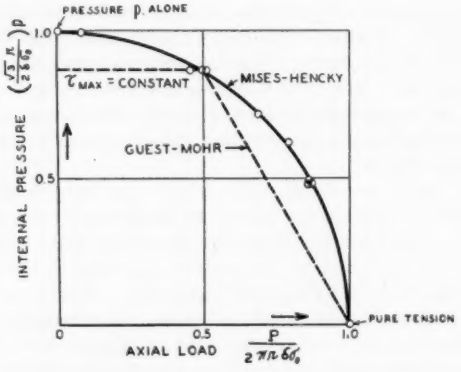

FIG. 18-LODE'S TESTS OF 1926. (INTERNAL PRESSURE & AXIAL LOAD)

of Lode's recent tests are given in Fig. 18, in which the quantity in the first bracket of [VII] is the abscissa, and the quantity in the second bracket the ordinate. The points referring to the tests

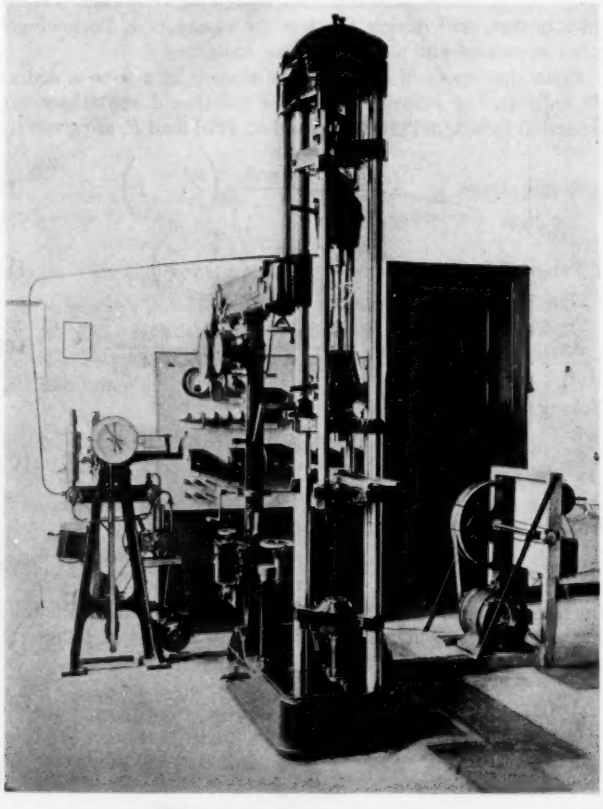

FIG. 19 COMBINED STRESS TESTING

fall close to the circle corresponding to the condition of yielding (Equation [VII]) or the condition of constant energy of distortion. The two straight lines in Fig. 18 correspond to the maximum-shear theory. Fig. 19 shows the testing equipment.

At the left is the Amsler high-pressure pump mounted on a pendulum manometer. In the center is the 20-ton Losenhausen testing machine shown with the test tube in position. The motor drive of the machine will be seen at the right of the figure. Fig. 20 is a closer view of the high-pressure apparatus.

2 *Tension-Torsion Machine.* This machine was built by

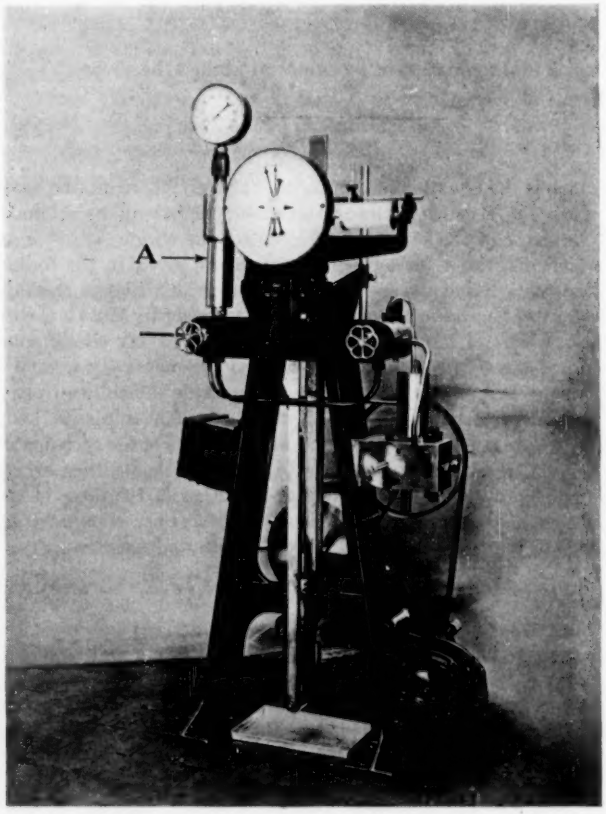

FIG. 20 AMSLER HIGH-PRESSURE PUMP

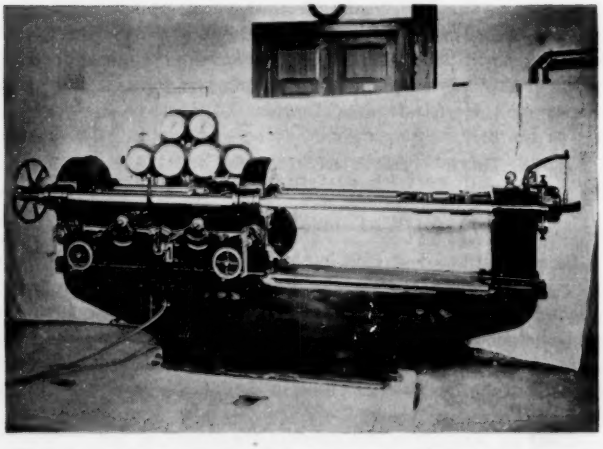

FIG. 21 LOSENHAUSEN TENSION-TORSION TESTING MACHINE

the Losenhausenwerk in Düsseldorf.[13] In it hollow specimens can be simultaneously distorted by applying axially a tensile load and by twisting the tube by a torque. Fig. 21 shows a view of the machine. It consists of two screw-type drives com-

[13] Designed by Baurat v. Bohuczevitz and Eng. Sontag.

bined into one machine. An electric motor through two friction drives operates the tension and torsion parts of the machine, which can be coupled together or used separately. It is possible to adjust the speed for axial stretching independently of that for twisting or also in a given ratio of the two. The axial load and the torque are measured by means of calibrated hydraulic-pressure gages (*messdose*) of the Losenhausen type. The grips and the attachments of the tube specimen to the machine are

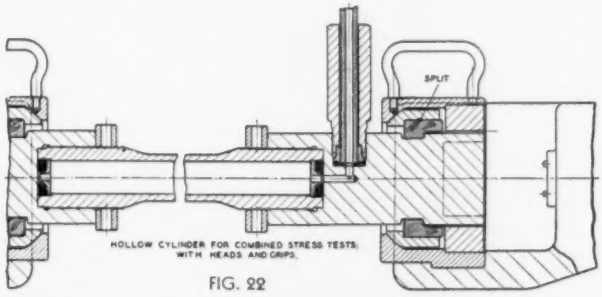

FIG. 22

shown in Fig. 22. The attachments are so designed that internal pressure can also be applied to the tubes or combined with tension or torsion or both. The capacity of the machine is 15 tons for tension and 150 kg-m for torsion. The machine has been used in various tests since the author left Germany, among others for one of the purposes for which he had it designed, namely, for experiments in which the axis of the applied-stress tensor is rotated relatively to the stressed body.

In this case of yielding there is no justification in assuming that the tensor of the elastic strains will at all times remain coaxial with the tensor of the permanent strains.

By combining the results of his tests described under (*a*) with a few torsion and combined torsion-tension tests, Dr. Lode attempted to investigate whether an appreciable effect of the mean tensile stress $\sigma = (\sigma_1 + \sigma_2 + \sigma_3)/3$ might be ob-

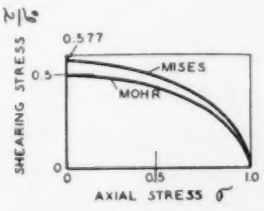

FIG. 23. - σ AND τ FOR TENSION-TORSION

served on the constant k in Equation [15] or on the radius of a section of the surface of yielding normal to its axis. The results were negative for steel, thus indicating that no appreciable effect of the mean pressure on the constant appearing on the right side of the condition of plasticity, Equation [1] or [15], might be present.

(*b*) Tests by G. I. Taylor and H. Quinney

In a recent paper[14] the first-named author has extended his most careful observations on the plastic deformations of single metallic crystals[15] to polycrystalline ductile metals. For obtaining the critical values of the principal stresses at the plastic limit, Taylor and Quinney subjected tubes to a direct axial load and to torsion. By measuring the change of the internal volume of the tube during the strain by filling it with water and reading the movement of a column in a capillary tube, they were able to determine also the relation existing between the quantities μ and ν in a more perfect way than was the case in Lode's early tests. The volume of the bore of a tube stretched plastically in axial tension should not change. The same is true for pure torsion, and hence also for all combinations of both, provided that $\mu = \nu$. Hence the possible changes of volume of the water

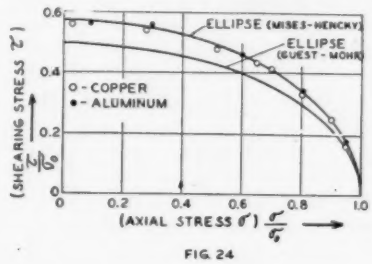

FIG. 24

inside the bore could be utilized to find any observable deviations from the law $\mu = \nu$. These tests led to the results reproduced in Figs. 24, 25, and 26. According to Equation [1], yielding in a tube subjected to tension-torsion should start when

$$\sigma^2 + 3\tau^2 = \sigma_0^2 = \text{const.} \quad \text{[VIII]}$$

where σ is the axial tensile and τ the shearing stress, and σ_0 the yield stress for pure tension. However, according to the theory of maximum shear (Guest-Mohr), yielding would start as soon as

$$\sigma^2 + 4\tau^2 = \sigma_0^2 = \text{const.} \quad \text{[IX]}$$

Plotting σ and τ as rectangular coordinates, the expressions above give ellipses with the semiaxes σ_0, $\sigma_0/\sqrt{3}$ and σ_0, $\sigma_0/2$, respec-

[14] "The Plastic Distortion of Metals," Phil. Trans. Roy. Soc. London, Series A, vol. 230, pp. 323–362.

[15] "The Distortion of an Aluminum Crystal During a Tensile Test," Bakerian Lecture, Proc. Roy. Soc. London, vol. 102 (1923), p. 643, and subsequent papers.

tively (Fig. 23). Figures 24, 25, and 26 taken from Taylor and Quinney's report show that for aluminum or copper the test points very closely follow the upper ellipse corresponding to Equation [VIII], disproving Equation [IX]. For mild steel, however, the agreement between the observations and the curves was by no means as good. All points were found lying above the von Mises ellipse. In any case they were closer to this than to the other ellipse. As the observations of the volume filled with water showed anomalies which appeared closely connected with the breaks of the stress-strain curve, most probably the different behavior of mild steel in these tests must be attributed to the non-uniformity of the first yielding over the length of the specimen (yielding in thin layers) due to the phenomenon of upper and lower yield points. The previous and varying thermal heat treatment of the steel specimen may have also been instrumental in causing some of these discrepancies.

Finally, Fig. 26 shows the test results of Taylor and Quinney with regard to the kinematics of the plastic flow. The scattering of the points in Lode's μ, ν diagram appears to be eliminated here, and for the relation $\nu = f(\mu)$ very distinct curves were obtained, although not very different from the straight line $\mu = \nu$.

One very interesting result was that the curves for the hexagonal metal cadmium and for lead approached the straight line $\mu = \nu$ much closer than did those for metals (copper, aluminum) with a regular lattice. The points for the amorphous heated glass were almost exactly on the line $\nu = \mu$, as was to be expected for viscous flow of a substance. It seems probable that the type of lattice structure within the individual grains has something to do with the shape of the $\nu = f(\mu)$-curve. This was suspected by Lode, who tried to explain the shape of the actual curve $\nu = f(\mu)$ by the statistical effect of a great number of grains oriented at random with their axes, but yielding according to the well-known modes of the single metallic crystals.

Summing up the conclusions from the preceding tests by Taylor, Quinney, and Lode, it appears (1) that the condition of yielding for ductile metals is, within experimental errors, well expressed by the condition

$$\tau_1^2 + \tau_2^2 + \tau_3^2 = \frac{\sigma_0^2}{2} = \text{const} \ldots\ldots\ldots [X]$$

and (2) that when suppressing the clearly observable deviation of the curves $\nu = f(\mu)$ from the straight line $\nu = \mu$ in the first approximation and for the purpose of a simple mechanics of the plastic state, the relation

$$\nu = \mu \ldots\ldots\ldots\ldots\ldots\ldots [XI]$$

is sufficiently accurate to express the third law of yielding for the ductile metals.

(c) Tests by M. Ros and A. Eichinger[16]

Among a number of other tests, Ros and Eichinger compared the behavior of various carbon steels and of cast steels in hollow or solid specimens subjected to tension or compression combined with internal pressure, and also to torsion. For each material they plot three kinds of stress-strain curves, namely, (1) the maximum stress σ_1 versus the maximum strain ϵ_1, (2) the maximum shearing stress τ_{max} as a function of the maximum shear γ_{max}, and (3) the shearing stress τ_n acting in the octahedral planes of the stress or strain tensor as a function of the corresponding strain γ_n (see Equations [12] and [14]). The various stress-strain curves which they obtained for different stress distributions differed from each other considerably when plotted according to the schemes (1) and (2), but these curves came closer together in the third diagram. Their conclusion, therefore, was that Equation [X] is the best representation of the condition of yielding.

By plotting the continuous stress-strain curves over a longer interval of the strains observed on various bars the comparison of the curves becomes less exact, because on account of the small differences in the speed of testing or in the structure of the metals which cannot be avoided, the deviations will accumulate gradually until finally the curves diverge. These and other tests by Ros Eichinger not discussed here indicate the superiority of the condition of yielding (Equation [X]) over the Guest-Mohr condition. If they had used the testing method described under (1) and (2) above (Lode, Taylor, and Quinney) they would have arrived probably at a still closer agreement between theory and tests.

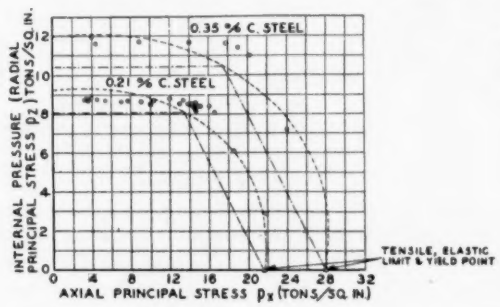

FIG. 27.—TESTS WITH THICK-WALLED TUBES BY G. COOK

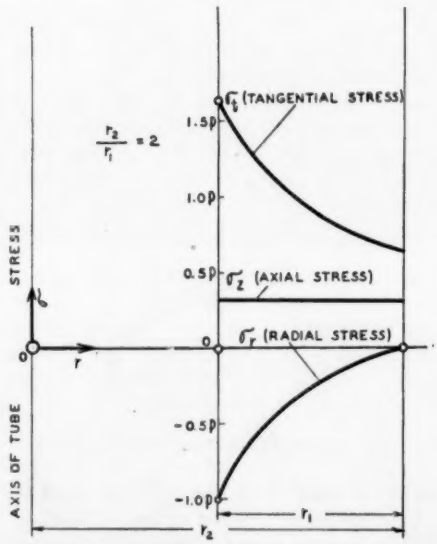

FIG. 28.—ELASTIC STRESS DISTRIBUTION IN THICK-WALLED TUBE PRODUCED BY INTERNAL PRESSURE

In all these tests, yielding of the ductile metals was observed parallel to the direction of the intermediate stress σ_2 [except in the case when $\sigma_2 = (\sigma_1 + \sigma_3)/2$], thus disproving Mohr's conclusions about the mode of yielding.

Corroborating Lode's conclusions, they found no appreciable influence of the mean stress $\sigma = (\sigma_1 + \sigma_2 + \sigma_3)/3$ on the maximum shearing stress τ_{max} during yielding within the comparatively wider range of stress distributions tested here compared to Lode's tests.

[16] "Versuche zur Klärung der Frage der Bruchgefahr. III. Metalle." Diskussions-bericht No. 34. Eidgenossische Materialprüfungsanstalt, Zürich, 1929.

(*d*) Tests by G. Cook

While the recent tests described under (*a*), (*b*), (*c*) were all made with regard to yield stresses, G. Cook has in a recent paper[17] attempted to investigate the elastic limit under combined stress in order to discover whether a similar effect is observable in regard to the elastic limit in previously unstressed materials. Thick-walled tubes of two steels (with 0.35 and 0.21 per cent carbon, respectively) were tested by simultaneously applying to them internal pressure and an axial load. The ratio of the outer to the inner diameter of the tubes, however, was chosen extremely large, namely, $r_2 : r_1 = 2$. This leads to the elastic stress distribution shown in Fig. 28 in case the tube is subjected to internal pressure p alone and is closed. To this distribution is added axial tension σ by which σ_z is changed into $\sigma_z + \sigma$. The tests were conducted by applying an axial load first and then increasing the pressure until the first slight signs of permanent set became observable. For this purpose, also, the radial and axial extensions were measured. The observed points were then plotted in a diagram similar to that indicated by Equation [VII] or Fig. 18, which is reproduced here in Fig. 27. In this last figure the axial principal stresses $\sigma_z + \sigma$ or the quantities

$$\sigma + \frac{pr_1^2}{r_2^2 - r_1^2}$$

are plotted as abscissas, and the radial principal stresses at the highest-stressed inner surface $r = r_1$ of the hollow tube, that is, $\sigma_r = -p$ or the pressures p, are used as ordinates.

To the condition of yielding, Equation [X], there corresponds here also an ellipse which is indicated in Fig. 27, and to Guest-Mohr's condition, the two straight lines. The points reproduced from Cook's tests (Fig. 7, p. 572) do not seem to fit either of these two curves. The whole comparison is unfortunately obscured by introducing an "elastic limit" in the case of a rapidly changing stress distribution in the radial direction, such as that present in thick-walled tubes of such large ratio of outer to inner radius ($= 2$).

In a case of non-homogeneous stress distribution like the one tested by Cook in which the tangential stress σ_t at the instant of first yielding at the inner surface $r = r_1$ of the tube is more than 2.5 times larger than at the outer surface $r = r_2$, the danger is great that the critical instant of first yielding may have escaped observation.

It must be difficult to observe in a stress-strain curve the first instant when the yield stress is just reached in the infinitesimal layer coinciding with the *inner* surface of a thick-walled tube, when all readings of the extensions have been made at the *outer* surface. The possible presence of an upper and lower yield stress in tension (the two diagrams shown in Fig. 5 of the paper by Cook seem to indicate that a drop of stress was observed in the tensile tests) might have further obscured the comparison. In some of the published stress-strain curves in which the pressures p are plotted above the radial extensions of the tubes, more or less sharp breaks also appear which seem to support the view of the author that at these states of stress probably larger portions of the tubes were already yielding. Assuming that the yield stress for pure tension was possibly overestimated (by taking an upper yield stress), this would reduce the ellipse in Fig. 27 to a smaller-sized one and would bring the observation points of the pressures p *above* the ellipse, as should be expected if higher pressures were observed than those producing first yielding.

The cylinders in these tests were first axially loaded with a stress such that, with the addition of the stress due to internal pressure, yielding would start. When internal pressure was then added, the ratio of the principal stresses $\sigma_1 : \sigma_2 : \sigma_3$ during the raising of the pressure p until yielding started was not kept constant. It is possible that yielding under such circumstances starts at different values of σ_1, σ_2, σ_3 from those when the three principal stresses $\sigma_1 : \sigma_2 : \sigma_3$ are increasing proportionally until they reach the plastic limit. This is a point that needs further testing.

Summing up the preceding remarks, it seems probable that some systematic influences not taken into account might have been the reasons for the deviations observed in these last tests.

(*e*) Concerning the "Elastic Limit" Under Combined Stress

A word in regard to this may perhaps be in order. More recent tests, particularly tests in which both the principal stresses increase according to some law and at the same time the principal axes of the stress tensor gradually change their position in space with regard to the material, show that the directions of the three axes of the tensor of the elastic parts of the total strains at a given instant do not coincide with the directions of the three axes of the stress tensor. This has the consequence that, particularly after a yield test has been made under a given ratio of $\sigma_1 : \sigma_2 : \sigma_3$ and then another yield test is made on the same test piece in which $\sigma' : \sigma_2' : \sigma_3' \neq \sigma_1 : \sigma_2 : \sigma_3$, a transition curve will be observed starting from the elastic straight line, combining any two corresponding stresses and strains σ_n and ϵ_n and depending on the previous operations until the plastic limit is again reached. In other words, the stresses σ_{1e}, σ_{2e}, σ_{3e} at the point where a transition curve starts, or the stresses referring to the "elastic limit," depend not only on the amount of strain hardening, but particularly also on the *change* of the ratios of the critical values of $\sigma_1 : \sigma_2 : \sigma_3$ from one test to another. It has already been stated that the reversing of the stress directions (for example, change from tension into compression or reversing of the directions of a pure shear) has a large effect on the shape of the transition curve and brings the elastic limit practically down to zero. For these and other reasons not mentioned here, it must be conceded that the "elastic limit" for a given material will in general depend also on the previous history of the straining of the material, and therefore lose much of its significance as a limiting state of stress.

V—THE MORE GENERAL KIND OF YIELDING OF POLYCRYSTALLINE MATERIALS

For single metallic crystals as well as for the polycrystalline ductile metals, it has been repeatedly shown that the addition of a uniform tensile or compressive stress will not change the magnitude of the principal shearing stresses τ_1, τ_2, τ_3 at a plastic limit.

For other less compact materials, in which the grains are not well cemented together, this may be different. For such materials the diameters of the three principal-stress circles for which μ has the same value but the mean stress

$$\sigma = \frac{\sigma_1 + \sigma_2 + \sigma_3}{3} \quad \text{[XII]}$$

varies, will depend on σ. For any given type of stress $\sigma_1 > \sigma_2 > \sigma_3$ corresponding to a given μ, the radius of the largest stress circles

$$\tau_2 = \frac{\sigma_1 - \sigma_3}{2}$$

will continuously change, either with $\frac{\sigma_1 + \sigma_3}{2}$ or with

$$\sigma = \frac{\sigma_1 + \sigma_2 + \sigma_3}{3}$$

[17] "The Elastic Limit of Metals Exposed to Triaxial Stress," Proc. Roy. Soc. London, Ser. A., vol. 137 (1932), p. 559.

Introducing at the plastic limit

$$\tau_2 = \frac{\sigma_1 - \sigma_3}{2} = f\left(\frac{\sigma_1 + \sigma_3}{2}\right) \ldots\ldots\ldots [XIII]$$

would be what Mohr assumed. As it is scarcely probable that the intermediate principal stress σ_2 would remain without any influence on the value of τ_2, other mathematical relations have recently been suggested by means of which the experimental facts just mentioned might find more adequate expression.

While F. Schleicher[18] for this or similar reasons has suggested that the total elastic-strain energy might be assumed as a function of the mean pressure, $\sigma = (\sigma_1 + \sigma_2 + \sigma_3)/3$, that is,

$$\sigma_1^2 + \sigma_2^2 + \sigma_3^2 - \frac{2}{m}[\sigma_2\sigma_3 + \sigma_3\sigma_1 + \sigma_1\sigma_2] = f(\sigma) \ldots [XIV]$$

where m is Poisson's ratio, W. Lode[19] and W. T. Burzynski[20] suggest the expression of the condition of this more general kind of yielding by assuming that the energy of distortion is a function of σ. Referring to what has been said above with regard to the significance of the octahedral shearing stress τ_n (Equation [14]) it is here suggested that this last condition might now be expressed by assuming that "the octahedral shearing stress τ_n (acting in the octahedron planes of the stress tensor), or

$$\tau_n = \frac{2}{3}\sqrt{\tau_1^2 + \tau_2^2 + \tau_3^2} = f(\sigma) \ldots\ldots\ldots [XV]$$

shall now be considered as depending on the mean stress $\sigma = \frac{\sigma_1 + \sigma_2 + \sigma_3}{3}$."

Although both conditions, Equations [XIV] and [XV], at a closer examination do not seem to differ much mathematically and can be transformed into each other under certain conditions, the second expression must receive the preference for various reasons. One is that Equation [XIV] contains Poisson's ratio m, which does not appear explicitly or implicitly in Equation [XV]. As Burzynski points out, it is possible when adjusting the constants in Equation [XIV] to fit the tests, to be led to absurd conclusions with regard to the value of Poisson's ratio m.

Reasons for the superiority of the relation Equation [XV] over the old Mohr relation Equation [XIII] become more obvious when discussing the shapes of the surface of yielding corresponding to these relations. They are the same as those advanced in favor of the Mises condition of Equation [X]. If the order of σ_1, σ_2, σ_3 is interchanged, the Mohr relation, Equation [XIII], leads to three sets of cylindrical surfaces intersecting each other along sharp edges, while Equation [X] is that of a single continuous surface of rotation having the diagonal of the first octant of the σ_1, σ_2, σ_3 planes as its axis. The improbable exceptional behavior of the intermediate stress has also been eliminated by assuming the validity of Equation [XV] instead of that of Equation [XIII].

The tests made by T. v. Kármán, Böker, Ros and Eichinger, and Brandtzaeg on brittle materials, such as marble, sandstone, or concrete, tend to show that the yielding of such materials, which under the ordinary tensile test would behave as brittle materials, will, under increasing mean pressures

$$\sigma = -\left|\frac{p_1 + p_2 + p_3}{3}\right|$$

approach the laws of the yielding of the ductile metals. Experimental evidence shows that the surface of yielding must approach asymptotically a cylindrical surface at high hydraulic pressures. This is a consequence of the intercrystalline mechanism of gliding in the individual crystal grains of any polycrystalline material, even though under ordinary conditions (low mean pressures σ) it may be as weak as some of the less strong materials mentioned above. By compressing the aggregate of loose crystals under a high mean pressure, the former starts to yield provided that the pressures in certain directions attain the required magnitude, and in a way similar to that in which a ductile metal would act under low mean pressures.

VI—RUPTURE

We come finally to a brief discussion of some of the mechanical conditions which may express or be used to determine the danger of a material separating into fragments. It must be said, however, that it cannot be anticipated here with the same certainty or experimental evidence that in the conditions of rupture the principal stresses σ_1, σ_2, σ_3 will figure as the only or the principal variables as expressed in the relations of yielding. In amorphous solid and strong materials not having a pronounced crystalline grain structure or with a submicroscopic crystalline structure, however, this may, to a certain extent, be the case. In such materials one kind of rupture is known, the circumstances of which have perhaps been the best described, although they may still be obscure enough.

(*a*) Brittle Fracture Due to Tensile Stress

In its original form, the theory of strength advanced by O. Mohr left it quite undecided whether the critical conditions stipulated in this theory might be applied to failure due to yielding (plastic flow) or to rupture. This point has been brought out particularly by von Kármán's tests with brittle crystalline materials, such as marble or sandstone, subjected to combined stress. In general, tests seem to indicate that if at least one of the three principal stresses is a tensile stress, failure due to tensile fracture in such materials occurs when the largest of the tensile principal stresses reaches a value equal to the tensile strength in pure tension. The surface of rupture is perpendicular to the maximum tensile stress. Thus in this region neither Mohr's enveloping curve nor the surface of yielding can have any significance. For example, using the representation of the surface of yielding in its general form given by Equation [XV], this would mean that this surface cannot be extended beyond the region where one of the three principal stresses is a tensile stress and has at least reached the tensile strength of rupture. Thus for the rupture due to tensile stresses, Rankine's theory of maximum principal stress may be taken as the hypothesis representing the experimental facts. The states of stress producing the tensile failure when represented by points in the system of rectangular coordinates σ_1, σ_2, σ_3 engender also a certain surface $H(\sigma_1, \sigma_2, \sigma_3) = 0$ which might be called "the surface of rupture." According to the present hypothesis this surface consists of the three mutually perpendicular planes:

$$\sigma_1 = c, \quad \sigma_2 = c, \quad \sigma_3 = c \ldots\ldots\ldots\ldots [XVI]$$

where c is an essentially positive stress (equal to the tensile strength in pure tension). The "surface of yielding" has thus to be limited toward its tensile region by the "surface of rupture" consisting here of the three mutually perpendicular planes as just described.

(*b*) Sliding Fracture

Another kind of fracture is known in brittle crystalline materials, and can also be observed when ductile materials break

after considerable permanent strain. The surface of rupture is a plane inclined at a certain angle to one of the principal-stress planes. This kind of fracture occurs, for example, in compression tests made with cylinders of brittle materials (cast iron), in which cases nearly plane oblique surfaces of rupture may sometimes be observed.

A closer examination of such fractures may, however, disclose that the phenomenon is not altogether so simple as it may appear at the first glance. Long before a surface of rupture finally forms, it will be seen that the structure of the material has undergone changes. The crystalline structure is gradually loosened, minute cracks appear in the grains or the latter exhibit discoloration in thin samples. This is particularly the case in compression tests when in the perpendicular direction to the principal compressive stress, no external stresses act. A more or less solid crystalline material, the grains of which have been first cemented together by their boundary substances, when subjected to a gradually increasing uniaxial compressive stress, will show a disintegration of the grain structure or a gradual weakening of its strength and its internal structure. Certain grains which will be oriented favorably with regard to the stress field, will start to yield and deform by slip in their crystallographically determined gliding planes. Other grains which are in an unfavorable direction for slip may be ruptured. If soft inclusions are present (that is, points of weakness, as, for example, the graphite inclusions of a cast iron), the result will be that the whole structure of the material will be changed under the increasing stress. Another important fact may be mentioned, to which Griffith seems to have first called attention, namely, that in pure uniaxial compression, failure may still be due to local tensile stresses.

For example, the graphite inclusions in cast iron are equivalent to minute cracks, and if such cracks are oriented at random in a field of compressive stress, tensile stresses will be developed along certain of the cracks. The final surface of rupture will be inclined to the principal compressive stress. For this kind of fracture perhaps Mohr's theory may be sufficient as a working one upon which to predict the fracture and its orientation. Assuming that the radii of Mohr's largest principal-stress circles would be known for pure shear τ_s and for pure compression τ_c (see Fig. 29) so that τ_s would be the strength for pure shear and

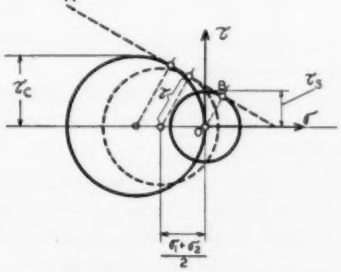

FIG. 29- CONDITION OF SLIDING RUPTURE

$2\tau_c$ the strength for pure compression, according to Mohr and Duguet a tangent AB to these two circles may be drawn. For intermediate cases of stress, the maximum shearing stress τ_{max} or the radius of the largest principal-stress circle

$$\tau_{max} = \frac{\sigma_1 - \sigma_3}{2} \quad \text{[XVII]}$$

at the instant of a sliding fracture would have to be chosen so that this circle becomes tangent to AB (circle shown by broken lines in Fig. 29). As condition of rupture, the relation

$$\tau = \frac{\sigma_1 - \sigma_3}{2} = \tau_s + \left(1 - \frac{\tau_s}{\tau_c}\right) \cdot \frac{(\sigma_1 + \sigma_3)}{2} \quad \text{[XVIII]}$$

may be used, provided that $\sigma_1 > \sigma_2 > \sigma_3$, which can be read from Fig. 29.

(c) Fracture of Ductile Materials

In general, in ductile materials the state of stress at the instant of final rupture is almost without exception of a more or less complex nature, even if the material has first been subjected to a simple and homogeneous state of stress. This is particularly true for the rupture in an ordinary tensile or compression test. Consequently the fracture in these tests is also not of a simple nature, and more exact rules cannot be given beyond the empirical proceeding of taking a certain load in the stress-strain diagram and dividing it by the characteristical area of the original or the actual cross-section.

Discussion

Pierre F. de Bethune.[21] In section IV(d) of the paper, Dr. Nadai discusses the discrepancy between the von Mises-Hencky law and the tests of G. Cook.

The writer agrees entirely with the author's opinion on the previous history of the material. It is certain that a prior plastic deformation induces in the material an anisotropy which cannot be overlooked in a further deformation, especially if that deformation has not the same anisotropy. This can be physically expressed in terms of slip planes in every crystalline grain, and the writer thinks that it would not be difficult to find examples of slipping along a previously established set of planes in a specimen subjected to stresses which would induce movement along another set of planes if the material had not been previously deformed.

However, this explanation implies a previous plastic deformation, and Dr. Nadai refers to that when he speaks of transition curves. Now the writer would remark that in the case of a first yielding the former history of the material would have no effect, or at least a trifling one.

Another point he would make is that, next to the principal stresses σ_1, σ_2, σ_3, account should perhaps be taken of the partial derivatives with regard to space: $\partial\sigma/\partial x$, $\partial\sigma/\partial y$, $\partial\sigma/\partial z$. These are nil in the case of the work by Lode, Quinney, and Ros and Eichinger, where the stress distribution is nearly homogeneous, but have some value in the case of the experiments by Cook.

The writer bases this opinion on the fact that the plastic yielding of the grains occurs to the same scale as that of the individual grains, and that at that scale the metal is no longer homogeneous. The response of that heterogeneity to the stress must be different if at that scale the stress is also heterogeneous, i.e., if the terms of the form $\partial\sigma/\partial x$ have a sufficiently high value.

H. Hencky.[22] The connection between the so-called "testing of materials" and the methods of applied mechanics is not a very satisfactory one at the present time. One principal reason is that the problem of strength is not only a problem of mechanics but also one of colloidal chemistry. Therefore theoretical statements seeking to explain matters along purely mechanical lines are often overthrown by new experimental results. However, the author's critical exposition of the problem contains many suggestions for further research and helps to counteract any discouraging influence resulting from theoretical shortcomings.

In connection with further research, and referring to the em-

[21] Louvain, Belgium.

[22] Massachusetts Institute of Technology, Cambridge, Mass.

pirical formula for creep recommended by the author in some of his papers, namely,

$$\sigma = \sigma_1 + \sigma_2 \log_e (v/v_0)$$

which connects the strain velocity v with the stress, the writer would suggest changing it to

$$\sigma = \sigma_1 + \sigma_2 \log_e [1 + (v/v_0)]$$

because in this form it would be applicable to all strain velocities and could be easily generalized for triaxial stress. This last formula has important consequences as regards the theory of the rolling mill, which cannot be elaborated here, and the writer would ask whether the author has any objections to making the change.

Another point that the writer would discuss concerns the general theory of yielding of polycrystalline material. As is well known, the state of stress in a crystalline aggregate is turbulent. This is explained very clearly by Moore and Kommers in their treatise on "Fatigue" and was known to Heyn a long time ago, as the author has shown in some of his papers.

Now the stresses entering the plasticity condition are obviously only the average stresses. There must be, however, a plasticity condition limiting the amount of possible stress fluctuations. The hidden elastic energy connected with the stress fluctuations at the grain boundaries seems much more important for the plastic behavior than any possible influence of the hydrostatic stress, and the author is requested to state whether methods of measuring the amount of stored-up elastic energy have already been developed. Obviously this energy behaves in a manner quite analogous to that of heat energy.

P. G. McVETTY.[23] In this paper the author has brought into agreement theoretical analysis and actual test data relating to the behavior of metals under the action of combined stresses. It is of interest to note that this very complete discussion is restricted to temperatures low enough to avoid creep effects. In a previous paper[24] the author has discussed the problem of creep under the action of simple stresses at elevated temperatures. Up to the present time, however, very little has been done on the problem in which creep occurs under the action of combined stresses. The introduction of the concept that the stress-strain relations depend also upon the temperature and the rate of application of the stress adds complexity to the analysis of the problem and to the experimental work necessary to effect its solution.

There may be some question as to the desirability of attacking the problem of combined stresses at high temperature until more is known about the laws governing the action of creep under simple stress. Practical considerations indicate the urgent need of such an investigation to establish a more direct relation between creep tests and actual design problems. In many cases a rational basis for design awaits further analysis of creep laws and further verification of such laws under conditions simulating those of service.

Creep tests are necessarily tedious, and the amount of information obtained per unit of time is extremely small. It is generally agreed that creep tests can seldom, if ever, extend to times approaching the expected life of materials in service. In this respect all creep tests may be considered accelerated tests. By extending our knowledge of the laws governing creep under various conditions we may extrapolate the results of short tests made either at higher stresses or higher temperatures with greater assurance of accuracy. To do this for simple stresses only is valuable, but more rapid progress may be made if investigation of the combined stress problem is carried out at the same time.

A careful study of these papers relating to creep and combined stresses will do much to guide future experimental work. In this way much time may be saved by following a definite program of correlated tests. It is hoped that this paper will stimulate further analytical study of creep under the action of combined stresses, together with the experimental work necessary to establish and verify the laws involved.

BENJAMIN MILLER.[25] The author sees fit to discuss only two of the theories of strength: the maximum-shear theory and the maximum-energy-of-distortion theory. Since the maximum-strain theory is still the most popular in the handbooks which are used by the engineer who has not made a special study of the subject, it would be extremely valuable to have a definite statement that the maximum-strain theory has been disproved appear in a paper such as this. Furthermore, if the maximum-energy-of-distortion theory has had general acceptance by those who are specialists, it should be recognized in those publications of the Society, such as the Boiler Code, which are used as a guide by governmental and other regulatory bodies.

The writer is particularly interested in the subject of pressure piping. The Society is now engaged in preparing a Code for Pressure Piping, and one of the things on which agreement has not been reached is the relation between the dimensions of a pipe, the strength of the material in the pipe, and the load required to cause failure. The several theories of strength lead to strikingly different forms for this relation. These are usually presented as pipe-thickness formulas, or as curves showing the ratio of failure pressure to critical stress as a function of the ratio of wall thickness to diameter. Since no such formulas or curves based on the maximum-energy-of-distortion theory have been published, so far as the writer knows, he has prepared those given below.

According to all theories of strength, the inner skin of a tube subjected to internal pressure is first to reach the critical condition as the internal pressure is increased. By the maximum-energy-of-distortion theory the relation is

$$S_0^2 = 3\left(\frac{P}{4K(1-K)}\right)^2 + \left(\frac{(1-2K)^2P}{4K(1-K)} - S_z\right)^2 \quad \text{[A-1]}$$

in which

S_0 = limiting stress in the tension test (yield point)
S_z = average axial tension
K = ratio of wall thickness to external diameter
P = pressure when the inner skin reaches the critical condition.

Two cases which are of practical importance yield expressions which are relatively simple. One is the case in which there is no axial stress, $S_z = 0$. The expression in this case is

$$P_1 = 2K\,S_0\,\frac{2(1-K)}{\sqrt{3 + (1-2K)^4}} \quad \text{[A-2]}$$

As K decreases, the fraction approaches unity, so that for thin tubes Equation [A-2] can be approximated by

$$P_1 = 2KS_0 \quad \text{[A-3]}$$

Equation [A-3] is the familiar Barlow's formula, which is thus seen to be theoretically correct for thin tubes with no axial stress. For showing the difference between the exact and the approximate forms, it is convenient to rewrite [A-2] as

$$P_1 = 2KS_0(1-J) \quad \text{[A-4]}$$

[23] Westinghouse Research Laboratories, East Pittsburgh, Pa. Mem. A.S.M.E.

[24] A. Nadai, "The Creep of Metals," A.S.M.E. New Haven Meeting, June, 1932.

[25] Henry L. Doherty & Co., New York, N. Y.

in which J is a correction to Barlow's formula. J is a function of K; the function is plotted in Fig. 30 for values of K up to 0.1, which includes most commercially important pipe. It is of interest to note that the correction is only $2^1/_2$ per cent for a pipe whose thickness is one-tenth the external diameter.

The second case is that in which the pipe wall carries the load due to the internal pressure on unstayed closed ends. The expression in this case is

$$P_2 = 2KS_0 \frac{2}{\sqrt{3}} (1 - K) \quad \text{[A-5]}$$

For thin tubes the factor $(1 - K)$ differs by a negligible amount from unity, so that approximately

$$P_2 = 1.155\, P_1 \quad \text{[A-6]}$$

Equation [A-6] indicates that the pressure required to bring the inner skin to the plastic state is about 15 per cent greater if the tube has unstayed closed ends than if there is no axial stress. The engineer concerned with pressure piping cannot neglect this important difference between the conclusion reached on the basis of the maximum-energy-of-distortion theory and that on the basis of the maximum-shear theory, which is that the pressure for failure should be the same in the two cases.

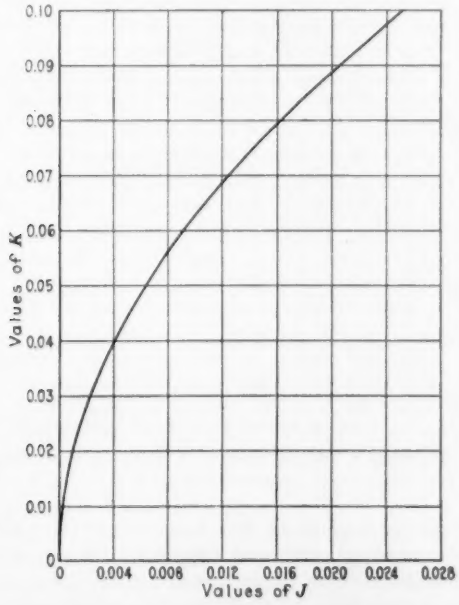

FIG. 30 DEVIATION (J) OF YIELD PRESSURE CALCULATED BY BARLOW'S FORMULA FROM YIELD PRESSURE FOR INNER SKIN CALCULATED BY MAXIMUM-ENERGY-OF-DISTORTION THEORY FOR VARIOUS VALUES OF THE THICKNESS, EXTERNAL-DIAMETER RATIO (K) FOR TUBES WITH NO AXIAL STRESS

Since engineers are reluctant to use theories which are subjects of controversy, the recent practice has been to run internal-pressure failure tests on samples of the pipe to be used in important pipe lines. Such tests have been made by welding heads to the ends of the sample and loading to failure by internal hydrostatic pressure. Observations of the volume of water pumped in and the corresponding pressures could be used to plot a stress-strain curve from which the yield pressure could be determined. The operating pressure was then set at some fraction of the yield pressure. It has been suggested that such a method of determining safe operating pressure be inserted in the Pressure Piping Code referred to above.

In purchasing pipe to be used at 800 lb per sq in., for example, it might be specified that the yield-pressure in such a test be not less than 1200 lb per sq in., which would involve a factor of safety of 1.5. But according to Equation [A-6] the true failure pressure under the operating conditions of no axial stress would be not 1200 lb per sq in., but rather 1040 lb per sq in., and the factor of safety not 1.5 but 1.3.

Further, it might be specified that every length of pipe be tested to 1000 lb per sq in. in the regular pipe-testing machine, in which the pipe is subjected to axial compression. Since axial compression lowers the yield pressure according to the theory, pipe might fail in the routine test which had safely passed the special high-pressure test.

In order to show graphically the change in yield pressure with axial loading, it is convenient to transform Equation [A-1] to

$$(3 + a^4)n^2 - 2(a^2 + a^3)qn + (1 + a)^2(q^2 - 1) = 0 \quad \text{[A-7]}$$

in which

n = ratio of yield pressure to that given by Barlow's formula
q = ratio of axial tension to yield tension
$a = (1 - 2K)$ = ratio of inside to outside diameter.

Equation [A-7] may be represented by a family of ellipses, one for each value of K. Two of these are shown in Fig. 31,

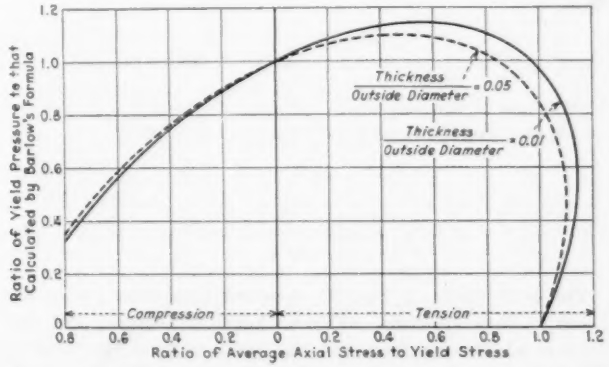

FIG. 31 CHANGE OF YIELD PRESSURE FOR INNER SKIN WITH AXIAL LOADING

the solid line for a thickness $^1/_{100}$ of the external diameter, and the broken line for a thickness $^5/_{100}$ of the external diameter. The curves, or the equation from which they were drawn, may be used to determine the yield pressure under any condition of axial stress if it is known for some other condition of axial stress.

So far, the discussion has been confined to the yield of the inner skin. But the author has pointed out that it is difficult to observe this first yielding, and much easier to observe the yield of the outer skin. The question arises, therefore, as to the pressure which will cause the outer skin to yield. The maximum-energy-of-distortion theory leads to an answer in only the first case—that of no axial stress.

A solution for this case has been given in the author's book "Plasticity," but due to an error in integration the solution there given is not correct. The correct solution is

$$P_1' = \frac{2S_0}{\sqrt{3}} \sin (30° - A) \quad \text{[A-8]}$$

$$a = 1 - 2K = \sqrt{\frac{\sqrt{3}\, e^{\sqrt{3}\,(A - 30°)}}{2 \cos A}} \quad \text{[A-9]}$$

Equation [A-8] may, for convenience, be rewritten as

$$P_1' = 2KS_0(1 + J) \quad \text{[A-10]}$$

in which J is again a correction to Barlow's formula. J is a function of K; the function is plotted in Fig. 32.

By making certain additional assumptions, it is possible to get an approximate solution for the second case—that of no axial plastic strain. This approximate solution is also given in the author's book; in the present notation it is

$$P_2' = \frac{2}{\sqrt{3}} S_0 \log_e \frac{1}{1-2K} \quad \text{[A-11]}$$

This may also be put into a form similar to [A-10]:

$$P_2' = 2KS_0 \frac{2}{\sqrt{3}} (1+J) \quad \text{[A-12]}$$

J as a function of K has also been plotted in Fig. 32.

In the present paper the author gives an Equation [VII] which is said to represent the condition of yielding, and which he has assured the writer in private correspondence is meant to represent the condition for yielding of the outer skin. Equation [VII] leads to

$$P_1'' = 2KS_0 \frac{2(1-K)}{\sqrt{(1-2K)^4 + 3(1-K)^4}} \quad \text{[A-13]}$$

for the case of no axial stress, and to

$$P_2'' = 2KS_0 \frac{2}{\sqrt{3}} \frac{1}{1-K} \quad \text{[A-14]}$$

for the case of the tube with unstayed closed ends. Equations [A-13] and [A-14] can also be written in the form of

$$P_1'' = 2KS_0 (1+J) \quad \text{[A-15]}$$

$$P_2'' = 2KS_0 \frac{2}{\sqrt{3}} (1+J) \quad \text{[A-16]}$$

The solid circles in Fig. 32 represent Equations [A-15] and [A-16]. The agreement between [A-10] and [A-15] and that between [A-12] and [A-16] are very good, especially for values of K not greater than 0.05. This makes it possible to use the author's Equation [VII] as at least a first approximation for the yield of the outer skin under all conditions of axial loading.

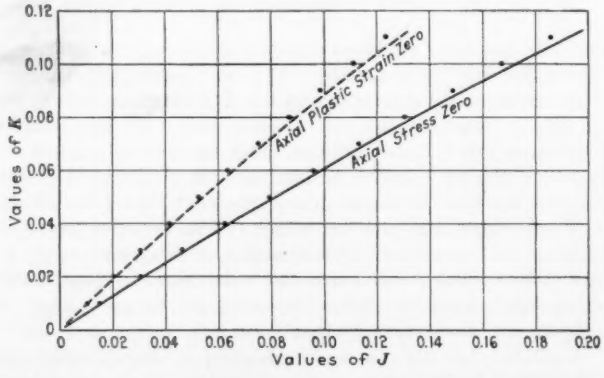

FIG. 32 SOLID LINE: DEVIATION (J) OF YIELD PRESSURE CALCULATED BY BARLOW'S FORMULA FROM PRESSURE CALCULATED FOR YIELD OF OUTER SKIN BY TRIGONOMETRIC FORMULA FOR VARIOUS VALUES OF THE THICKNESS, EXTERNAL-DIAMETER RATIO (K)

Solid Circles Near Solid Line: Deviation (J) of yield pressure calculated by Barlow's formula from pressure calculated for yield of outer skin by Equation [VII] for various values of the thickness, external-diameter ratio (K).

Broken Line: Deviation (J) of $2/\sqrt{(3)}$ times yield pressure calculated by Barlow's formula from pressure calculated for yield of outer skin by logarithmic formula for various values of the thickness, external-diameter ratio (K).

Solid Circles Near Broken Line: Deviation (J) of $2/\sqrt{(3)}$ times yield pressure calculated by Barlow's formula from pressure calculated for yield of outer skin by Equation [VII] for various values of the thickness, external-diameter ratio (K).

In conclusion, the writer would stress again the great practical as well as theoretical importance of this subject, and he suggests that manufacturers as well as users of pipe should continue experiments to test the theory and to determine what modifications must be made because of the differences between the ideal material postulated in the theory and the actual materials which engineers must use.

Equation [VII] in the present notation becomes

$$S_0^2 = 3\left(\frac{P^*(1-K)}{4K}\right)^2 + \left(\frac{(1-2K)^2 P^*}{4K(1-K)} - S_s\right)^2 \quad \text{[A-17]}$$

in which P^* is the pressure when the outer skin reaches the critical condition.

Equation [A-17] differs from [A-1] only by the position of the factor $(1-K)$, which is in the numerator of the first term in [A-17], but is in the denominator of the first term in [A-1]. S_s is the average axial tension in both equations, but it is important to remember that in the case of yield of the outer skin the axial tension is not constant in the cross-section.

To show graphically the change of yield pressure with axial loading, it is convenient to transform [A-17] to

$$\left[\frac{3}{16}(1+a)^4 + a^4\right] n^2 - 2(a^2+a^3)\, qn + (1+a)^2(q^2-1) = 0 \quad \text{[A-18]}$$

in which the symbols have the same meaning as in the similar Equation [A-7]. Equation [A-18] may also be represented by a family of ellipses, two of which are plotted in Fig. 33.

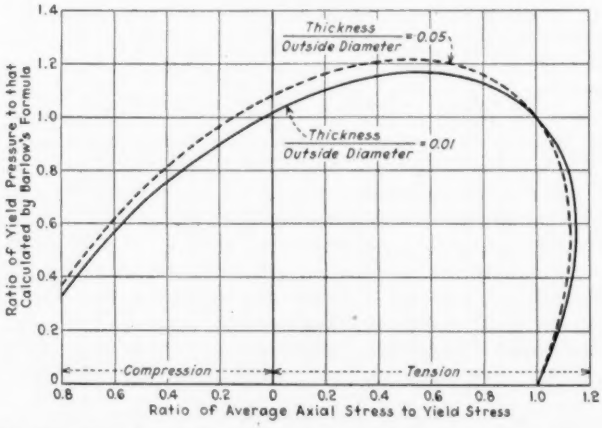

FIG. 33 CHANGE OF YIELD PRESSURE FOR OUTER SKIN WITH AXIAL LOADING

It should be emphasized that Equations [VII], [A-17], and [A-18] are empirical, and must depend for their acceptance on the tests of Lode which are represented in Fig. 18 of the paper. Lode's tests were made on steel tubes having internal diameters of 20 to 30 mm and wall thicknesses of 3 to 3.8 mm. The ratio of thickness to external diameter, the value of K, was in these tests not less than 0.08 and not greater than 0.14; the actual range was possibly less, but cannot be determined from the information given in the paper. On the basis of these tests as shown in Fig. 18 we may provisionally accept Equations [VII], [A-17], and [A-18] for K-values up to about 0.1, as well as Fig. 33.

R. G. STURM.[26] The causes of failure are both fascinating and

[26] The Aluminum Research Laboratories, New Kensington, Pa.

of great importance. Pursuit of them has occupied the minds of many investigators and the equipment of many laboratories. Dr. Nadai has brought together the theories and test results from a number of the most important investigators in such a way that clear comparisons may be made among them.

After carefully studying the various theories and data given, the writer was impressed with the fact that strains have been measured to indicate the beginning of plastic action. Upon the measurement of strains, then, depends the validity of the data used to substantiate the various theories. The strains resulting from stresses are dependent upon the modulus of elasticity and Poisson's ratio for the material in the test specimen. As long as these values remain constant the stresses and strains will be proportional.

If a material exhibits a tendency for the modulus of elasticity to decrease very gradually and for Poisson's ratio to increase simultaneously, readjustments in the strains will take place which under certain combinations may render the change in the ratio of resultant measured strain to computed stress imperceptible, while under other combinations a similar change would be quite noticeable in the measured strain. Thus not only the state of elastic stress but also the state of elastic strain may enter vitally into the interpretation of measurements to verify the applicability of any theory.

In the case of Taylor and Quinney's tests based on the change of internal volume of a tube subjected to direct stress and torsion, one result will be obtained if Poisson's ratio is taken as 0.30, as for purely elastic action, but if it is taken as approaching 0.50, as for completely plastic action, another result will be obtained. Actually Poisson's ratio may vary continuously after the first immeasurably small plastic strain is produced until the metal is yielding freely. This free yielding does not occur at the yield strength in all materials. Precise measurements of volume changes, then, should be interpreted in the light of this gradual change in Poisson's ratio.

It seems to the writer that changes in Poisson's ratio at stresses near the yield point will affect the strains measured. If this is the case, the measured strains should also be interpreted in the light of the change in Poisson's ratio with stress. Since the verification or nullification of any of the theories of strength depends upon measured strains, the proper interpretation of strain measurements is necessary. Perhaps the author has investigated this phase of the problem and could point out to what extent changes in Poisson's ratio at the start of plastic action would affect measured strains.

Author's Closure

The author appreciates the attention and the criticism for his brief summary of the critical conditions for certain types of failure due to yielding, and he will attempt to reply to the various valuable remarks brought out during the discussion as far as the limited space will allow.

Mr. Bethune points to an interesting effect—namely, to the results which will be observed when taking stress-strain readings while a material yields by a repeated action of stresses in cycles. This is a subject about which probably not quite sufficient information is yet available, particularly when the principal axes of stress corresponding to the principal stresses σ_1, σ_2, σ_3 are changing their orientation with respect to the strained body. The elastic anisotropy in the material due to the preceding plastic deformation was probably not very pronounced, because it needs probably much larger plastic strain (such as could be produced by cold rolling or wire drawing only) to produce a preferred orientation of the crystal grains. The strains to which the specimen was subjected in the tests mentioned were, however, much smaller.

The author is indebted for the remarks of two of the discussers, who have indicated the need and desirability to include in the present considerations also the phenomena of slow creep of metals, which, as stated in the paper, had to be omitted, the subject having been confined to that kind of plasticity of metals in which the speed of deformation has not a greater influence on the yield stress. The relation suggested by Dr. Hencky (in the second place) for the expression of a law of creep cannot quite adequately express the known physical facts, as has been pointed out by the author on a previous occasion. The reason is simply because continuity demands that the function $\sigma = f(v)$ expressing the relation between stress σ and rate of creep $v = d\epsilon/dt$ for quite small velocities v should be an odd one around the point $v = 0$. Since this point has been raised by Dr. Hencky, it may perhaps be remarked that another simple function will at least satisfy three conditions assumed to be of importance for certain creep phenomena observed in metallic materials—namely, (*a*) a logarithmical speed law connecting stress σ and rate of creep $v = d\epsilon/dt$ at comparatively large rates of creep; (*b*) a linear relation for quite small stresses or rates of flow, and finally, (*c*) the condition of continuity according to which σ changes into $-\sigma$ if v changes its sign. A creep law which will satisfy these three conditions is (σ stress, $v = d\epsilon/dt$ creep rate):

$$v = v_1 \sin h \frac{\sigma}{\sigma_1}$$

v_1, σ_1 being constants. The last equation leads, for small rates of creep v, to the law of pure viscous flow

$$\sigma = \frac{\sigma_1}{v_1} \cdot v$$

with the "viscosity coefficient" $\eta = \sigma_1/v_1$, and for large creep or strain velocities v the same expression converges toward the function

$$v = \frac{v_1}{2} e^{\frac{\sigma}{\sigma_1}}$$

or

$$\sigma = \sigma_1 \log \frac{2v}{v_1}$$

to the logarithmical creep law.

An equivalent of the amount of elastic stored-up energy in a cold-worked metal has been determined by various investigators. As far as the author recalls, it has been probably first determined by W. Hort in Goettingen some 25 years ago, who measured the amount of heat produced by permanently stretching steel bars in a calorimeter by tension. He found that less heat was produced than would correspond to the thermal equivalent of the work of deformation. G. I. Taylor and W. S. Farren[27] more recently arrived at the conclusion that for steel about 13 per cent of the total work of stretching does not reappear as heat and becomes latent. The increase of internal energy of the material amounted to 13.5 per cent of the work done in the case of steel, 8.5 per cent for copper, 7.5 per cent for aluminum, and 5 per cent for single crystals of aluminum. One remarkable result of the tests by Taylor and Farren was that the ratio of the increase of internal energy to the work of deforming the bars was about the same during the gradual stretching, so that this increase of energy does not appear to have a relation to the amount of cold work or strain hardening.

Mr. McVetty's valuable remarks deserve the support of those interested in a better knowledge of the general physical laws

[27] Proc. Royal Soc. London, Ser. A, vol. 107, 1925, p. 422.

describing the creep phenomena in metals at elevated temperatures. It can be hoped that on questions of the kind mentioned by Mr. McVetty which have not yet found satisfactory treatment, such as creep under combined stress etc., further work by engineers will be done in the near future on account of the various applications from which these questions originate.

To Mr. Sturm's observations, that the strains (which accompany the beginning of plastic actions) were utilized in the determining of the limiting conditions of stress, it may perhaps be replied that in investigations of the kind quoted in the paper it has been indeed the practice not only to measure the forces alone, but also to register the strains together with the stresses. This has decided advantages. The question which is here of importance, and which has also been raised in some of the remarks made by Mr. B. Miller, is whether the right quantities (stresses) upon whose values the reaching of plastic limits depends have been actually sharply enough determined by the tests or not. When using tubes of the sizes mentioned and observing the pressures or forces when the test pieces were yielding *continuously* through the whole wall thickness, it seems to the author that it should not be too difficult to establish the correct relations between observed force resultants and the specific average yield stresses to determine these latter properly. An exact knowledge of the elastic constants of the material does not seem necessary for this purpose; the stresses, however, have to be corrected with regard to the permanent deformations the tubes will have suffered during the gradual yielding.[28] In connection with this point, perhaps mention should be made that the simple expressions such as Equations [2] and [3] for the stress-strain relations can only be considered as expressions for these as long as the elastic parts of the strains are negligible or small compared to their plastic parts. These relations can certainly not be exact expressions of the stress-strain relations if the plastic parts are of the same order of magnitude as the elastic parts or even smaller than these latter.

Coming now to Mr. B. Miller's remarks in which he notes that the author sees fit to discuss only two of the theories of strength, it was the latter's understanding that among the various rules which have been suggested in the course of time and in former years, there were a few which would not satisfy certain fundamental conditions, such as, for example, the rule according to which a strength theory which will lead to a *closed* surface of yielding $F(\sigma_1, \sigma_2, \sigma_3) = 0$ can be discarded at once. A limiting state of stress at which yielding starts can be represented by a point P having the rectangular coordinates σ_1, σ_2, σ_3 in space, by these letters the principal stresses again being designated. As stated in the paper already, it follows at once that all points P representing possible states of stress at a plastic limit will be found along a certain surface: "the surface of yielding" $F(\sigma_1, \sigma_2, \sigma_3) = 0$ characteristic for a given material. As by three equal pressures $\sigma_1 = \sigma_2 = \sigma_3 = -p$ yielding cannot be produced in a material, a point in the σ space having this property cannot be found along the limiting surface of yielding. This latter must therefore be an open surface around the space diagonal $\sigma_1 = \sigma_2$, $\sigma_2 = \sigma_3$ toward its negative side. The theories of strength which lead to intersection points of their surface $F(\sigma_1, \sigma_2, \sigma_3) = 0$ with the straight line $\sigma_1 = \sigma_2$, $\sigma_2 = \sigma_3$ in space in the negative quadrant have to be rejected. To these belong both the maximum stress or maximum strain theories, while the maximum shear theory and the constant octahedral shearing-stress theory lead to open surfaces.

[28] When the permanent strains are already predominant, but still not too large strains (of an order of magnitude of a few per mille or so), Equation [2] being a satisfactory expression of the facts, this equation can be used for correcting for the permanent strains by which the original dimensions of the tubes have changed.

The author was particularly interested to learn from various conversations he had with Mr. Miller that the economical designing of the long pipe lines which are used for transporting oil in the United States through thousands of miles, makes it desirable to utilize the material to its utmost safe stress limits and that a pipe line designed according to Equation [15], or *the condition of constant octahedral shearing stress* $\tau_n = \sqrt{2} \cdot \sigma_0/3 = 0.47\sigma_0$ (σ_0 being the yield stress for pure tension), will be 16 per cent lighter (and consequently so much cheaper) than if the wall thickness is computed by using the maximum shear criterion.

Mr. Miller emphasizes the need to distinguish carefully between the various cases which might occur when thick-walled tubes are subjected to high internal pressure, particularly with regard to the conditions imposed upon the tube at the ends. He also calls attention to the considerable difference which will be found between the pressures in such tubes (the wall thickness of which is perhaps of the order of a tenth of the mean diameter) for first yielding at the inner surface of the tubes and the pressures for a complete yielding of the tubes. In tubes having thicknesses similar to those tested by W. Lode, the pressures producing *first yielding* will be considerably lower than those producing *complete yielding*. As the instant at which a tube first starts to yield in an infinitely thin layer at the inner surface cannot be detected by any method, extensometers fastened to the tube can be utilized only to make visible the instants at which yielding has reached the outer surface of the tube or proceeds through the entire tube. W. Lode has compared the pressures and axial forces only in these latter cases, which follows clearly from a comparison of the stress-strain curves he has observed while his tubes were stretching.

It may appear paradoxical that an equation such as Equation [VII] which has been derived by using the formulas [I]–[III] based on the theory of elasticity could furnish the correct values of the *average* stresses when the tubes are yielding through their whole thickness. This is, however, the case. In fact, for the tubes of the sizes quoted, the curves representing the radial, the tangential, and the axial stresses σ_r, σ_t, σ_z as functions of the variable radii r can all be replaced by straight lines, and it is perhaps noteworthy that this is true in both cases—namely, when the strains are purely elastic and also in the case of complete yielding. If the wall thickness δ is of the order of a tenth of the mean diameter $2r_0 = r_1 + r_2$ or smaller (r_1 inner, r_2 outer, r_0 mean radius of tube), it is convenient to express the stresses σ_r, σ_t, σ_z not as functions of the variable distance r of a point from the axis of the tube, but as functions of another variable

$$x = r - r_0 \qquad \text{[B1]}$$

x being the distance of a point from the center of the wall thickness δ, and to develop all expressions into powers of the small quantity x, retaining only first-order terms. In other words, for tubes with $\delta \leqq 1/10$, the stresses will, with sufficient accuracy, become expressible by linear functions of x. In fact, an elastic stress distribution in a thick-walled tube as given by Equations [I]–[III] might be rewritten in the form:

$$\left.\begin{aligned} \sigma_r &= -\frac{p}{2}\left(1 - \frac{2x}{\delta}\right) \\ \sigma_t &= -\frac{p}{2}\left(1 + \frac{2x}{\delta}\right) + \frac{pr_0}{\delta} \\ \sigma_z &= -\frac{p}{2} + \frac{pr_0}{2\delta} + \frac{P}{2\pi r_0 \delta} \end{aligned}\right\} \qquad \text{[B2]}$$

Taking now, for example, the case of a tube closed at both ends subjected to internal pressure p only, the plastic stress distribu-

tion for complete yielding, using the theory of constant octahedral shearing stress, may also be established for a comparison. It is given by

$$\sigma_r = -p - R, \quad \sigma_t = -p - R + \frac{2\sigma_0}{\sqrt{3}}$$

$$\sigma_z = -p - R + \frac{\sigma_0}{\sqrt{3}} \ldots\ldots [B3]$$

where R stands for

$$R = \frac{2\sigma_0}{\sqrt{3}} \log \frac{r_1}{r} \ldots\ldots [B3a]$$

The pressure p producing complete yielding is found to be equal to

$$p = \frac{2\sigma_0}{\sqrt{3}} \log \frac{r_2}{r_1} \ldots\ldots [B4]$$

Expanding again into powers of x:

$$\log \frac{r_1}{r} = \log \frac{1 - \frac{\delta}{2r_0}}{1 + \frac{x}{r_0}} = -\frac{1}{r_0} \cdot \left(\frac{\delta}{2} + x\right)$$

the expressions [B3] become

$$\sigma_r = -\frac{p}{2}\left(1 - \frac{2x}{\delta}\right), \quad \sigma_t = -\frac{p}{2}\left(1 - \frac{2x}{\delta}\right) + \frac{pr_0}{\delta},$$

$$\sigma_z = -\frac{p}{2}\left(1 - \frac{2x}{\delta}\right) + \frac{pr_0}{2\delta} \ldots\ldots [B5]$$

and the pressure p for complete yielding can now be computed also from the equivalent formula to [B4]:

$$p = \frac{2\sigma_0}{\sqrt{3}}\left(\frac{\delta}{r_0} + \frac{\delta^3}{12r_0^3}\right) \ldots\ldots [B6]$$

From [B5] the average stresses, or what is the same as the stresses for $x = 0$, are found:

$$\sigma_r = -\frac{p}{2}, \quad \sigma_t = -\frac{p}{2} + \frac{pr_0}{\delta}, \quad \sigma_z = -\frac{p}{2} + \frac{pr_0}{2\delta} \ldots [B7]$$

These are exactly the same expressions as would have been obtained should the stress expressions (Equation [B2]) derived for a purely *elastic* state be used with the pressure p chosen according to [B4] or [B6]. In other words, if the *average* stresses of an elastic stress distribution (as given by the formulas [VI]) in a thick-walled tube are adjusted so that in addition they satisfy the plasticity condition (Equation [23]), the corresponding pressure will be about the same as the one at which yielding in the tube would have developed to the (outer) surface.[29]

Comparing Mr. Miller's computations in Fig. 32, it appears from the present point of view that an expansion into powers of x or δ up to the first order is completely sufficient for computations of the stresses in thick-walled tubes, both in the elastic as in the plastic state.

The author could not verify the error found by Mr. Miller in an expression published by the author on a former occasion, as details are not completely given; to his justification he may only add that a few simple and important special cases which are included in the former results obtained by a supposedly erroneous integration checked perfectly, which does not make it to him so probable that the integration would have contained errors.

The author is particularly indebted to Mr. Miller for having shown in detail that, using his own methods when constructing certain curves (such as indicated in Fig. 32) and comparing them with points which were computed by Mr. Miller using the author's Equation [VII], a very good agreement was also obtained. He was wondering a little, however, that notwithstanding these facts and a few of the other reasons which the author endeavored to bring out in his paper infav or of Equation [VII] and of the physical assumptions on which it was based, Mr. Miller emphasizes in his final remarks the "empirical" nature of this particular condition or equation, while the nature, the content, or form of some of the other formulas expressing in terms of stress the statements contained in the maximum shear or the maximum strain theory did not seem to give him reasons for any remarks. With Messrs. Sturm and Miller and the other discussers of the report, the author agrees completely that further critical discussion of the various points which were brought out during this discussion will probably be useful. For example, the lack of isotropy in actual rolled material and the case in which the plastic strains become comparable to the elastic ones deserve more attention. Some new attempts to test particularly this last case in tubes can perhaps be reported later.

[29] Equations [B2] can, by the way, also be used to compute the pressure at which first yielding starts. If the ratio $\delta/r_0 = 1/10$ according to plasticity condition [23] and using the exact (elastic) theory, first yielding would start at a pressure

$$p_1 = 0.191\sigma_0$$

while the approximate formula [B2] gives a value:

$$p_1 = \frac{\sigma_0}{\sqrt{27}} = 0.192\sigma_0$$

Similarly complete yielding in a tube with $\delta/r_0 = 1/10$ has to be expected, according to the exact formula [B4], at a pressure

$$p = \frac{2\sigma_0}{\sqrt{3}} \log \frac{11}{9} = 0.232\sigma_0$$

While the approximate formula [B6] gives a pressure in good agreement:

$$p = \frac{2\sigma_0}{\sqrt{3}} \cdot \frac{\delta}{r_0} = 0.231\sigma_0$$

Working Stresses

By C. RICHARD SODERBERG,[1] PHILADELPHIA, PA.

This paper gives a general review of the fundamental aspects of the problem of strength and safety of machine parts. After an introductory discussion of the nature and scope of the problem, it offers suggestions for selecting working stresses for those conditions of applications of materials for which adequate knowledge is available.

THE problem of mechanical strength is one of the most important considerations in the dimensioning of machine parts. The designer arrives at a practical solution of this problem by (1) an appraisal of the conditions of service in so far as stress is concerned, (2) an appraisal of the strength of the materials under these circumstances, and (3) a decision as to the margin he is willing to allow between actual service conditions and failure. This last decision is expressed through a set of conventions and rules for establishing *working stresses*, that is, a condition of service which, with regard to the limitations of the strength of the materials, gives the desired insurance against failure. The object of the present paper is to review the fundamental aspects of this process in the light of our present knowledge of our engineering materials.

In the appraisal of the conditions of service in so far as stress is concerned, an abstraction is made from other, perhaps equally important, aspects of the service. Of these may be mentioned appearance, considerations of standard parts and stock sizes, corrosion and wear, problems of assembly and repair, and so on. In the present discussion all of these extraneous considerations will be neglected, but their importance must not be underestimated. Not infrequently, they justify an apparently nonchalant treatment of the problem of strength. In addition, the present discussion will be restricted to those conditions of service where phenomena of structural instability, such as buckling, do not occur. Finally, it will cover only the general problems encountered in the machine industry. It is fully realized that many problems in other fields, such as, for example, civil engineering, require additional specialized treatment.

In endeavoring to define the strength of a material, it is important to remember that strength can be defined only against the background of a certain arbitrary method of testing. In general, this method of testing discloses some form of "failure," which is then selected by the designer as the contingency against which he wants to guard. In a few rare cases the conditions of test happen to agree rather closely with the conditions of service; this happy state of affairs is a rare exception, however. Most frequently the appraisal of strength for a certain actual condition of service represents a wide extrapolation from the conditions of testing.

Granting that the designer's reasoning is sound up to this point, the next step is an evaluation of the risk that he finds it advisable to assume with regard to a possible occurrence of the predicted form of failure. If he is in the fortunate position of being able to tolerate a small percentage of failures, experience will soon point the way to an economical ultimum. In most cases, however, failure spells disaster, and progress in industry has made the consequences of such disasters ever drier.

The vague nature of the process of selecting working stresses must be kept in mind, however, whenever there are temptations in the direction of theoretical elaborations. It is not unlike the process of appraising the soundness of a monetary investment where there is also a problem of reaching a balance between returns and predictable chances of failure. It will be apparent, from the following discussion, that there are as yet very wide gaps in the field of required knowledge, gaps that at present must be filled in by good intuitive judgment.

NOMENCLATURE

Symbol	Units	Designation
a	in.^{2}	Area of cross-section
E	lb/in.^{2}	Modulus of elasticity ($\partial\sigma/\partial\epsilon_e$): E', a value modified for external flexibility
E_p	lb/in.^{2}	Modulus of strain hardening ($\partial\sigma/\partial\epsilon_p$): E_p', a value modified for external flexibility
k	lb/in.	Rigidity (scale) of spring
l	in.	Length
n	1	Factor of safety
p	lb/in.^{2}	External pressure
u	1	Factor of utilization
t	hr	Time: t^*, time parameter
v	1/hr	Strain rate ($\partial\epsilon_p/\partial_2$): v_0, v_1, material constants
ϵ	1	Strain: ϵ_e, elastic strain; ϵ_p, plastic strain; ϵ_0, initial value of strain
γ	1	Shear strain
σ	lb/in.^{2}	Normal stress: σ_i, general limit; σ_e, endurance limit; σ_y, yield point; σ_u, ultimate strength; σ_w, working stress; σ_0, initial stress or steady stress: σ_1, σ', σ'', material constants; σ^*, σ^{**}, stress parameters
τ	lb/in.^{2}	Shear stress: τ_w, working stress

THE MEASURABLE PHYSICAL PROPERTIES OF MATERIALS

The art of testing the physical properties of engineering materials is an extensive one, but the number of tests which actually determine mechanical "strength" is very small. There are only two tests that can be used directly for predicting failure quantitatively, if the word failure is considered in a somewhat restricted sense. These are the tensile test and the fatigue test. No criticism is implied here of the many other forms of tests,

---

[1] Manager, Turbine Apparatus Division, Westinghouse Electric and Manufacturing Company, South Philadelphia Works. After receiving his university education, Mr. Soderberg was graduated as naval architect from Chalmers' Institute of Technology, Göteborg, Sweden, in 1919. He received a fellowship from the American Scandinavian Foundation in 1919 for the study of shipbuilding in the U.S.A., and spent 1919–1920 at M.I.T. and the University of Michigan. He was employed as draftsman by the New York Shipbuilding Corp. in 1921, and in 1922 by the Westinghouse Company, where he worked until 1928 on vibration and other dynamical problems connected with heavy traction railway equipment and large power machinery. After two years with the Swedish General Electric Company in the design of large turbo-generators and turbines, he returned to the Westinghouse Company in East Pittsburgh, and was transferred to his present location in May, 1931.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

such as impact tests, bend tests, hardness tests, etc. The purpose of the latter group of tests, however, is either to establish or confirm results that eventually must be derived from the tensile test, or to measure properties other than actual strength. The conventional bending fatigue test would undoubtedly be replaced to advantage by an alternating tensile test if the mechanical difficulties associated with such a test were not too great. The same is probably true of the impact test. In view of this we may regard the fundamental knowledge of the materials, accessible to the designer, as the results obtained by applying a principal stress along the axis of a cylindrical bar. Practically everything else is derived knowledge. Thus, while in actual practice, and in the theories of elasticity and plasticity, we treat stress or strain in the most general three-dimensional aspect, the measurable properties concern practically only the extremely specialized case of a cylindrical bar in tensile or compressive stress.

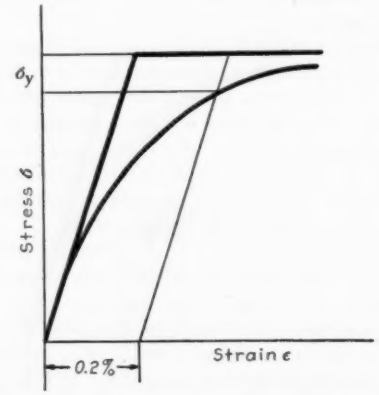

FIG. 1 DEFINITION OF YIELD POINT

The tensile test also furnishes the material for defining the term "failure." When applied to the conventional tensile test at normal temperature, this may mean an actual break of the test piece (ultimate strength), or it may mean a sudden increase in strain without a correspondingly large increase in stress (yield point). It may also mean a departure from the straight-line law between stress and strain (proportionate limit), or it may mean a cessation of the elastic properties (elastic limit).

It is gradually becoming recognized that of all these possibilities, the yield point and the ultimate strength offer the most rational limits of failure. The former applies to ductile materials and the latter to the brittle ones. When, for ductile materials, the stress-strain curve does not exhibit a definite discontinuity, the stress corresponding to a permanent deformation of 0.2 per cent, Fig. 1, has become a widely accepted definition of the yield point.

Even for ductile materials, the results obtained by applying stresses above the yield point are of interest in furnishing a definition of ductility. The general configuration of the stress-strain curve is, in fact, one of the most important sources of information concerning plastic flow. The arbitrary definition of strength and failure just given may sometimes appear to break down in the light of the common effects of strain hardening, after-flow, elastic hysteresis, etc. In such an event, however, it is usually because aspects other than stress assume dominating importance. This is the case encountered with annealed copper at normal temperatures, or of soft steel at elevated temperatures.

When the test piece is subjected to alternating stress, the failure assumes the character of brittle failure under steady stress. The endurance limit is now the criterion of strength, and may be taken as the stress amplitude at which a very large number of cycles ($> 10^7$) are required to produce failure.

When the tensile test is conducted at elevated temperatures, the mechanism of failure changes completely, at least for the ductile materials, which are the only ones for which reliable tests are available. The speed of deformation now assumes a dominating importance, and the test has no meaning unless associated with a strain rate. With this added qualification, the nomenclature established for the tensile test may be retained. Most structures are such, however, that their operativeness depends on the preservation of physical dimensions and initial stresses. Thus, while no actual failure may be involved, the stresses must be limited to values that will preserve the geometrical configuration of the structure within certain established limits. No single-valued quantity of real importance can be extracted from these tests; our only recourse in this case is to extrapolate the results of the tests to the actual conditions and base the stresses on the predicted deformations.

THE NATURE AND SCOPE OF THE PROBLEM OF WORKING STRESSES

This restricted range of the measurable properties of engineering materials has injected a considerable amount of mechanical routine into the procedure of selecting working stresses. When this procedure is viewed from a more general standpoint, however, the following aspects must be considered:

1 An evaluation of the stresses or strains existing in the structure
2 A decision with regard to the methods of test which will reveal the physical properties of the material most relevant to the conditions of service
3 A decision with regard to the type of failure which is likely to occur
4 An extrapolation from the actual tests to the actual conditions of service
5 A choice of margin between the actual conditions of service and those that would produce failure thus defined.

The first aspect, the evaluation of the stresses or strains, is the most obvious and straightforward, and will be almost entirely disregarded in the present paper. This problem offers no difficulty beyond mathematical complexity, provided that the conventional and sometimes questionable premises of the theory of elasticity may be assumed to hold. These are homogeneity of the materials and adherence to Hooke's law. It is true that these are never wholly fulfilled, but the deviations rarely cause real difficulties. At any rate, the uncertainties introduced in this manner are of secondary importance when compared with those encountered in the remainder of the problem.

Due to obvious limitations, it is not always possible to continue through the steps 2 to 5 in the manner suggested. Every problem of strength would become the subject of controversy and receive individualistic treatment. This is undoubtedly desirable from a scientific point of view, but would be derogatory to the normal requirements of business efficiency. The only solution of this difficulty is an orderly classification of the available knowledge on the subject. Such a classification can be accomplished only by somewhat dogmatically settling certain points of controversy. This is true of all branches of applied mechanics, but in most other fields the progress has penetrated beyond the point where alternative interpretations differ seriously.

It is proposed, therefore, to group the available information on the subject of strength in the following tentative classification:

1 Types of Materials
   - *a* Brittle materials
   - *b* Ductile materials

2 Operating Temperature
   - *a* Normal temperatures
   - *b* Elevated temperatures

3 Mode of Stress Application
   - *a* Steady stress
   - *b* Variable (alternating) stress
   - *c* Impact stress

4 Type of Stress
   - *a* Tension and compression
   - *b* Pure shear
   - *c* Combined stress.

Practically every group of this classification can be made the subject of controversy, and none, except the last, can be defined except by arbitrary limits.

Considering first the distinction between brittle and ductile materials, it must be appreciated that both the mode of stress application and the type of stress are involved. Materials which normally fall under the classification of brittle materials may be made to deform plastically under certain conditions, so that the terms "brittle" and "ductile" refer to states rather than types of materials.[2] Many objections of this nature disappear, however, when it is realized that most of our useful engineering materials, which are important from the point of view of strength, fall into one or the other of these classifications. One could, in fact, define brittle materials as "cast iron like" and ductile materials as "mild steel like" and arrive at a fairly satisfactory classification for general practical purposes. Furthermore, practical conditions are such that the brittle materials play a very unimportant rôle in applications where strength is of real importance. In what follows, therefore, very little attention will be given to brittle materials. It is tentatively proposed that the limit be set at 5 per cent elongation in the standard tensile test piece.

The operating temperature is a somewhat arbitrary specialization of a more general heading which might have been denominated "Conditions of Use." It is of profound significance in the machine industry, however, because the higher temperatures inject an entirely new mechanism of failure. The boundary between "normal" and "elevated" temperatures is necessarily vague, but eventually a satisfactory definition will undoubtedly be formulated by reference to the melting point of the material.[3] In the present connection, elevated temperatures are defined as that temperature range at which the permanency of physical dimensions and initial stresses limit the utilization of the material. For most of the ferrous alloys this limit may be placed at about 500 F.

The mode of stress application is likewise somewhat vague. The distinction between impact and other forms of stress offers the least difficulty because it is already established in rigid dynamics. However, the case of impact stress is rather rare, and very little information on the prediction of failure under impact is available. The conventional impact test cannot be used for this purpose except for qualitative comparison of different materials. Just when a stress is steady or variable, on the other hand, may be the subject of much controversy. In actual practice, all stresses undergo many changes during the life of a machine or a structure. The frequency of a fatigue test is not of fundamental importance, within wide limits, so that the real criterion is the total number of reversals to which the structure will be subjected. If this is of the order of 10^7, the stress should be regarded as variable; if it is of the order of 10^3, it may be classified as steady. No more specific line of demarcation can be drawn, except for individual materials. It may be necessary to point out that the case of pulsating stress is to be regarded, in this classification, as a special case of superposition of steady and alternating stress and not as a separate mode of stress application.

The "type of stress" is established by the existing conventions in the theory of elasticity. It is possible to argue that other specialized types of stress, such as hydrostatic pressure, may be included in the classification. Such cases, however, are tacitly included under "combined stress."

As yet this scheme of classification is inadequately fortified with reliable knowledge. Certain combinations, such as the case of impact stress, brittle materials under variable stress or elevated temperatures, and ductile materials under variable stress and elevated temperatures, are practically unknown, and until more knowledge is available, they must be kept out of discussions on working stresses. Practical applications, where necessary, must be made with extreme conservatism. The remaining parts of this paper will be devoted to a brief discussion of those combinations for which fairly adequate knowledge is available at the present time.

MATERIALS AT NORMAL TEMPERATURES

(*a*) Factor of Safety and Utilization of Strength

Let it be assumed that the failure of the element in question depends only on a certain stress σ, and that failure occurs when this stress reaches the value σ_i. The working stress σ_w will then be defined by the relation

$$\sigma_w = u\sigma_i \qquad [1]$$

where u is the factor of utilization. It is evident that $0 < u < 1$. The more common factor of safety is defined by $n = 1/u$. Failure is characterized by $u = n = 1$.

The principal object of the present paper is to suggest rules for defining rationally the quantities σ_i and σ_w. Once this is achieved, the designer will be able to interpret his experience in a rational manner. The actual choice of margin between working stress and failure, the actual factor of safety, must remain the designer's own prerogative. This process, however, involves certain frequently recurring fundamental considerations which it may be profitable to review.

The accuracy by which σ_i and σ_w can be determined is of fundamental importance. It is evident that the more accurately they are known, the more fully can the available strength be utilized with safety. The inaccuracy of σ_i concerns not only the errors of measurements but also those of judgment in definition.

The value of σ_w which is used in [1] often represents an extreme condition of service which is, in itself, an emergency. Common examples of this are the conditions under test pressures for containers and overspeed tests for rotating machinery. Although complete assurance against failure must be obtained in such cases as well, it is not necessary to provide the same degree of safety as in those cases where σ_w represents permanent operating conditions.

σ_w may also represent an assembly stress which will drop to a lower value should yielding start. This is the case of a rotating disk shrunk on its shaft. Obviously, the assembly stress may be raised much above the stress produced directly by the centrifugal force.

These examples suggest a range of values of u corresponding

[2] Nadai and Wahl, "Plasticity," Engineering Societies Monographs, p. 58.

[3] "Homologous temperatures," first introduced by Ludwik, are absolute temperatures of equal proportions of the melting point and may be used for this purpose. See Nadai's "Plasticity," p. 275.

to a uniform degree of economic safety. The question of giving a value of u to each combination is a matter to be decided by the responsible designer. The following may be stated with regard to the extreme limits: In the most favorable case of accurately known stresses and material properties, it should be possible to utilize 75 to 80 per cent of the strength of the materials, that is, $u = 0.7$ to 0.8. In the other extreme condition, such as may occur in cases of variable stress, it should not be necessary to go below $u = 0.25$ to 0.30.

(*b*) Ductile Materials Under Steady Stresses

The yield point in tension, as obtained from the ordinary

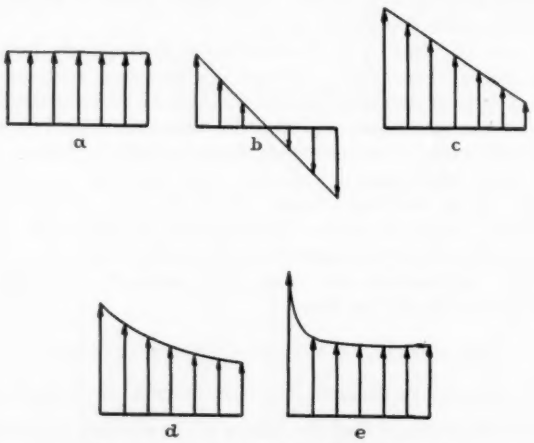

Fig. 2 Types of Stress Distribution

tensile test, furnishes a unique definition of failure. The working stress may thus be expressed as

$$\sigma_w = u\sigma_y \quad [2]$$

This conception enables the designer to effect an economical use of his materials whenever the conditions correspond to those of the tensile test. However, this is seldom the case, so that the above convention must be discussed in the light of the possible deviations from the ideal conditions of the tensile test.

The first deviation of importance occurs when the stress is of the tensile or compressive type but varies in magnitude over the cross-section (Fig. 2). This simple deviation from the test conditions opens an important field of controversy. The general question of combined stresses also enters into the controversy, but it is only in special cases that this aspect is of importance. An example of such a case is the shear stress occurring in the web of an I-beam. This aspect will be discussed in connection with the general case of combined stresses. Apart from this, however, it is by no means self-evident that the various cases shown in Fig. 2 should be covered by the same limiting stress, nor is such a conclusion supported by experiment.

All that can be said with certainty about these cases is that when the stress variation is "sharp," Fig. 2(*e*), only the mean stress has real influence upon failure. This condition is usually referred to as "stress concentration," which may thus be neglected in ductile materials under steady stress. In all the other cases the maximum stress must be considered in predicting failure. The actual importance of the maximum and the mean stress is associated with the external conditions of yielding, which must eventually determine whether it is a question of "sharp" or "moderate" variation of the stress over the section.

Other deviations of importance may be listed under the heading of combined stresses. This presents a more difficult and somewhat controversial extrapolation from the tensile test. The more recent investigations on the subject appear to settle the controversy in favor of the Mises-Hencky interpretation of failure.[4] When considering the purely practical aspects of the problem, however, the simpler maximum-shear theory will cover the facts with sufficient accuracy. Under this interpretation, the failure is attributed to slip in the planes of maximum shear. In the ordinary tensile test the failure at the yield point is actually a shear failure in planes inclined 45 deg to the axis of the specimen. The maximum shear stress is one-half the maximum tensile stress, so that for pure shear Equation [2] is modified into

$$\tau_w = u\frac{\sigma_y}{2} \quad [3]$$

The same reasoning is easily extended into combinations of tension and shear, Fig. 3(*a*), one of the most common of which is the case of bending and torsion. Instead of a single-valued working stress, there is now a case of superposition of one stress upon the other. The maximum-shear theory predicts failure for combinations falling on the ellipse $(\sigma/\sigma_y)^2 + 4(\tau/\sigma_y)^2 = 1$, Fig. 3(*b*). The utilization of the portion u of this strength is represented by another ellipse, contracted in scale by the factor

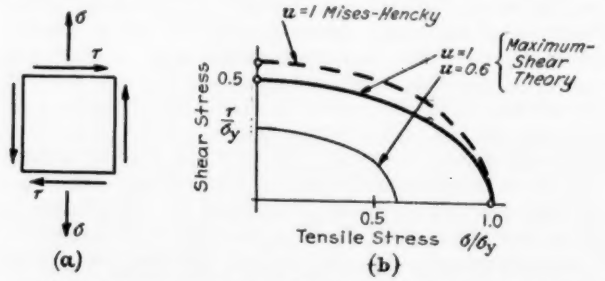

Fig. 3 Superposition of Shear and Tensile Stress

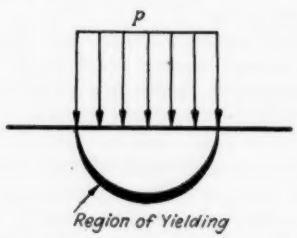

Fig. 4 Failure Under Contact Pressure

u. On this basis the working stresses are determined by the relation

$$\sqrt{\sigma_w^2 + 4\tau_w^2} = u\sigma_y \quad [4]$$

This particular case may be used to advantage to point out the difference between the maximum-shear theory and the more correct Mises-Hencky theory. In Fig. 3(*b*), the latter is represented by another ellipse,[5] the maximum ordinate of which is $1/\sqrt{3} = 0.577$, instead of $1/\sqrt{4} = 0.5$.

The results obtained from the tensile test are generally accepted as holding for compression as well. For practical purposes this is true for most of our ductile materials up to the point where structural instability becomes of importance. There is another form of compression, however, which presents a much more complicated phenomenon and also has real practical importance. This is the problem of contact stresses between sur-

[4] Nadai, "Plasticity," chap. 13.

[5] See paper in present symposium by Dr. Nadai on "Theories of Strength."

faces in machine parts. A great deal of experimental and theoretical work has been done on this subject and the results have practical value. In the common case of uniform pressure along a strip of material, Fig. 4, the predicted yielding will occur along the semicircle shown. The value of the pressure at which yielding starts is $p = \pi/\sqrt{3}\ \sigma_y = 1.81\ \sigma_y$, and is obtained by assuming that there are no friction forces on the contacting surfaces.[6] In reality, this friction is of great importance, since it restricts the lateral contraction. For this reason, actual failure will not take place for pressures of the order of $2\sigma_y$, a value which is thus on the safe side for practical applications.

It may be worth while to point out that contacts of moving surfaces, such as occur in gears or bearings, present an entirely different problem, and one which is beyond the scope of the present paper.

(c) Ductile Materials Under Variable Stress

For conditions similar to those prevailing in the conventional fatigue bending test, the endurance limit σ_e gives a unique definition of failure, so that the working stress may be expressed as

$$\sigma_w = u\sigma_e \qquad [5]$$

The inaccuracies of extrapolation to other circumstances are in this case now much greater than in the previous one.

The maximum stress now plays a much more dominating rôle even in the case of stress concentration. However, there

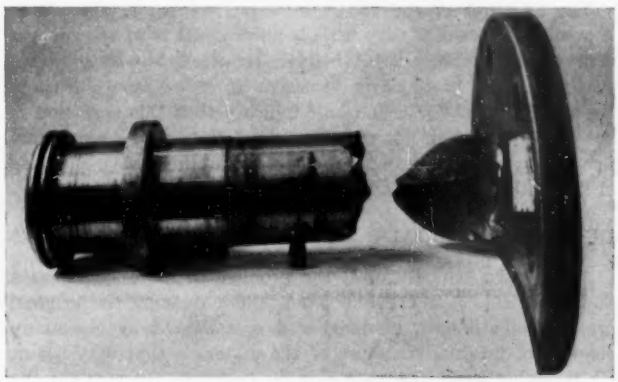

Fig. 5 Failure Under Variable Torsion

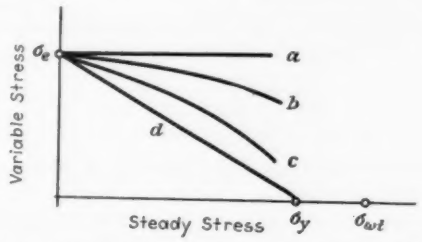
is a tendency similar to that described for steady stress in that failure is precipitated by the maximum stress when the variation of stress is "moderate," and by a stress somewhat smaller than the maximum stress when the variation is "sharp." Many results are available with regard to the actual influence of stress concentration,[7] but it is difficult to establish definite general rules. In general, the factors of stress concentration obtained by the theory of elasticity are about double those obtained by fatigue tests on grooved specimens of ductile materials. It is important to remember, nevertheless, that σ_w in [5] represents a stress in excess of the mean stress.

The difference in behavior of the ductile materials under steady and variable stress is associated with the different mechanisms of failure. The failure under variable stress is closer to the brittle type of failure under steady stress, and the two phenomena do indeed display certain similarities. The case of combined stresses is accordingly somewhat complicated.

[6] Nadai, "Plasticity," p. 247.

[7] See paper in present symposium by Peterson on "Stress Concentration Phenomena in Fatigue of Metals."

The knowledge available so far indicates that the configuration of the failure may be interpreted in the light of the maximum-strength theory, but that the numerical value of the endurance limit in torsion comes close to one-half the endurance limit in bending; a relation that would point to the maximum-shear theory. Fig. 5 illustrates a typical failure under variable torsion stress, the 45-deg cracks pointing to failure in planes of maximum stress. It is worth noting that the steel in the shaft shown in Fig. 5 was found to be dirty, and it is conceivable that good material may show different types of failure, although failures of this kind are rare with satisfactory materials. The subject



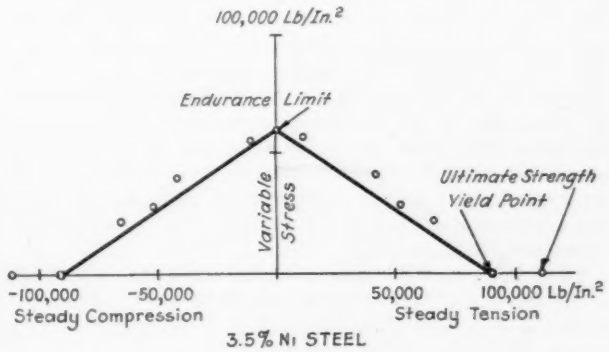


Fig. 6 Superposition of Steady and Variable Stress

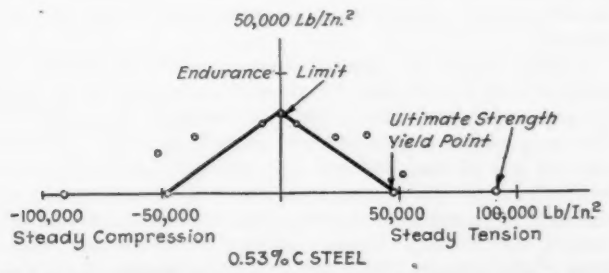

Fig. 7 Examples of Superposition of Steady and Variable Stress

is somewhat too controversial to permit definite conclusions being drawn. Until further information is available, it appears safe to predict failure on the basis of the maximum-shear theory. Whenever possible, an actual endurance test under the combined stress in question should be made.

Another important phase of the subject concerns the problem of the simultaneous existence of steady and variable stresses. This is a case of superposition not unlike that of tensile and shearing stress. Given a material with the yield point σ_y and endurance limit σ_e, subjected to a steady stress σ_0 and a variable stress σ_v, what is the probable combination for failure? The available results indicate the existence of many forms of superposition, from practical lack of interdependence to actual linear

superposition, Fig. 6. The reason for this absence of conclusive data may be ascribed to the fact that the ultimate strength is more closely related to the endurance limit than to the yield point. The linear form of superposition is particularly simple, however, and in general not far from the actual result in most materials, as illustrated by the two examples of Fig. 7.[8] Under this assumption, failure under the simultaneous application of σ_0 and σ_v takes place for the combinations $(\sigma_0/\sigma_y) + (\sigma_v/\sigma_s) = 1$, so that an appropriate rule for the working stresses becomes

$$\frac{\sigma_{0w}}{\sigma_y} + \frac{\sigma_{vw}}{\sigma_s} = u \quad [6]$$

For materials that exhibit the laws of superposition given by the curve b or c in Fig. 6, this law may be changed to

$$\sqrt{\left(\frac{\sigma_{0w}}{\sigma_y}\right)^2 + \left(\frac{\sigma_{vw}}{\sigma_s}\right)^2} = u \quad [6a]$$

but this modification may sometimes fall on the unsafe side of the experimental results.

The case of variable stress is important because of the remarkable influence of factors which do not commonly influence strength. The question of finish, ordinarily not of fundamental importance in strength problems, may assume real importance. Cases where unmachined specimens have shown 50 per cent lower strength than polished specimens of the same material have been recorded. This influence appears to be greater for alloy steels than for carbon steels.[9] The phenomenon known as "corrosion fatigue" covers cases where apparently slight intensities of corrosion affect the endurance limit profoundly, even to the point of raising doubts as to its existence.[10] There is not much doubt that this phenomenon is secondary to stress concentrations produced in the corrosion pits and possibly in intercrystalline cracks.

A less pronounced influence is caused by the surface condition of the specimens. The existence of plating has been found to affect the endurance limit profoundly,[11] possibly due to static stresses introduced by the plating.

These phenomena must be taken care of in individual cases. When more knowledge becomes available, the present concepts in the case of variable stress may have to be changed fundamentally.

Finally, there is another phenomenon which has seemed to warrant more investigation for the case of variable stress than for any other case. This is the phenomenon of "size effect."[12] The results of a fatigue test are affected appreciably by the physical size of the specimen. No adequate explanation has been offered for this phenomenon, but it is fortunately not of sufficient importance to warrant elaborate attention in connection with working stresses. In view of the peculiar conditions of the ordinary fatigue test, it must be considered extraordinary that the size effect is not much larger than the available results indicate. Here the test is made for a calculated bending stress which can only be inferred from the static loading of the specimen.

The case of variable stress represents perhaps the most important and most difficult case in connection with working stress. It is a case, moreover, where standardized rules of convention can do more harm than elsewhere. It is therefore necessary to study one's own special cases particularly closely in this field. One of the most important sources of information arises through the configuration of the cracks. The literature available on this subject is worthy of study.[13]

(*d*) Brittle Materials

The conditions of failure for brittle materials under steady stress are very similar to those for the ductile materials under variable stress, the ultimate strength σ_u being the limiting stress.

The effect of stress distribution is very similar to that for the ductile materials under variable stress, and the rules just discussed for ductile materials under variable stress may be used for brittle materials under steady stress.

The brittle materials frequently have fundamentally different properties for tension and compression; the ultimate strength in compression is often very much greater than for tension. This is particularly the case for cast iron and represents one of the most important reasons for its successful application to many important stress problems. It is necessary, therefore, to deal with two values for the ultimate strength: the tension value σ_{ut} and the compression value σ_{uc}, the latter frequently being four to five times as great as the former.

Under combined stress, the brittle materials may generally be treated by the maximum-stress theory, but in reality the failure problem is much more complicated.[14]

The behavior of the brittle materials under variable stress is a subject on which very little is known. It is to be expected that brittle materials will behave erratically under variable stress and be particularly sensitive to stress concentration. Results obtained for cast iron[15] indicate that this suspicion is not always justified. It must be regarded as good design practice, however, to avoid variable stresses of appreciable magnitude in the brittle materials.

DUCTILE MATERIALS AT ELEVATED TEMPERATURES

At elevated temperatures, the problem of failure assumes a double aspect. On the one hand, there remains the original problem of strength, modified and complicated by the many changes of internal structure of the materials that may occur. On the other hand, there appears the question of preserving the physical dimensions and initial stresses during a certain part of the life of the structure. The former aspect must be treated by the same fundamentals as those given in the preceding sections of this paper, modified for the many possibilities of unorthodox behavior of the materials. The latter aspect will be covered in greater detail in the following discussion.

The information upon which changes in the geometrical and mechanical aspects of a machine are predicted must be obtained from interpretations of long-time creep tests. The nomenclature surrounding the subject of plastic deformation of metals has been enriched rapidly during the past years, and it is now possible to discuss the subject in well-defined terms.[16]

As long as the conditions of service are similar to those obtaining in the long-time creep test, the result of the latter should

be applicable. This is almost never the case, however, and it is gradually becoming recognized that the conventional high-temperature testing must be complemented by something more fundamental than the long-time creep test. Until this feeling has become translated into concrete results, there is no other choice but to make the best of the available results of this form of testing.

No result on the subject is more important than the law, originally formulated by Ludwik, that if the strain rate is increased by geometric increments, the corresponding stress is increased approximately by arithmetical increments. This law is usually written—

$$\sigma = \sigma' + \sigma'' \log_e \frac{v}{v_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

where σ', σ'', and v_0 are constants of the material and $v = d\epsilon_p/dt$ is the time rate of increase of the plastic strain, or the strain rate. The law can claim only approximate validity within a limited range of strain rate because of the absence of accurate test results. The principal source of information for establishing this law has been the long-time creep test, but there are also available results obtained by somewhat different methods,[17] which give very satisfactory confirmation of the law.

When the results of long-time creep tests are analyzed in this manner, it is found that there is a different stress-strain-rate relation for each value of the plastic strain, the difference usually

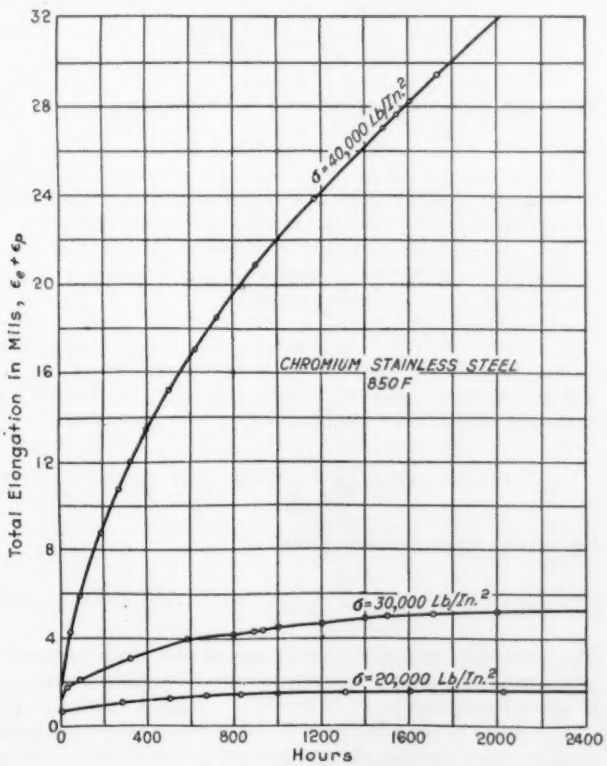

FIG. 8 CREEP CURVES

being a nearly constant addition to the stress for equal increments of the strain. This is due to the phenomenon of strain hardening. When the long-time creep test is continued into large plastic strains at the higher temperatures, an opposing annealing phenomenon sets in, so that the effects of strain hardening may be reversed. It has been customary to record experimental confirmations of Equation [7] for the minimum strain rate.

Notwithstanding the great efforts that have been applied to this problem, very little in the way of a quantitative solution is available. Practically no tests have been made with controlled strain rates, a method of testing that appears to have the greatest

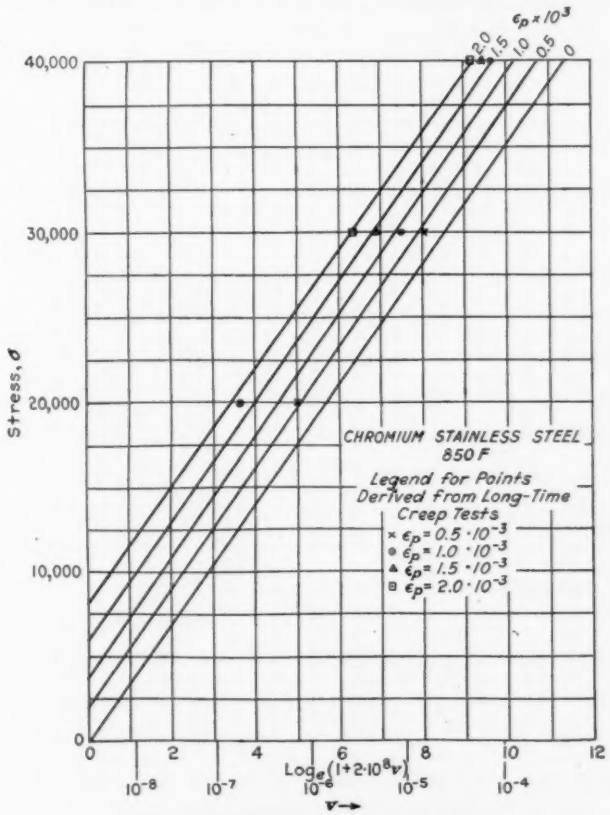

FIG. 9 STRESS-STRAIN-RATE RELATIONS

possibilities of all for short-time tests. It is particularly in the region of very low strain rates that our knowledge of the stress-strain-rate relation is deficient. A limit is soon reached in this direction on account of the limit of time and accuracy of measurements. For example, if the smallest strain that can be measured is 10^{-5}, it will require over ten years to obtain information about a strain rate of 10^{-10} 1/hr. The idea of such a test is nonsensical; laboratory experiments of this type cannot be extended beyond one or two years, and therefore we shall never escape the necessity of extrapolation.

The lack of data for the smaller creep rate suggested a long time ago the existence of an actual limit in stress below which a strain rate of zero can be supported. Succeeding investigations have dispelled this supposition so that the theory of a creep limit is now definitely abandoned. It must not be forgotten, however, that this is an academical argument that probably will never be fully settled.

Equation [7] does not pretend to cover very small strain rates, so that it must be modified by postulating some rational behavior in that range. A reasonable assumption is to make $\sigma = 0$ for $v = 0$. This condition can be satisfied by the law

$$\sigma = \sigma_1 \log_e \left(1 + \frac{v}{v_1}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

where σ_1 and v_1 are now the constants of the material.

[17] H. Deutler, *Physikalische Zeitschrift*, vol. 33 (1932), p. 347.

In order to make a simple correction for strain hardening, it is advisable to introduce the coefficient of work hardening,[18] $E_p = \partial\sigma/\partial\epsilon_p$. The experimental evidence does not indicate an actual constant E_p, but this will be assumed in the following; the error introduced by this simplification is not important in the light of the use that is made of the results. The influence of the plastic deformation upon the stress-strain-rate relation may thus be taken into account by the addition of the term $E_p\epsilon_p$; it then takes the form

$$\sigma = \sigma_1 \log_e \left(1 + \frac{1}{v_1}\frac{d\epsilon_p}{dt}\right) + E_p\epsilon_p \quad [9]$$

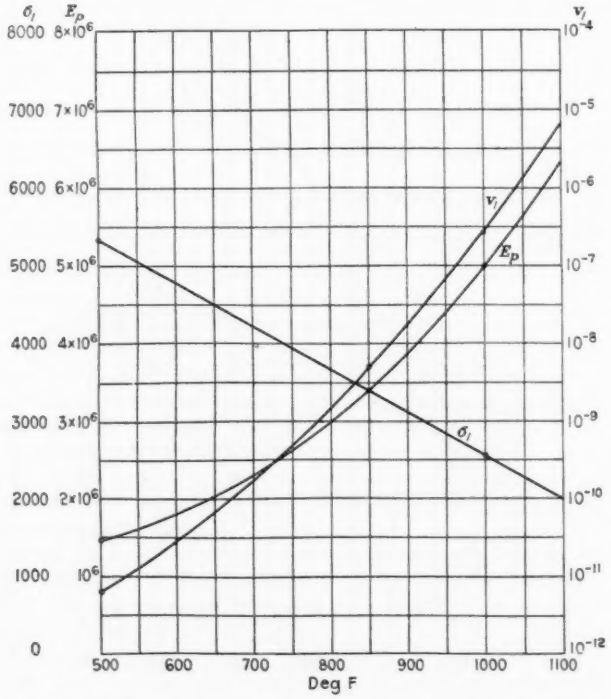

FIG. 10 MATERIAL CONSTANTS OF CHROMIUM STAINLESS STEEL

Fig. 8 shows a typical example of long-time creep curves, obtained from tests on chromium stainless steel at 850F. The points shown in Fig. 9 were obtained by analysis of the material shown in Fig. 8; the procedure consisting in plotting strain rate against strain for the different values of stress. The straight lines of Fig. 9 represent the best fit that can be made of the proposed function [9] and the most reliable of these points. The stress-strain-rate relation for zero strain is obtained by extrapolation and serves as the basis for determining the constants σ_1 and v_1. Fig. 10 gives values of these constants obtained for the same material as functions of the temperature.

The fit obtained in Fig. 9 between the function [9] and the test points is far from perfect, but it is not entirely unsatisfactory in view of the nature of the fundamental material of Fig. 8. It is fair to state, moreover, that the agreement obtained is generally better than that illustrated in Fig. 9.

The curves of Fig. 10 have an unusually simple form and one may be tempted to see some significance in this fact. The basic material is too fragmentary to lend much weight to such speculation, however. In the following discussion, more emphasis is given to the method of dealing with the fundamental experimental material than to the intrinsic nature of the latter.

[18] Nadai, "The Creep of Metals," A.S.M.E. New Haven Meeting, 1932. It may be suggested that this expression be modified into "modulus of strain hardening" to emphasize its relation to the modulus of elasticity.

In extrapolating such results to practical cases, it is instructive and generally sufficient to have access to a simple approximate solution of a relaxation problem of certain general aspects. Consider a tensile-test specimen A loaded in the manner shown in Fig. 11, so that the total elongation is constant. By varying the rigidity of the spring B from zero to infinity, all relaxation combinations of interest may be obtained. A solution of this problem for the stress-strain rate relation [9] is considered of sufficient interest to be included in this discussion.

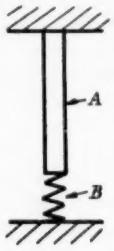

FIG. 11 RELAXATION MODEL

If the area and length of the specimen are denoted by a and l, respectively, the modulus of elasticity of the material by E, and the rigidity of the spring by k, it is possible, by introducing a modified modulus of elasticity

$$E' = E\frac{k}{k + E\frac{a}{l}}$$

to treat the problem in terms of the usual stress and strain relations. The effect of strain hardening is similarly influenced by the presence of the spring; this is taken care of by introducing a modified modulus of strain hardening,

$$E_p' = E_p\frac{k}{k + E_p\frac{a}{l}}$$

The stress-strain relation can now be written as

$$\sigma = \epsilon_e E' + \epsilon_p E_p' \quad [10]$$

where ϵ_e and ϵ_p are the elastic and plastic strains, respectively, also modified for the existence of the spring.

The essential feature about the relaxation phenomenon under discussion is that the total strain will remain constant. Thus, if the initial strain is denoted by ϵ_0,

$$\epsilon_0 = \epsilon_e + \epsilon_p \quad [11]$$

The initial stress may be written $\sigma_0 = \epsilon_0 E'$. Eliminating ϵ_e from [10] and [11] and introducing the stress parameter

$$\sigma^* = \epsilon_e E' = \frac{E'}{E' - E_p'}\sigma - \frac{E_p'}{E' - E_p'}\sigma_0 \quad [12]$$

the plastic strain may be written as

$$\epsilon_p = \frac{\sigma_0 - \sigma^*}{E'} \quad [13]$$

The seemingly arbitrary introduction of the stress parameter serves to eliminate the complications injected by the phenomenon of strain hardening.

The object of the analysis is to derive stress-time and strain-time curves from the stress-strain-rate relation [9]. This is equivalent to a solution of the differential equation

$$\frac{1}{v_1}\frac{d\epsilon_p}{dt} = e^{\frac{E'(\epsilon_0 - \epsilon_p)}{\sigma_1}} - 1$$

for the boundary conditions $t = 0$, $\epsilon_p = 0$, $\epsilon_0 = \sigma_0/E'$. Introducing the time parameter

$$t^* = \frac{1}{v_1}\frac{\sigma_1}{E'} \quad [14]$$

the stress-time relation is found to be

$$t = t^* \log_e \frac{1 - e^{-\sigma_0/\sigma_1}}{1 - e^{-\sigma^*/\sigma_1}} \quad \ldots\ldots\ldots\ldots [15]$$

The corresponding strain-time relation is obtained by introducing the relation [13] between ϵ_p and σ^*. Fig. 12 shows a graph of Equation [15] for values of t between 0 and 0.08 t^*. Fig. 13 gives a more extensive plot on a logarithmic time scale.

When the quantities σ_0/σ_1 and σ^*/σ_1 are large, Equation [15] can be written with sufficient accuracy in the simple form

$$t = t^*[e^{-\sigma^*/\sigma_1} - e^{-\sigma_0/\sigma_1}] \quad \ldots\ldots [16]$$

These results make it possible to predict the time required for the stress to drop from an initial to a final value for an arrangement of the type shown in Fig. 11, provided that the constants σ_1, v_1, and E_p' are known. The influence of strain hardening is usually not of fundamental importance, but it serves to improve the material for each successive reestablishing of the initial stress. The foregoing results require only slight modification to apply to the subsequent relaxations as well.

If the first relaxation proceeds from the initial stress σ_{0a} to a final stress σ_a, there has taken place a permanent plastic strain $(\sigma_{0a} - \sigma_a)/E'$. This strain must be added to the initial strain produced by the assembly stress in the restored state. If the latter is made σ_{0b}, the time required for the stress to drop to the value σ is found to be

$$t = t^* \log_e \frac{1 - e^{-\sigma_{0b}/\sigma_1}}{1 - e^{-\sigma^{**}/\sigma_1}} \quad \ldots\ldots\ldots\ldots [17]$$

where σ^{**} is a new stress parameter determined by the relation

$$\sigma^* = \frac{E'}{E' - E_p'}\sigma - \frac{E_p'}{E' - E_p'}(\sigma_{0b} + \sigma_{0a} - \sigma_a) \ldots [18]$$

and t^* retains its value as determined by [14].

It is evident that σ^{**} differs from σ^* only by the substitution of $\sigma_{0b} + \sigma_{0a} - \sigma_a$ for σ_{0b}. This suggests an obvious rule for extending the results to further periods of relaxation.

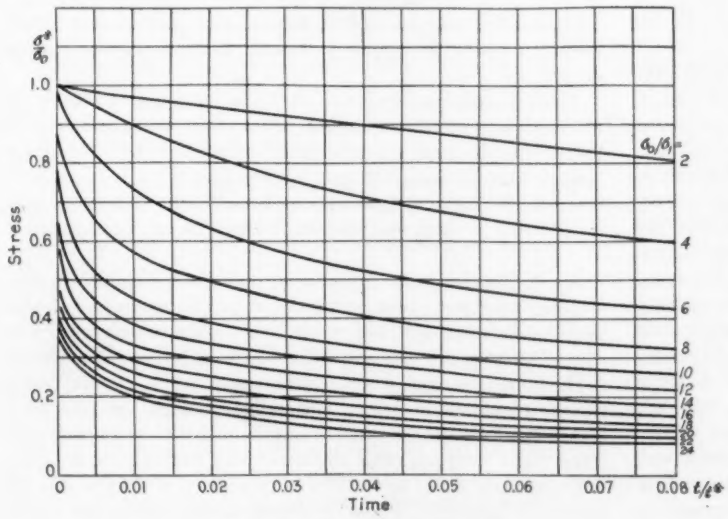

FIG. 12 RELAXATION CURVES

In order to illustrate the significance of the above results, they will be applied to one of the most common applications of materials at high temperatures, namely, a flange bolt. Let the material be chromium stainless steel at 850F, as covered by Fig. 10. The following values are obtained for this material: $\sigma_1 = 3450$ lb per sq in., $v_1 = 5 \times 10^{-9}$ 1/hr, $E' = 25 \times 10^6$ lb per sq in., $E_p' = 3.4\ 10^6$ lb per sq in., and $t^* = 27{,}200$ hr.

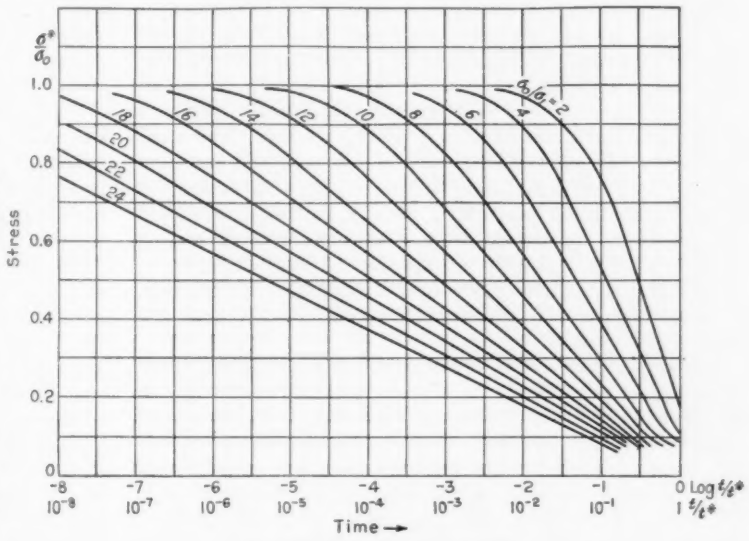

FIG. 13 RELAXATION CURVES

Let the bolt be given an initial stress, permitted to relax to a lower stress, retightened to the same initial stress, and again permitted to relax. Table 1 gives the time of relaxation for both of these periods for several values of the initial and final stress and for two values of the modulus of strain hardening. As a matter of interest, Table 2 gives corresponding values of the relaxation time for the same material under similar conditions, but at 750 F.

If conditions permitted an initial stress of 30,000 lb per sq in. and the retightening of the bolts every 4000 hr, it is evident from these results that the joint must be designed to operate with a stress of about 10,000 lb per sq in. at 850 F, and about 19,200 lb per sq in. at 750 F. The sensitivity of the relaxation phenomena to operating temperatures is worthy of note.

The influence of strain hardening is somewhat overestimated in the above results, since the lower value of E_p is consistent with the test points only for a different set of values for v_1 and σ_1. Carrying out a solution under this new premise, the final result will not be found to differ very materially from the above.

In accordance with Table 1, the stress falls from 30,000 lb per sq in. to 10,000 lb per sq in. in 4000 hr. The strain rate for this material at 30,000 lb per sq in. and zero plastic strain is about 26×10^{-6} 1/hr. If this remained constant, the stress

TABLE 1 RELAXATION OF CHROMIUM STAINLESS STEEL AT 850 F

Initial stress, lb per sq in.	Final stress, lb per sq in.	Time of relaxation, hours: First tightening $E_p' = 3.4 \times 10^6$	First tightening $E_p' = 1.7 \times 10^6$	Second tightening $E_p' = 3.4 \times 10^6$	Second tightening $E_p' = 1.7 \times 10^6$

20,000	15,000	9,890	9,110	11,400	9,890
20,000	10,000	40,400	37,200	57,100	42,300

would drop to 10,000 lb per sq in. in about 30 hr, or in less than 1 per cent of the actually predicted time. These figures serve to illustrate the importance of considering the relaxation phenomenon correctly.

This example will serve to illustrate the fundamental reasoning to be followed in establishing working stresses. The same method may be used, with greater or less accuracy, for other details. In more complicated structures, such as parts of a turbine cylinder, for example, it may be difficult to establish accurate values for the elasticity of the structure (k), and an accurate analysis is usually not possible. The most important aspects of the analysis cover overall deformations, however, so that it is possible to deal with average stresses and thus simplify the analysis.

Very little can be said as yet about conditions under combined stress or variable stress. It appears probable that creep in plastic metals occurs in all planes and not only, as is often stated, in planes of maximum shear. Until further knowledge is available, however, it does not appear unreasonable to predict creep under combined stresses on the basis of the maximum-shear theory. Irregularities in the distribution of stress are very effectively obliterated at elevated temperatures and can always be neglected, provided that the corresponding external deformations are not objectionable. The case of variable or alternating stress should be treated with extreme caution until more knowledge is available.

The question of margin between actual and predicted performance is somewhat different from the case of failure at normal temperatures. When deformation or relaxation is accompanied by inevitable disaster, it goes without saying that the utilization of the properties of the materials must be fully as cautious as in all other applications. Cases where creep is accompanied by disaster are very rare, however. It may be stated that the fear of creep has in many cases been permitted to dominate designs too extensively. What is frequently defined as safe and comfortable conservatism in this respect may bring far-reaching consequences of a pernicious nature. In permitting the physical dimensions of details such as bolt diameters, wall thicknesses, etc., to swell out to unreasonable proportions, the designer invites other and just as dangerous forms of operating troubles, such as thermal distortions, unreliable materials, and so on. Here, as in many other activities of the engineer, narrow and dogmatic adherence to prematurely established concepts is infinitely more dangerous than practical, intuitive judgment.

There is one aspect of the application of materials that must be treated with extreme conservatism, however, before operating temperatures are increased much beyond the present range. This is the inevitable change of microscopic structure which will become more and more important as the temperatures approach the recrystallization temperatures. Carbide spheroidization[19] in carbon steels is perhaps the most important of these aspects, particularly since it produces a profound change in the plastic properties. The general problem of stability of the cohesion is of utmost importance, because the failures associated with this problem are particularly subtle.

[19] R. W. Bailey and A. M. Roberts, "Testing of Materials for Service in High-Temperature Steam Plant." Proc. of Inst. M.E., vol. 122 (1932), p. 209.

Discussion

A. V. DE FOREST.[20] One interesting point brought out in the paper is the examination of failures which occur in service. If we could accurately analyze the conditions of failure we could then learn amazingly rapidly not to repeat the same mistake. Unfortunately the first reaction to a failure on the part of the engineer is to make the part either heavier or of stronger material without stopping to inquire as to whether failure was caused in the first place by a lack of either of these qualities. A typical example is the well-known habit of changing material when the failure is due to design, and vice versa.

Among the more complicated problems in this field, the author has well brought up the general question of brittle and ductile behavior. All too many metallurgists do not recognize that mere static ductility is frequently of no importance in machine parts, as failure usually occurs before deformation has exceeded the strain available in the most brittle materials.

An even more important point is also raised, and that is the necessity of knowing the working and accidental stresses which are applied to any structure. In an attempt to partially solve this problem, the writer has devised a recording strain gage, sufficiently light and sufficiently inexpensive to apply to many problems involving dynamic stress due to impact loading, fatigue conditions, and stresses due to resonant vibration. This system of measurement consists in a direct record scratched by a diamond on a metal or glass target without a mechanical amplification. The resulting record is measured or photographed under a suitable magnification. In this way a recorder can be built which weighs but a fraction of an ounce, and the only expensive part is the magnification unit which may be used on a large number of individual instruments. This device is commercially made by Baldwin Southwark of Philadelphia, and has been successfully applied to such complicated stresses as occur during airplane maneuvers.

The penultimate paragraph of the paper contains a most important piece of advice, namely, that intuitive judgment is far better than analysis based on undigested concepts. If only designers would intuitively put large fillets at each junction of two straight lines on their drawing board, many failures ascribed to material, or otherwise successful design, would be obviated.

G. B. KARELITZ.[21] Apparently, when we talk of working stresses, we always keep in mind the main stresses in a loaded member, introducing such corrections as are necessary to take care of stress concentration. The writer wishes to call attention to the numerous cases where failure occurs locally, causing nevertheless considerable grief. Generally speaking, in case of a highly localized failure, one has to deal with a three-dimensional-stress state. All problems connected with such a state are quite difficult, mainly due to scarcity of experimental data on the behavior of materials under localized three-dimensional stress. As pointed out in the paper, the present method of treatment consists in extrapolating information obtained from unidirectional simple tests to three-dimensional cases.

That this method is unreliable can be easily demonstrated on, say, ball bearings. The stresses obtained by the application of the Herz formula are of the order of 200,000 to 300,000 lb per sq in., or even higher. The shearing stresses obtained from consideration of the difference between the principal stresses is of the order of 80,000 lb per sq in. The number of stress cycles in the material runs into millions, yet failure does not occur. It would be worth while to undertake an investigation of working

[20] Consulting Engineer, Bridgeport, Conn.

[21] Westinghouse Elec. & Mfg. Co., Lester, Philadelphia, Pa. Mem. A.S.M.E.

stresses in the case of "surface loading," where a highly localized stress exists under the surface of the metal at the point of application of a concentrated load.

The failure of gear teeth due to pitting is another instance of wide interest. The present theory of pitting explains it by the effect of shearing stresses under the surface of the tooth material, as caused by the contact pressure between the teeth. Citing as an example the case of high-speed reduction gearing, the Navy specifications allow a load of 95 lb per inch face per inch diameter of pinion. This is equivalent to a shearing stress of approximately 11,000 lb per sq in. in the tooth material. This tooth load is considered to be perfectly safe, yet it must be admitted that the stress is fairly high when compared with the fatigue limit for low-carbon steel. There are a number of high-speed reduction gears working successfully at a shearing stress of the order of 18,000 lb per sq in. Apparently, the general criterion of safe working stress is hardly applicable here, and a special treatment is necessary. It would be very profitable and timely to institute a program of research to elucidate the question of allowable working stress for such cases as ball and roller bearings, gear teeth, and similar machine details.

KENNETH G. MERRIAM.[22] It is to be regretted that the very logical notion of "utilization factor," as proposed by the author, has not been in use in airplane design. To become familiar with the present state of affairs in airplane-design procedure, the reader is urged to study the following definitions which are taken from the 1932 issue of "Airworthiness Requirements of Air Commerce Regulations for Aircraft," published by the Aeronautics Branch of the U. S. Dept. of Commerce:

1 *Basic Load.* The basic loads on (or stresses in) an airplane or part when the airplane is at rest or in a condition of unaccelerated flight.

2 *Design Load.* The load for which a member is designed. It is usually obtained by multiplying a basic load by a specified load factor.

3 *Ultimate Load.* The load that caused failure in a test or the load that, according to computations, should cause failure in a member.

4 *Load Factor.* The ratio of some other load to the basic load in which the relative distribution of forces is the same. This other load may be any of the following: The load applied during some special maneuver, the maximum probable load on the airplane or part, the design load, or the ultimate load.

5 *Margin of Safety.* The ratio of the ultimate strength of a member minus the design load to the design load. Usually a member with a positive margin of safety is satisfactory, and one with a negative margin of safety is unsatisfactory.

6 *Factor of Safety.* The ratio of the design load or the ultimate load to the maximum probable load. In airplane design the least factor of safety is usually about 2.

To the writer it would seem desirable to redefine items (2) and (4), and to have item (5) supplanted by the notion of utilization factor, as defined by the author. Realizing that this is a matter requiring very careful study, the writer proposes the following imperfect definitions as a basis for further discussion by airplane designers and others concerned:

2 *Design Load.* The maximum probable load on a member for the condition under investigation, obtained by multiplying the basic load by a specified load factor which is defined below.

4 *Load Factor.* The ratio of the maximum probable load on the member for the condition under investigation to the basic load.

5 *Utilization Factor.* The ratio of the design load to the ultimate load. In airplane design the maximum utilization factor is usually about 0.50.

So far as the writer can see, these new definitions would cause airplane and machine designers to speak a common language when discussing working stresses.

BENJAMIN MILLER.[23] The title of Fig. 1 should be "Definition of Yield Strength for 0.2 Per Cent Set," and the definition of yield point should be "The stress in a material at which there occurs a marked increase in strain without an increase in stress." The paper would then be in line with the A.S.T.M. Tentative Standard E 8-32 T.

In the fifth paragraph following Equation [1], the author states that under favorable circumstances it should be possible to utilize 75 to 80 per cent of the strength of the material. He says further on that although the Mises-Hencky theory is more correct than the maximum-shear theory, the maximum-shear theory is sufficiently accurate for practical purposes. He then points out that the difference between the theories is (for pure shear) the difference between 0.577 and 0.5.

There seems to be a contradiction here. For if a material fails in tension at a stress value of 1000, and it is desired to use the material in shear with utilization of 80 per cent, by the Mises-Hencky theory the working stress can be 462 units, but can only be 400 units by the maximum-shear theory. Therefore if the maximum-shear theory is used in the practical case the factor of utilization will be not 80 per cent but less than 70 per cent, and there will be a 15 per cent waste of material. On the other hand, the shear test may be easier to make than the tension test. Suppose in such a shear test a strength of 577 units is found. Then, if the maximum-shear theory is used, the tensile working stress for 80 per cent utilization will be calculated to be 923 units, so that the factor of utilization on the Mises-Hencky theory would be 92.3 per cent, which might leave an insufficient margin of safety.

Until the law of yielding is established with an uncertainty of much less than 15 per cent, it seems idle to talk of factors of utilization of 75 to 80 per cent.

A. NADAI.[24] With regard to the mathematical form to be suggested to the designer for defining the condition of yielding, it seems to the writer that one of the various reasons which might be brought up in favor of the acceptance of the expression

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_0^2$$

(σ_0 yield stress for pure tension, σ_1, σ_2, σ_3 principal stresses) is that not only do the results of a larger number of more recently

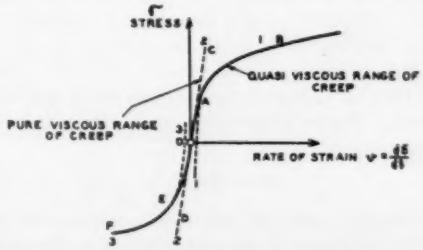

FIG. 14 CONDITIONS OF A VELOCITY-STRESS CURVE AT ORIGIN AT A GIVEN ϵ = CONST.

and carefully made tests under combined stress seem to settle the question in its favor but also mechanical reasons lend further support to this condition and certain important general symmetry properties inherent therein or in the mathematical consequences to which it may lead when further applied to plastic equilibria

[22] Assistant Professor, Divisions of Applied Mechanics and Aeronautics, Worcester Polytechnic Institute, Worcester, Mass. Assoc. Mem. A.S.M.E.

or plastic states of stress in bodies. It is not possible to develop these reasons here in detail; suffice it to say that Equation [1] is to be preferred to the expression $\tau_{max} = \text{const}$ (τ_{max} being the maximum shearing stress for the stress distribution σ_1, σ_2, σ_3), both from a mathematical as well as from a physical point of view.

Most timely and valuable contributions to the treatment of actual problems of turbine designers are the author's brief remarks on strength at elevated temperatures and the permanent deformations of metals under prolonged loading. The rational design of certain heavy parts in steam turbines and of all kinds of heavy apparatus subjected to high pressures and elevated temperatures seems to depend to a greater or less extent on two major problems of the creep of metals, namely, the laws of plastic flow under constant load or constant stress and on those of the relaxation from stress or of the processes under which a given stress distribution may gradually disappear and stress will readjust itself with time. Despite a few valuable attempts which have recently been made by mathematicians and by engineers to analyze such cases on an exact basis and although a considerable amount of empirical information has been already gathered on the creep of metals for design purposes, it cannot be said that the theory of this particular kind of plastic deformation has kept pace with the present needs of industry. To these circumstances may perhaps be attributed the surprising fact that a closer agreement in the interpretation of results of the simplest tensile tests among the various investigators has not yet been reached. From this point of view a discussion of some of the assumptions made or of the mathematical expressions suggested may be in order and of practical interest. Only one point will be considered here.

For example, the first attempts by Ludwik and by Cassebaum to express from tensile tests how the yield stress σ at normal temperatures depends on the rate of strain $v = \partial\epsilon/\partial t$ pointed to a logarithmic expression or law such as that given in Equation [7] of the paper. While this law holds for *rapid* speeds of deformation, it evidently fails for small rates of strain converging to zero. The recent tests by Deutler have verified and extended the law from the rates of strain of an ordinary tensile test to the extremely high rates encountered in impact tests (speed ratios: 1 to 1 million) for a few ductile metals tested at normal temperature. The parameters σ', σ'', and v_0 depend on the unit strain ϵ with the understanding that the stresses σ producing the various rates of stretching $v = \partial\epsilon/\partial t$ are to be compared for a given and the same plastic elongation $\epsilon = \text{const}$.

As far as a possible extension of this relation to quite small rates of flow or strain is sought at normal temperatures, certain conditions of uniformity have to be satisfied by the function connecting the stresses σ and velocities v. It must, for example, be assumed that for compression the same speed law holds as for tensile stresses. Hence satisfactory expression of this law in the form of a function

$$\sigma = f(v) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [19]$$

for small values of v, including zero speeds, will have to be an odd function of the variable v in the neighborhood of the point $v = 0$. The simplest function satisfying at this point the condition of uniformity is

$$\sigma = \phi v \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [20]$$

with ϕ as a constant, which is the expression of pure viscous flow. This is one of the reasons which led the writer long ago to assume tacitly that if a speed law like [19] at a constant $\epsilon = \text{const}$. exists in the neighborhood of zero rates of strain, the curve expressing the speed function must have an inflection point and may be approximated for small rates of flow by the straight line [20]. Although the material available from tensile creep tests made with metals at elevated temperatures is not yet conclusive enough to justify acceptance of a law similar to the one (Equation [7]) found to express the facts adequately at much higher rates of strain and at normal temperature, it has been independently suggested in slightly altered form by a few investigators as a possible expression of the creep law of metals at high temperatures and under higher speeds of stretching. Under the expectation that this law is probably valid at elevated temperatures in a limited range of the variables (plastic strain ϵ, plastic rate of strain $v = \partial\epsilon/\partial t$ and stress σ) in the following, and until more conducive information may become available, a slightly modified working hypothesis for predicting creep deformations is proposed. If for constant strains $\epsilon = \text{const}$. in a certain range AB (Fig. 14) of the positive velocities v the logarithmic relation of Equation [7] is found to express the speed law in a satisfactory manner, then the true speed-stress curve may perhaps resemble the curve shown in Fig. 14. This curve is drawn to pass through the origin O, ($v = 0$) where σ follows first a steeply inclined straight line such as OC. At a certain stress it will leave this straight line and will bend and rapidly approach a logarithmic curve such as that shown in Fig. 14 in the branch of a curve AB. The corresponding must be true on the negative side of the speed axis (i.e., for compression). Thus the curve *FEOAB* consisting of portions of two identical logarithmic curves (1) and (3) symmetrically situated with respect to the origin O (*but not passing through this latter point*) and of a straight line (CD) might perhaps represent the speed laws, at least in a certain limited area of the ϵ,v-plane. Whether it is perhaps sufficient to draw the straight line *COD* directly as the common tangent to the two logarithmic curves (1) and (3), or whether the straight line has to be assumed more steeply inclined than the common tangent line, as indicated in Fig. 14, must, on account of lack of proofs and information, be left an open question.

R. E. Peterson.[25] It has occurred to the writer that in connection with certain applications the need for "high-strength" steels has been overemphasized and the additional cost involved perhaps not justified. For instance, in the case of a shaft having a groove and subjected to alternating stress, the strength in terms of different steels would be such as shown in Fig. 1 of the writer's paper in this symposium. Thus, in this particular case, steels with ultimate strengths of 90,000 and 180,000 lb per sq in. (ordinary endurance limits approximately 45,000 and 90,000 lb) actually show but relatively little difference in fatigue of grooved specimens (approx. 30,000 and 37,000 lb respectively). Furthermore, the higher-strength steel would perhaps be brittle, i.e., of lower impact value, so that an occasional overload would be more serious. Consequently, the choice of materials for the case of variable stress together with stress concentration must be carefully considered and not merely based on ultimate strengths or ordinary endurance limits.

The paper states that "it must be regarded as good design practise to avoid variable stresses of appreciable magnitude in brittle materials." Certain heat-treated alloy steels are quite brittle (approaching 5 per cent elongation). Dr. Gillett[26] states: "Despite some individual opinion to the contrary, there is no acceptable evidence that a high static elastic ratio or high ductility, such as may be obtained by suitable alloying and heat treatment, at all improves the endurance ratio. In an endurance test of a small specimen a strong, brittle steel acts just like an equally strong, ductile steel." It would seem that the reason for avoiding brittle materials should not be so much on account of the presence

[25] Westinghouse Research Laboratories, East Pittsburgh, Pa. Assoc-Mem. A.S.M.E.

[26] H. W. Gillett, "Effect of Alloying and Heat Treatment on the Endurance Limit of Steel." Proc. A.S.T.M. (1930), part I, p. 291.

of variable stress but more because of the possibility of impact. In ordinary machine parts, impacts due to accidental overloading or other unforeseen causes may result in fractures or local cracking if the material is brittle.

Heat-treated helical springs having high Brinell hardness and quite low ductility are widely used for variable-stress application. Two reasons may explain why this is possible: absence of pronounced stress concentration, and reduction of impact effect due to large deflection with resulting increased time interval.

With respect to "size effect" in fatigue, the paper states that "it is fortunately not of sufficient importance to warrant elaborate attention in connection with working stresses." This seems to be the case in the reference noted which concerns specimens without stress-concentration effect. However, for geometrically similar specimens with holes or fillets a decided size effect seems to exist in fatigue tests,[27] i.e., endurance strength obtained with large specimens may be only half that obtained with specimens of ordinary size. Much work remains to be done on this question, and while it is too early to make definite recommendations, yet it would also seem that the question should not be dismissed as being of insufficient importance.

In discussing the effect of unmachined surface on fatigue strength, mention is made of cases where 50 per cent lower strength is obtained as compared with polished specimens. It might also be added that tests of leaf springs[28] have shown still greater reductions, as much as 79 per cent. This tremendous decrease is generally attributed to surface decarbonization.

RONALD B. SMITH.[29] The latter part of the paper is of special concern to those who must apply materials to engineering structures at high temperatures. Admitting the controversy existing over the behavior of materials at elevated temperature, the author has approached the problem as an engineer, with a solution that, while not exact, will cope with ordinary design requirements.

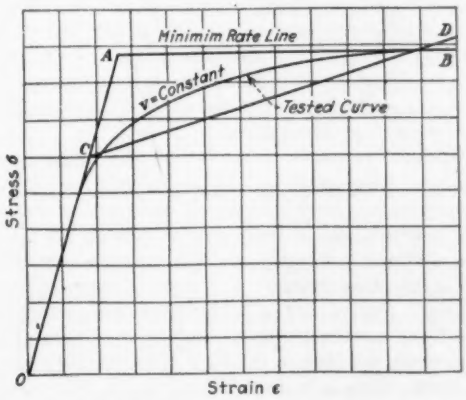

FIG. 15 HIGH-TEMPERATURE STRESS-STRAIN DIAGRAM

Tests at elevated temperature lead to a σ-ϵ diagram, at constant velocity, as shown in Fig. 15. Plotting the usual conception of the Ludwik equation, based on minimum creep rates, is tantamount to constructing the minimum-rate line *OAB;* however by applying the rate equation as a function of ϵ_p, the author approximates the stress curve by *OCD*, where *C* is determined logarithmically.

With the temperatures in vogue in central-station design this is the better approach to the relaxation problem. That the test data are in finer agreement with this analysis than one would gather from Fig. 9 of the paper, is evident from Fig. 16, which is a replot from Ernest L. Robinson's paper "Materials at High Temperature." The tests were made on cast manganese steel at 842 F. As creep continues the stress for all values of plastic

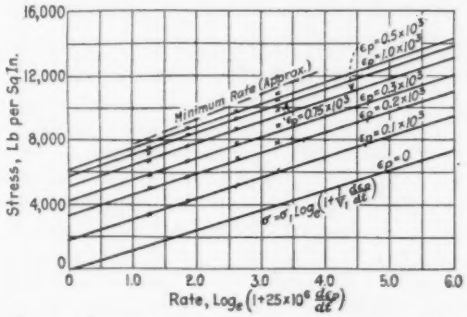

FIG. 16 STRESS-STRAIN-RATE RELATIONS FOR CAST MANGANESE STEEL AT 842 F

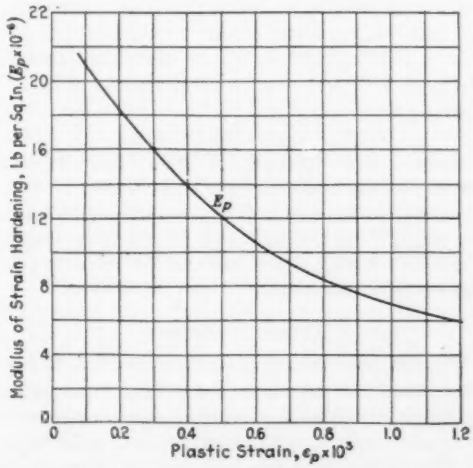

FIG. 17 STRAIN-HARDENING MODULUS FOR CAST MANGANESE STEEL AT 842 F

strain approaches the constant-rate line so prominent as a logarithmic relation in high-temperature literature heretofore.

The evidence from considerable test data indicates that, like Fig. 16, the additional strength resulting from strain hardening does not follow a constant modulus of strain hardening. It is probably some exponential function similar to Fig. 17. Equation 9 can be readily modified for this variation.

$$\sigma = \sigma_1 \log_e \left(1 + \frac{1}{v_1}\frac{d\epsilon_p}{dt}\right) + f(\epsilon_p) \ldots\ldots\ldots [9a]$$

Since $$\sigma^* = \sigma - f(\epsilon_p) = \sigma_0 - E'\epsilon_p$$

the function is easily integrated and Equation [15] becomes

$$t = t^* \log_e \frac{1 - e^{-\sigma_0/\sigma_1}}{1 - e^{-[\sigma - f(\epsilon_p)]/\sigma_1}} \ldots\ldots\ldots [15a]$$

where $$\epsilon_p = \frac{\sigma_0 - \sigma + f(\epsilon_p)}{E'}$$

That the exponential relation is more rational than the assumption of a constant modulus is shown in Fig. 18 where the creep curve for a stress of 8000 lb per sq in. has been calculated by a

graphical integration of [9a] and compared with the test data. If a constant mean value of the modulus is selected the agreement is poor.

Notwithstanding the author's admission that the test results are too meager to justify analysis of Fig. 10, it may not be amiss

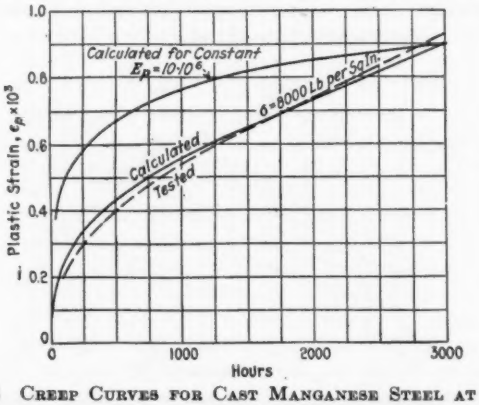

FIG. 18 CREEP CURVES FOR CAST MANGANESE STEEL AT 842 F

to mention the general trend that one would anticipate. Numerous investigators[30] have found that strain hardening disappears at high temperatures. This would conform to a negative slope in the E_p-function, and in case it be represented exponentially, to a flattening of the curve and a reduction in the quantitative value.

Another property of crystalline materials at elevated temperatures is viscosity. Roughly, it is to be expected that stress and rate may be represented by[31] $\sigma = \phi\ (d\epsilon_p/dt)$.

The viscosity ϕ decreases with temperature, and the relation between σ_1 and v_1 should be such that in satisfying Equation [9a] for a constant velocity, they result in an increase in stress as the temperature is reduced.

AUTHOR'S CLOSURE

The importance of recording strain gages, referred to by Dr. De Forest, cannot be overestimated. They have played a very important role in correctly evaluating obscure circumstances of loading in such structures as ships, bridges, railroad rails, and so on. The device mentioned should be of great value on account of its small size, permitting its application to conditions where the usual types of strain gage are not applicable.

The complicated cases of three-dimensional loadings, referred to by Mr. Karelitz, belong to a section of the problem that is particularly difficult. We have to admit that our knowledge of what goes on just under the surface of a ball race or a gear tooth is limited. Another example of this class of phenomenon is the problem of erosion of turbine blading due to impingement of water drops at high speed. It would seem that all of these phenomena have to be set aside for a treatment of an entirely different order than that advanced by this paper. The ambiguous property of materials defined as hardness is probably closest to the actual circumstances for these cases.

The confused terminology in the subject of strength is to be deplored. While the confusion must be eliminated by careful definition of existing terms, rather than by the injection of entirely new terms, it has seemed worth while to the author to continue the use of the term "utilization factor." Wherever working stresses must be defined with precision, the term appears to justify its existence. The modifications proposed by Mr. Merriam in the terms used by the Aeronautics Branch of the U. S. Department of Commerce, injecting this term, would thus appear worth while. It is particularly in connection with superposition of several stresses that the use of the term leads to pronounced simplification.[32]

The proposal of Mr. Miller to change the name yield point to yield stress, to bring the paper into agreement with the A.S.T.M. standards, is a good suggestion. The apparent contradiction in the statement referring to the practicability of using 75 to 80 per cent of the strength of the material may be attributed to the lack of definition of what constitutes "favorable circumstances." This is a subject of great importance that belongs to every discussion of working stress, but which was considered of somewhat too local a nature to be included in the present paper. In applying materials to engineering structures, the possibility of predicting failure accurately varies over a large range. At the one end of this range there is the case of applying ductile materials in the form of a tensile test piece. At the other end there is the case of complicated forms of stress applied to materials of doubtful properties. In the former case the results of the tensile test may be applied directly without the intermediate interpretation of a strength theory. No case can be more favorable than this, and under such circumstances it is not unreasonable to utilize 75 to 80 per cent of the known strength.

Dr. Nadai's comments on the paper are very valuable. It is undoubtedly true that something would be gained by building up rules for working stresses around the von Mises relation for plastic flow. There is a question, however, if the added implication would be justified in view of the general uncertainty of the practical aspects of the subject.

In suggesting the creep law $\sigma = \sigma_1 \log_e (1 + v/v_1)$, the tacit assumption is made that when v is very small the law becomes $\sigma = \frac{\sigma_1}{v_1} v$, where the quantity σ_1/v_1 has the dimension of viscosity and is identical with ϕ. This subject is of practical importance, since very small creep rates cannot be explored experimentally and still play a real rôle in machines intended to operate continuously for decades. It is entirely possible that we shall have to be content with theoretical reasoning in tracing the creep relations for very low creep rates.

Mr. Peterson's reference to the satisfactory fatigue properties of heat-treated alloy steels with low ductility is very interesting. The elongation is a poor measure of ductility for this type of material, however, and it may be that a more correct picture would be obtained if ductility could be measured quantitatively in a more satisfactory manner. It is true, on the other hand, that the designer's fear of brittle materials is associated with the behavior of the materials under unforeseen conditions of loading. If an overstress, whether in the form of an impact or not, may cause a crack, there is a very decided reason for conservatism in the use of the material.

The author wishes to express his appreciation for the work of Mr. Smith in investigating the justification for a constant value of the modulus of strain hardening. It is evident from Fig. 18 that very superior agreement between test and prediction is obtained by an assumption of a variable value for this quantity than that which is obtained by using an average constant value. The difference is not great for the typical case of relaxation; for the case of constant stress, there are usually available actual creep data. While it is thus probable that the use of a constant modulus of strain hardening is accurate enough for practical purposes, the complication of using a variable modulus is not too great to make it objectionable, particularly when the relaxation data are plotted in curves of the type shown in Fig. 13.

Metals at High Temperature—Test Procedure and Analysis of Test Data

By ERNEST L. ROBINSON,[1] SCHENECTADY, N. Y.

Tests on the flow of metals at high temperatures under stresses so small that the resulting distortions are less than one-tenth of 1 per cent show, throughout the duration of tests extending into the second year, continued reductions in rates of flow so that, for such small distortions, it is impossible to associate any particular rate of flow with a corresponding allowable stress. A statement of test results, to be of use, requires in addition to rate of flow and applied stress, certainly a record of total extension and possibly also a record of time elapsed. Furthermore, tests should be made under conditions of stress approximating the conditions of application in actual service.

THE construction of machinery for operation at high temperature requires information on which to base the selection of suitable materials. During the period before actual experience has been had at the higher temperatures this choice must be based on tests of new materials to see if they have properties as good relative to the more severe conditions as the older materials had under the former conditions.

There is one essential consideration, the relative importance of which may shift completely. At low temperatures materials are chosen largely with reference to strength. Allowable safety considerations dictate stresses so small that distortions (which are almost wholly elastic) are of the order of magnitude of 1 mil per inch or less, and are of minor consequence in comparison with strength considerations.

On the other hand, at high temperatures there are certain applications in which plastic distortions of intolerable size would occur long before there could be any danger of failure due to stress. Under these conditions the whole basis of design necessarily shifts from consideration of allowable stress to consideration of allowable distortion, and only such stresses as are accompanied by tolerable distortions can be permitted.

Under such conditions, testing should bear a strict relation to conditions of application.

During the past several years the General Electric Company has been conducting tests on the suitability of materials for use at high temperature.[2]

While there has been substantial agreement with other laboratories as to the flow-rate strength of certain standard materials, there are many cases where the values given by other laboratories appear considerably too high to correspond with the conditions of use represented by the General Electric tests.

It would be of decided advantage to all concerned if test results could be recorded in more complete form in order that corrections to corresponding conditions of application might be possible.

Conditions Insuring Greatest Usefulness of Test Results

It is the purpose of this paper to suggest several considerations that ought to be taken account of in test in order for the results to be of greatest usefulness.

The most difficult element is the time element. High-stress tests completed in a week or two have been found to reverse the relative desirability of materials as compared with tests of longer duration at stresses or extensions which might be tolerable in design. Certainly a one-year test is in no sense a ten-year application, and similarly no one-day test can replace a full-year test until both have been made and the correspondence established. The General Electric Company selected as quickly as possible on the basis of short-time tests of six to eight weeks' duration the most promising materials, and already has tests on the best of these materials proceeding into the second year.

Tests ought to be conducted under conditions approximating the conditions of service. Thus, if a material is to be subjected to steady stress which will not be subject to relief as time goes on, the material should be so tested. This requires the use of several samples at different loads, to define or "bracket" an allowable stress or extension.

Similarly, if a material is to be used for a bolt or assembled with a fit subject to relief as flow occurs, the test should be made in that manner or at least conducted with steps of successively reduced loading approximating a condition of constant elastic plus plastic extension.

A few General Electric tests have been made accidentally with successively increased loadings. These came about because the material proved better than originally thought. Such tests are difficult to interpret, and do not appear to have any corresponding application.

Formula for Correction Purposes

In order to present the importance of testing in the neighborhood of service conditions, a formula is offered which is roughly suitable for correcting from one condition to another. This formula is wholly inadequate for more than correction purposes. In fact, there would be no moral to this story if the formula were good over a long range of values. It represents approximately plottings which prove to be nearly straight lines on log-log paper

---

[1] Turbine Engineering Department, General Electric Co. Mem. A.S.M.E. Mr. Robinson was born at Canton, N. Y., on April 11, 1890. He was graduated from the St. Lawrence University in 1911 and from the Harvard Graduate School of Applied Science in 1914 (M.C.E.). For three years he was engaged in construction work and the design of steel and reinforced-concrete structures in New York and in water-power engineering in New England. During the war he served in the Oise-Aisne offensive as a 1st Lieutenant with the 302nd Engineers, U.S.A., and later as Captain and Adjutant of the 2nd Engineer Training Regiment. For the past thirteen years he has been employed by the General Electric Company in its Turbine Engineering Department.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

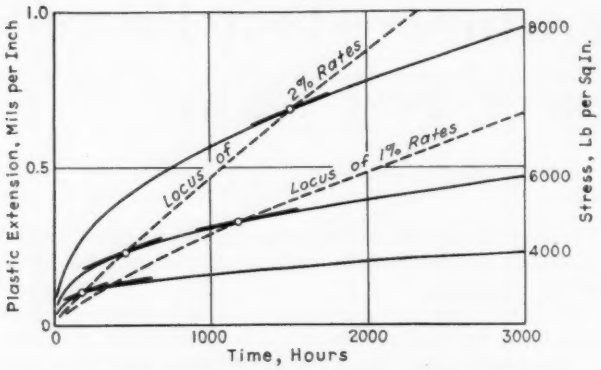

FIG. 1 BEHAVIOR OF TEST BARS UNDER STEADY STRESS
(Material, cast manganese steel; temperature, 842 F.)

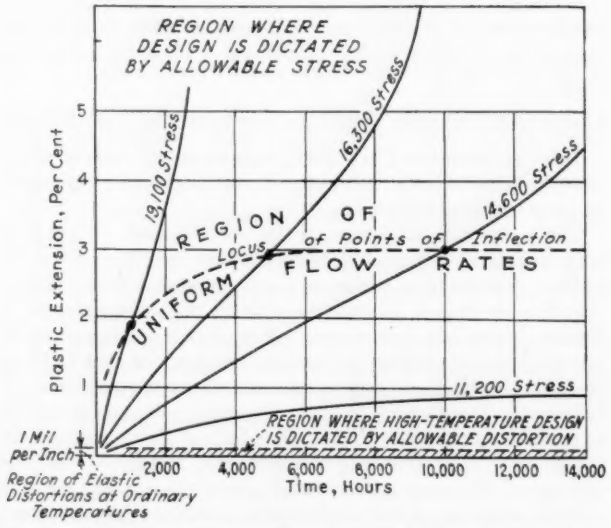

FIG. 2 REGIONS IN WHICH DESIGN IS DICTATED BY DIFFERENT CONSIDERATIONS
(Material, cast manganese steel; temperature, 842 F.)

over a range of one or two squares. Thus a satisfactory correction may be made to a tenfold extent, using a constant exponent, but not over a hundredfold range without using a different exponent.

Let S = applied stress
T = temperature
r = rate of flow
x = total plastic extension

Then

$$\frac{S}{S_0} = \left(\frac{T_0}{T}\right)^p \left(\frac{r}{r_0}\right)^{1/n} \left(\frac{x}{x_0}\right)^{1/k}$$

Expressed in words, the indicated relations are as follows:

1 For a particular previous extension and a specified rate of flow, the strength decreases as the temperature increases. Thus, in the case analyzed below, an increase in temperature of 50 F shows a reduction of one-third in the creep strength. The exponent p is approximately 7 over the range from 700 F to 1000 F.

Where stresses are fixed, and after some definite amount of previous extension, an increase of temperature of 50 F increases the rate of flow some tenfold (more or less). Thus a year's normal distortion may easily be caused by 5 weeks' operation of a machine at 50 F excess temperature.

2 For a particular temperature and a specified previous extension, a 50 per cent increase of stress causes a tenfold increase in the rate of flow. Thus the rate of flow may be reduced to one-tenth its former value by a reduction of stress of approximately one-third. The relation is approximately good for rates ranging from 0.1 per cent per 100,000 hr to 10 per cent per 100,000 hr. n is approximately 6 for the case illustrated hereafter.

3 For a particular temperature and a specified rate of flow, a tenfold accumulation of plastic extension enables the material to carry approximately double the stress at the specified rate. The relation is approximately good for extensions ranging from 0.1 mil per inch to 10 mils per inch, that is, from one-hundredth of 1 per cent to 1 per cent. k is approximately 3.5 for the case illustrated below.

This last characteristic is probably to a certain extent an indication of "strain hardening," the tests all being in the range where strain hardening is apparently incomplete.

THE TESTS CONDUCTED

General Electric tests for the most part cover total plastic extensions of approximately 1 mil per inch, that is, one-tenth of 1 per cent and rarely exceeding two-tenths of 1 per cent.

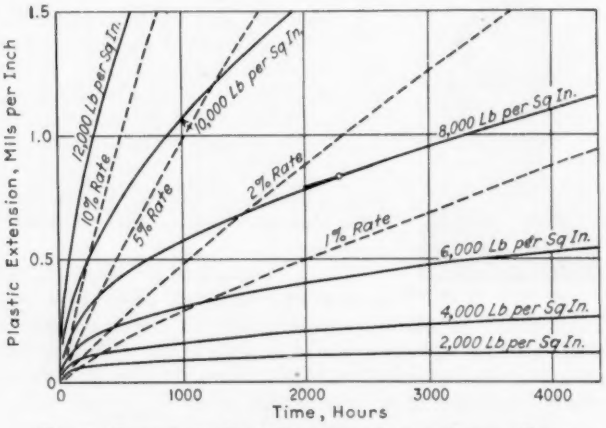

FIG. 3 RECORD OF TEST RESULTS—STEADY-STRESS TESTS
(Material, cast manganese steel; temperature, 842 F.)

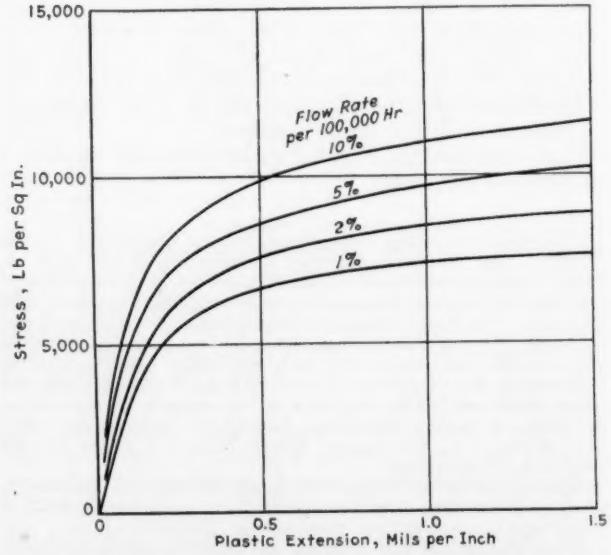

FIG. 4 HIGH-TEMPERATURE FLOW-RATE CHART
(Material, cast manganese steel; temperature, 842 F.)

Throughout this limited range, the materials tried improve in strength with stretching, the flow rate decreasing as the plastic extension increases.

Fig. 1[3] illustrates these relations. Thus with a 6000-lb stress a rate of 2 per cent per 100,000 hr is attained with an extension of 0.23 mil per inch. However, the same test bar after being stretched to 0.33 mil per inch showed a rate of only 1 per cent with the same load. Similarly a bar with 8000 lb stress allowed to stretch 0.68 mil per inch will carry its load at a 2 per cent rate, while a bar stretched only 0.1 mil per inch can carry only 4000 lb load at that rate. In no case has a rate been found steady with total extensions of less than 10 mils per inch or 1 per cent. Thus a test which yields a line, straight within the accuracy of the test data for a period of a month, a year later on will yield another line, equally straight for a month, but at a lesser rate.

Although the tests under consideration were confined to small extensions, it seems necessary to recognize that a material stretched to such amounts as, for instance, 10 per cent or 20 per cent, approaching the limits of ductility, would have to show increasing slopes instead of the decreasing rates described by the formula. In between there is a range of stretch at a steady rate such as that illustrated by Fig. 2.

Many very useful tests have been conducted with reference to this region, which doubtless have utility for applications in which total extensions of several per cent are allowable.

Returning to the region of small distortions, Fig. 3 shows complete curves for 1, 2, 5, and 10 per cent rates per 100,000 hr. Fig. 4 shows the basic information obtained from the series of

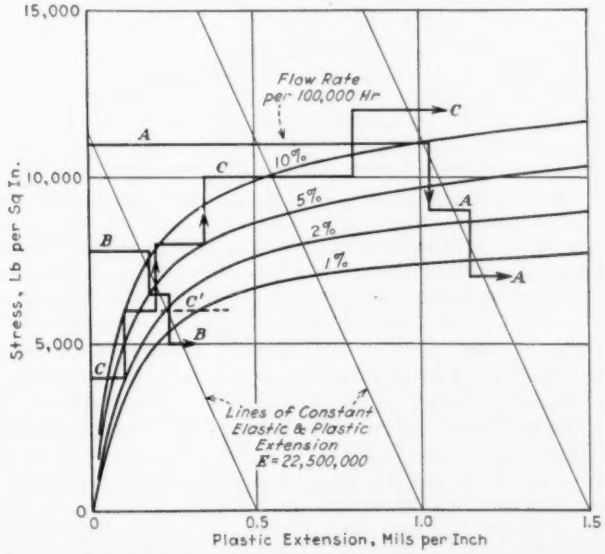

FIG. 5 HYPOTHETICAL FLOW-RATE TEST PATHS UNDER VARIOUS CONDITIONS

(Material, cast manganese steel; temperature, 842 F.)

test bars represented in Fig. 3. The lines of constant stress in Fig. 3 are simply horizontal lines in Fig. 4, crossing the lines of successively smaller rates.

Fig. 5 has been drawn in order to show the significance of the manner of conducting a test. The slant lines represent the conditions of bolts with several degrees of initial tightness, the elastic extension being relieved gradually as the plastic flow occurs.

A and *B* represent hypothetical test paths of single bars with stresses stepped down under conditions approximating constant extension, the results being plotted with the usual log-log graph in Fig. 6. Bar *A* has an initial stress of 11,000 while bar *B* has an initial stress of 7800. The test conducted at the higher stress level would be expected to show a 1 per cent flow-rate strength of

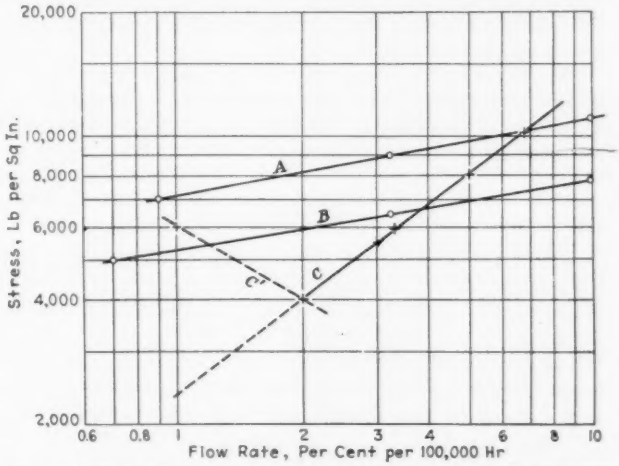

FIG. 6 LOG-LOG PLOT OF FLOW-RATE RESULTS UNDER CONDITIONS SHOWN IN FIG. 5

(Material, cast manganese steel; temperature, 842 F.)

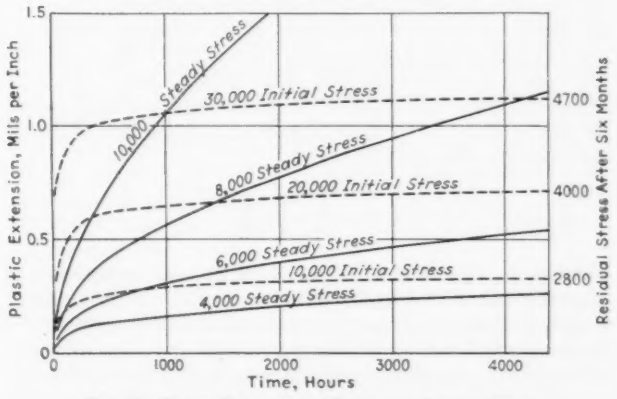

FIG. 7 FLOW WITH TWO TYPES OF APPLICATION

(Material, cast manganese steel; temperature, 842 F
All stresses in pounds per square inch.)

7200, while the lower-level test would show only 5500. In each case the rate is 1 per cent per 100,000 hr for the cited stress.

Path *C* illustrates the difficulty of drawing conclusions from a test in which the initial stress applied was too low. Subsequent increases of stress are likely to lead to unsystematic interpretations. Thus a little more patience at the 6000 stress would show a 1 per cent rate along the broken-line path *C'*, and actually reverse the slope of the log-log plot in Fig. 6.

The type of diagram presented in Fig. 4 gives the relations between three quantities which must be associated in order to define the flow-rate strength of a material at a certain temperature. Doubtless the elapsed time at a high temperature accomplishes chemical effects which may be of importance also. Thus a diagram of rates plotted on a stress-extension base like Fig. 4 can be drawn from a series of step-down tests at several extensions covering only a minor fraction of the time consumed in making the tests illustrated in Fig. 3. But as mentioned before, the definite relation between long- and short-time tests has still to be established. In the meantime it seems preferable to construct the diagram from tests made in imitation of the conditions of application.

[3] This and the succeeding diagrams are based on the material illustrated in Figs. 18 and 19 of the paper by Messrs. Coffin and Swisher mentioned in footnote 2.

Fig. 7 illustrates the two common types of application already referred to for which test information is sought. The solid lines show extension with a steady stress such as occurs in shells or casings with steady internal pressure. The broken lines show the plastic extension which occurs when the initial elastic extension is relieved by the plastic flow as in bolts or shrink fits. In these cases the residual stresses at the end of a six-month period are shown at the end of each curve.

From what has been shown it should be clear that a table of stresses for a nominal rate and a certain temperature needs to be supplemented by a record of extension, and preferably a complete extension-time diagram of the test.

Discussion

A. NADAI.[4] The numerous data on the flow of metals at high temperature which have been published during the last few years in this country, particularly the valuable results of tests to which the present paper makes reference, have recently stimulated further attempts to correlate the considerable information which has become available with time and to express it with the final aim to have it in a more exact or more analytical form available for the purposes of the design of high-temperature equipment.

The demand to express creep data by formulas which would be valid within a limited range of the variables which they contain should be supported. One natural suggestion which might be made in this respect leads to assume that during a tensile test the stress σ (taken per unit of area of the actual cross-sectional area A) might be approximated by a product of a function of the unit strains ϵ and of a function of the rates of strain $v = \partial\epsilon/\partial t$. It may be furthermore assumed that both of these functions would be power functions of their respective independent variables, thus assuming that the stress

$$\sigma = \sigma_0 \left(\frac{\epsilon}{\epsilon_0}\right)^n \left(\frac{v}{v_0}\right)^m \quad \ldots\ldots\ldots\ldots [1]$$

where σ_0, ϵ_0, v_0, n, and m are constants at a given temperature. This is practically the same expression, rewritten here by using a slightly changed notation and assuming that the temperature T is constant, which is the base of a number of conclusions contained in the paper. The author makes it clear that he does not want to have this function used or suggested for other than correction purposes, and that if it may be used, it may be good to represent a limited portion in the field of the variables ϵ or v.

It may perhaps be of some interest for the description of the creep phenomena of metals to try to draw a few simple conclusions, which would be the consequences of the product and the power function law as it was expressed by Equation [1]. It is implicitly assumed when introducing this equation that the elastic part of the strains or of the rates of strains may be of secondary order or be neglected, so that no claims are made to express, for example, any details referring to the elasticity of the bars. Assuming that the stretching in a tensile test at elevated temperature is observed while the load s (this shall be taken for the sake of convenience per unit of area of the *original* cross-sectional area A_0 with which the test was started) is kept constant, on account of the relations:

$$(1 + \epsilon)A = A_0 \quad \ldots\ldots\ldots\ldots [2]$$

$$sA_0 = \sigma A \quad \ldots\ldots\ldots\ldots [3]$$

which must hold during the test, it would follow that the load s would be given by the expression:

$$s = \sigma \frac{A}{A_0} = \frac{\sigma}{1 + \epsilon} = \frac{\sigma_0}{1 + \epsilon} \left(\frac{\epsilon}{\epsilon_0}\right)^n \left(\frac{v}{v_0}\right)^m \quad \ldots\ldots [4]$$

Hence in a tensile test made under a constant load s = const., the speed of strain v corresponding to this load at any strain ϵ is given by solving the equation:

$$\left(\frac{v}{v_0}\right)^m = \frac{s}{\sigma_0}(1 + \epsilon)\left(\frac{\epsilon}{\epsilon_0}\right)^{-n} \quad \ldots\ldots\ldots [5]$$

for the variable v.

Considering in this last expression for the variable v, s as a constant, the strain ϵ_i at which the minimum creep rate $v_{min.}$ will be observed might now be easily found by putting $dv/d\epsilon = 0$ and solving for ϵ. This furnishes an extremely simple result for the strain at which the minimum creep rate is reached; namely, the value

$$\epsilon_i = \frac{n}{1 - n} = \text{const.} \quad \ldots\ldots\ldots\ldots [6]$$

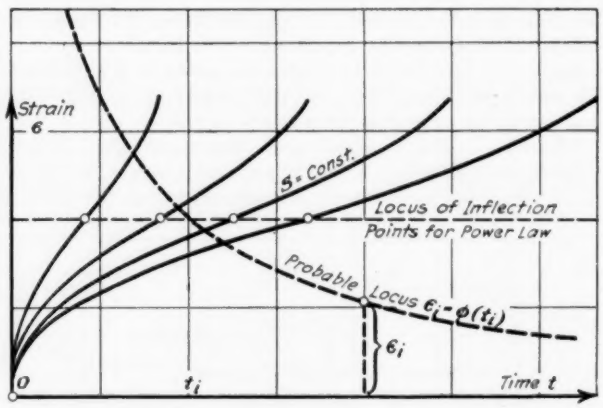

FIG. 8 TIME-ELONGATION CURVES FOR CONSTANT LOADS

Equation [6] indicates that this value depends *only* on the exponent n. The minimum creep rates under various loads s = const. will therefore all be reached at the same unit elongation $\epsilon_i = n/1 - n$, and the creep curves $\epsilon = f(t)$ for various constant loads s = const. will have their inflection points I on the same horizontal line as indicated in the sketch Fig. 8. Thus the locus of the inflection points is a horizontal line. The shape of the time-elongation curves $\epsilon = f(t)$ might also be found by solving [5] for

$$v = \frac{d\epsilon}{dt} = v_0 \left[\frac{s(1 + \epsilon)}{\sigma_0}\left(\frac{\epsilon}{\epsilon_0}\right)^{-n}\right]^{-m} \quad \ldots\ldots [7]$$

and through a subsequent graphical integration of this last equation.

As far as the writer could check the interesting property expressed by [6] just derived from the power function law, Equation [1] is not verified in actual creep-elongation curves.

In the range of loads where these curves in tests have shown inflection points, the locus of these latter in the ϵ, t plot was found to be a curve which is first steeply inclined at the small values of t (at high loads) and which tends to approach rapidly the t = axis for decreasing loads.

It might finally be mentioned that the assuming of a power law as expressed by Equation [1] has also the other consequence that all the creep curves in Fig. 8 for various loads s = const. might be constructed from one of them by multiplying the abscissas (t) of one curve by a constant factor.

The result found by creep tests, that the inflection points hav-

[4] Research Laboratories, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

ing the coordinates ϵ_i, t_i (t_i being the time at which the minimum creep rate $v_{min.}$ is reached, ϵ_i the corresponding strain) of the various time-elongation curves $\epsilon = f(t)$ taken for constant load s = const., seem to lie on a curve $\epsilon_i = \phi(t_i)$, the ordinates ϵ_i of which decrease with increasing t_i, seems not to support the result derived from Equation [1] that all the creep or time-elongation curves $\epsilon = f(t)$ for given loads s = const. could be obtained from each other by stretching their abscissas t by constant amounts in the direction of the time axis.

S. R. PUFFER.[5] The author has shown very clearly the evil effects of slight increase in temperature and stress or in a combination of the two, when a long life with slight deformation at elevated temperatures is required. To insure such a long life requires an accurate knowledge, not only of the materials themselves, but of the maximum conditions of stress and temperature to which they will be subjected.

There are other applications with high stresses and temperatures where a life of 1000 or 2000 hours, or even less, is acceptable, but where the conditions of temperature and stress, or even the rate of plastic deformation, are either unknown or exceedingly hard to determine.

Such conditions are encountered in general in the internal-combustion-engine field, and more particularly in the supercharging of aircraft engines by means of exhaust-gas turbines. Temperatures, instead of being in the neighborhood of 850 F, may range between 1200 F and 1600 F, subject to change without notice. Stresses which are carefully figured for an agreed maximum condition are always uncertain, because these maximum conditions are continually being exceeded, either in an attempt to break some record, by the pilot's maneuvers, increased output of the engine, or other similar reason.

Under such conditions it has been necessary to base the selection of materials and the design features on test bars pulled at the usual testing-machine rate, but at temperatures which cover the operating range. The values obtained are of course not expected to be absolute values for the material, as at these temperatures the effect of creep is very decided. By making such tests on a number of materials, results can be obtained which, although not absolute, are comparable. The only possible choice is to select the material which gives the highest comparative figures, and then start to look for something better.

P. G. MCVETTY.[6] The author's further analysis of some of the test results reported by Messrs. Coffin and Swisher indicates the trend toward interpolation and extrapolation of creep-test data in order to make them more suitable for design use. The curves of Fig. 2 show graphically the extrapolation possible by use of the empirical formula proposed by Mr. Levine and based on four creep tests at 6000, 9000, 12,000, and 15,000 lb per sq in. extended over a total time of 1500 hr. In the published data, the maximum plastic extension was somewhat less than 0.7 per cent, so that the original test curves superimposed upon Fig. 2 would fall within an area less than 1 per cent of that shown. This is mentioned merely to emphasize the extent of extrapolation necessary to bridge the gap between the usual creep-test data and actual service conditions.

The author has shown a locus of points of inflection on the creep curves. In any extrapolation of creep data the approximate location of such inflection points is a matter of vital importance because of the danger of an increasing creep rate within the life of the material in service. From Fig. 2 we might conclude that a plastic extension or creep of at least 3 per cent at any stress less than 14,600 lb per sq in. would be necessary before the creep rate would begin to increase. This appears to give us assurance with an ample margin of safety that inflection points on the creep curves need not be considered in the region where high-temperature design is dictated by allowable distortion. Before accepting this assurance, it seems desirable to review the evidence which supports it.

It is well known that inflections do occur, but they did not appear in the curves upon which Mr. Levine's formula was based. This empirical formula, involving stress, total plastic extension, and time, fits the observed data very well up to 1500 hr, but its use to predict the locus of inflection points cannot be recommended without further experimental evidence.

Little is known about the laws governing the change from a decreasing to an increasing creep rate. It is usually assumed that the plastic extension associated with the early stages of the creep test produces a strain-hardening effect which increases the creep resistance, thereby decreasing the creep rate. During the test the annealing effect of time and temperature is cumulative, leading to softening of the strain-hardened material and an increasing creep rate. When these two opposing forces are balanced we have what appears to be a constant creep rate. At low stresses the change of creep rate is so gradual that it is very difficult to locate the inflection point.

We do have some data on the laws governing the softening of strain-hardened material. It is well known, for example, that the time at a given temperature to produce softening decreases as the amount of plastic extension increases. From this we would expect that an increase in the time at a given temperature would cause a decrease in the plastic extension necessary to start softening. The application of this reasoning to Fig. 2 indicates that the locus of inflection points should start at a high value of stress and plastic extension in a short time and occur at gradually decreasing values of plastic extension as time goes on. Tests at higher stresses appear to support this viewpoint rather than the one shown in Fig. 2.

If we adopt this more conservative prediction of the locus of inflection points, we must admit the possibility of such inflections in the region of low values of stress and plastic extension after very long time. In other words, the creep curve and the locus of inflection points approach each other with increasing time. We are not yet able to say whether or not they meet within the service life of the material, but the possibility of passing the inflection point under service conditions must be kept in mind in predicting the total creep.

The author leaves some uncertainty as to the source of data given in Fig. 3. If these curves represent actual creep tests at six stresses over times up to 4500 hr, they furnish a more reliable basis for the subsequent analysis than that resulting from the application of the Levine formula to the four tests previously mentioned. Another series of tests of this kind would offer a valuable check on the validity of this formula in the region of lower stresses and longer times.

The author has considered an important problem upon which we have very little experimental data. This is the case of constant extension while the initial stress is reduced by the action of creep. This "relaxation" problem is complicated by the flexibility of adjacent members in addition to the assumed change from elastic to plastic deformation in the bolts themselves. Perhaps it should be emphasized that in this problem we are not so much concerned with the instantaneous value of flow rate for a given combination of stress and extension as we are in the stress change. Following a horizontal line in Fig. 3 (constant plastic extension) shows that stress falls rapidly at first and more and more slowly as time goes on. In the actual case, the flexibility

[5] Thomson Research Laboratory, General Electric Company, West Lynn, Mass.

[6] Research Laboratories, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

and creep of adjacent members cause relaxation to proceed along some line other than that of constant plastic extension or constant sum of elastic and plastic extension. The importance of a quantitative solution of this problem indicates the desirability of further experimental work in this field. For such an investigation particular attention must be paid to the first stage of creep, for it is in this that maximum stress changes may be expected.

The author has made a valuable contribution to our knowledge of the analysis of test data for practical application. He has shown the importance of conducting tests under conditions approximating those of service. He has also shown the importance of keeping in mind the limitations of the original data in any subsequent applications. Our future progress in high-temperature design depends on our skill in combining the knowledge of the metallurgist, the designer, and the testing engineer to establish a reliable basis for choice of materials and working stresses.

Author's Closure

Dr. Nadai points out some very interesting facts about the formula proposed by the author for correction purposes. In making his extrapolation he is kind enough to acknowledge the limitation stated by the author. Adequate comment is made difficult by the lack of numerical scales for strain and time in Fig. 8, contributed by Dr. Nadai. However, Dr. Nadai's Equation [6] gives, for the material under discussion, a locus of inflection points at a strain of 40 per cent, which gives some gage as to the scale of his diagram. Now the author's formula was for limited use in the region covered by Fig. 3. Fig. 3 is contained in the hatched area at the bottom of Fig. 2 and in a region less than half the width of the black boundary line at the bottom of Fig. 8. As stated in the paper, the formula is wholly inadequate for the implied extrapolation.

Mr. McVetty points out the extent of the extrapolation in Fig. 2 of the previously published data. First, it is necessary to bear in mind that Fig. 2 was extended into a region of little interest purely for the purpose of defining how limited is the cross-hatched area of importance. In defense of the diagram it should be noted that subsequent to the publication of the Coffin and Swisher paper the tests were continued up to 5440 hr and 1.84 per cent extension, and at the end of that time the curves were still following Mr. Levine's formula based on the first 1000 hr of test. As a probable estimate of inflection points, the author preferred Mr. Levine's formula.

Dr. Nadai's idea as to the probable shape of the locus of inflection points with very large strains may be entirely correct, and Mr. McVetty's apprehensions as to inflection points with small strains may be warranted at much higher temperatures, but there are no inflection points in Fig. 3, which was prepared by cross-plotting from the actual Coffin and Swisher tests, extending over a longer time and to far higher strains than shown.

In answer to Major Bull's inquiry at the meeting, the composition of the material as given by Coffin and Swisher is repeated here for convenience: C, 0.31; Mn, 1.40; Si, 0.36. Heat treatment: 900 C, 6 hr, furnace cool; 850 C, 4 hr, furnace cool; 700 C, 4 hr, furnace cool.

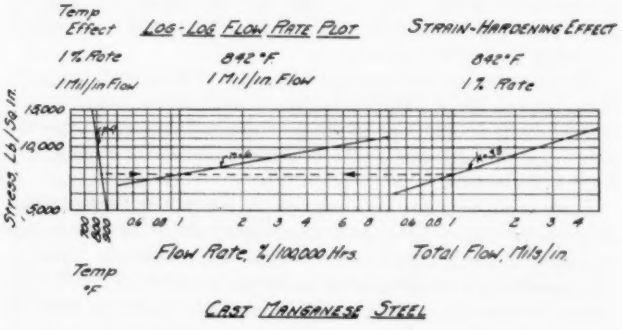

Fig. 9

In conclusion, Fig. 9 represents the author's correction formula and graphically portrays the triple dependence of flow rate on applied stress, temperature, and accumulated creep. In the middle is the usual log-log plot. At the left is given the temperature effect and at the right the strain-hardening effect. The use of such a diagram in preference to the formula will guard against unwarranted extrapolation. When test results are so plotted, deviations from the straight lines present to the eye the limitations of the data. And the diagram serves to bring out the different factors that must be recorded in order to describe the high-temperature performance of a material.

The New Theory of Plasticity, Strain Hardening, and Creep, and the Testing of the Inelastic Behavior of Metals

By H. HENCKY,[1] CAMBRIDGE, MASS.

The knowledge of the inelastic behavior of metals has experienced considerable growth in the last few years. To draw all the advantages possible from the experiments, frequently very difficult, an effort has been made to bring the entire development under some dominating physical ideas. These ideas are in fact very old, and deal mainly with the proper conception of the hidden elastic energy that is responsible for the statical component of the strain hardening. The analytical treatment of the inelastic behavior gives promise of being valuable not only in the testing of materials, but even for the designer of machines used in the forming of metals.

RECENT research work considering the problem of creep of materials at high temperatures has developed a secure basis on which the further experimental and theoretical study may proceed.[2] However, in the region of small strain velocities the experiment yields only erratic results and a theoretical extrapolation has to be made.[3] The aim of this paper is not to develop new ideas about plasticity, creep, and strain hardening, but to form a coherent picture and to extend the scope of the basic laws verified by experiment in such a manner that future experiments can be made under the guidance of a theory flexible enough to represent all phenomena of practical importance.

I—The Physical Facts Underlying the Behavior of Metals

It has been repeatedly emphasized that the postulates of the mathematical theories concerning the behavior of materials are not fulfilled. The engineer occupied with the testing of materials is especially likely to underestimate the value of theoretical research, which is not to the advantage of the increase of our knowledge. The reason for such prejudice is a misunderstanding of the meaning of mathematical theories.

The value of a mathematical theory is not that it gives a complete description of the behavior of any individual material, but that it furnishes a mental background against which the true behavior of a specimen can be distinguished and measured.

Theories are simply mental extensions of our physical instruments and have nothing to do with matter in itself. Every theory is developed by the mind, and therefore a theory can have practical value, but cannot be true in any absolute sense.

However, leading scientists and engineers have already recognized the valuable suggestions given by applied mechanics and mathematical physics and have tried to extend the classical theory of elasticity in order to reduce our knowledge of materials to physical constants which can be measured and defined free from individual arbitrariness.[4]

The mathematical theory must be based on the physical facts common to all plastic metals. The following facts have to be given consideration:

(1) All metals are polycrystalline substances. Stress and strain are defined only for such elementary particles as contain thousands of crystal grains. The true stresses at the grain boundaries we call microstresses and strains. The individual microstresses and strains cannot be measured at the time being, our instruments giving only statistical averages.

(2) Permanent set in the material can have two causes: The heat movement of the molecules in materials under stress can produce changes in the distance between points having a finite distance (thermal plasticity). The individual crystal grains can undergo finite deformations through sliding along certain planes (athermal plasticity).

(3) Plasticity in polycrystalline metals is always a mixture of thermal and athermal plasticity. However, for iron and steel especially, one can state that plasticity begins at a certain definite value of the intensity of stress. The intensity of stress is given by the following expression, where σ_1, σ_2, and σ_3 are the principal stresses and $\sigma = 1/3\ (\sigma_1 + \sigma_2 + \sigma_3)$ is the hydrostatic part of the stress:

$$\text{Intensity } \sigma_r = \sqrt{(\sigma_1 - \sigma)^2 + (\sigma_2 - \sigma)^2 + (\sigma_3 - \sigma)^2} \ldots [1]$$

The intensity is *essentially* a positive quantity and is independent of the intensity σ of the hydrostatic stress. The condition of plasticity is expressed by the equation:

$$|\sigma_r| = 2P = \text{constant}$$

---

[1] Associate Professor of Mechanics, Massachusetts Institute of Technology. Mem. A.S.M.E. Professor Hencky received the certificate of Civil Engineering from the Technical University of Munich (1908) and the degree of Doctor from the University of Darmstadt (1913). Before the war he spent a few years with the States Railways in Alsace-Lothringen in Strasbourg and in Russia. At the outbreak of the war he was taken prisoner in Charcow and was interned in the Ural district. Afterward he was a lecturer for three years in the Universities of Darmstadt and of Dresden and for eight years with the University of Delft, Holland, on applied mechanics. He has been with the Massachusetts Institute of Technology for three years.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] A number of practical problems has been treated by A. Nadai in his paper, "The Creep of Metals" (see footnote 2). Compare also, Gleason MacCullough, "Applications of Creep Tests," Trans. A.S.M.E., Applied Mechanics Division, July-September, 1933, vol. 1, no. 3, paper APM-55-12.

(4) At elevated temperatures the loaded material does not reach a static equilibrium, but shows a permanent creep. For high rates of strain an empirical formula is known, connecting strain velocity and stress. A workable theory of plasticity must embody this formula (as recommended by Nadai and Soderberg, loc. cit.).

(5) Just as we have the conception of active and passive earth pressure in the statics of loose masses, must we distinguish between the elastic-plastic system in the loading phase and the elastic-plastic system in the unloading phase. Practically only in the loading phase of a system can plasticity occur. The condition for loading is, with $\bar{\sigma}_r$ as the intensity of the microstresses:

$$\frac{d\bar{\sigma}_r}{dt} > 0; \quad \frac{d\sigma_r}{dt} = 0$$

The condition for unloading is:

$$\frac{d\sigma_r}{dt} < 0$$

We will see presently that it is possible to embody all these points in a mathematical theory which contains the classical theory as a special case and at the same time solves the problem of creep for small strain velocities without making arbitrary assumptions. Before we can give mathematical formulas we must explain what we should understand by the terms "stresses" and "microstresses."[6]

The macromechanical stress is the force acting on a small unit area consisting of the cross-sections of many hundreds of crystal grains. If we could measure the stress intensity in the individual grain, we would not find any constancy of the stress in passing from one crystal to another. Would it now have any practical meaning to introduce the true stress? Obviously not, because these individual stresses do not interest us very much. But the true elastic energy stored up in the body is of great interest to us because we have to pay for it an equivalent amount of mechanical energy.

The mechanical-energy equivalent connected with the average macromechanical stress is naturally smaller than the true elastic energy. However, we can now imagine a stress system $\bar{\sigma}_i$ ($i = 1, 2, 3$), which added to the system σ_i ($i = 1, 2, 3$) would yield just the amount of the true elastic energy. This system $\bar{\sigma}_i$ we will call the micro-stress system.

To help somewhat our imagination in handling these two systems, we assume each system to be connected with an elastic structure of its own and both structures as being forced to occupy the same space. Let us call these two structures the $\bar{\sigma}_i$ system and the $\bar{\sigma}_i$ system.

Assuming now for a moment that the $\bar{\sigma}_i$ system does not exist, we arrive at the classical theory of the ideally plastic body.

Denoting the principal strains by $\epsilon_1, \epsilon_2, \epsilon_3$, we can separate the change in volume by subtracting $\epsilon = 1/3(\epsilon_1 + \epsilon_2 + \epsilon_3)$, and get the pure deformation $\epsilon_i - \epsilon$ ($i = 1, 2, 3$).

In the elastic region, with $\sigma_r \leqq 2P$, we will have the law of Hooke in the form:

$$\sigma_i - \sigma = 2G(\epsilon_i - \epsilon) \ (i = 1, 2, 3) \ldots\ldots\ldots\ldots [2]$$

The strain is measured by the logarithm of the length after divided by the length before the deformation took place. The elastic law for changes of volume

$$\sigma = 3K\epsilon \ldots\ldots\ldots\ldots\ldots\ldots [2a]$$

remains the same in the elastic and in the plastic region. If $\sigma_r = 2P$, and we are loading the system further, we have to introduce the conception of intensity of strain:

$$\epsilon_r - \epsilon = \sqrt{(\epsilon_1 - \epsilon)^2 + (\epsilon_2 - \epsilon)^2 + (\epsilon_3 - \epsilon)^2} \ldots\ldots [2b]$$

giving the relation

$$\sigma_i - \sigma = 2P \frac{\epsilon_i - \epsilon}{\epsilon_r - \epsilon} \ (i = 1, 2, 3) \ldots\ldots\ldots\ldots [2c]$$

and satisfying the condition of plasticity $\sigma_r = 2P$.

The unloading of such a system proceeds always without further permanent set if the remaining stresses after unloading do not exceed the allowed stress intensity.

The difficulty with this ideally plastic body is that in loading a test piece the stress would be the same no matter with which velocity of strain we are performing the experiment above the elastic limit. Now the work done in straining the body must be transformed into heat vibrations, and this transformation takes time. Moreover, if we shorten that time, we must overcome the mass inertia of the molecules, which manifests itself in an entirely independent manner from the macromechanical mass accelerations taken care of in the fundamental equation of dynamics.

The ideally plastic body is therefore a statical possibility, but a dynamical impossibility. Moreover, as the metals have a grain structure, the true stress is discontinuous at the grain boundaries and a statical extra-resistance has to be accounted for. On account of the mathematical difficulties, we assume the simplest law possible for this hardening effect—namely:

$$\bar{\sigma}_i - \bar{\sigma} = 2H \ (\epsilon_i - \epsilon) \ldots\ldots\ldots\ldots\ldots [3a]$$

Accordingly we put $\bar{\sigma} = 0$. The total stress will be:

$$\sigma_i + \bar{\sigma}_i - \sigma = 2(G + H)(\epsilon_i - \epsilon) \ldots\ldots\ldots [3b]$$

It must be understood that the hardening effect exists *also in the elastic region*, but cannot be noticed there because the strain-hardening coefficient H is so small compared with G that even the fluctuations in the value of G are greater. We have now a two-phase system, or two elastic structures forced to the same deformations, only that one system ($\bar{\sigma}_i$) has, compared with the other (σ_i), a very small modulus of shear ($H \cong 10^{-3} G$). The σ_i system has the peculiarity that the stress intensity never can exceed a constant value $2P$. The stress intensity $\bar{\sigma}_r$ of the $\bar{\sigma}_i$ system is surely limited also, but at present we do not know much about those limitations. It is certain only that with increase of temperature a marked relaxation sets in. It is quite possible that a certain intensity of the microstress must be reached before relaxation begins. We shall come back to this point farther on.

Here we shall assume that relaxation immediately sets in, but only in the $\bar{\sigma}_i$ system. The σ_i system is not subject to any relaxation.

If we remember that the $\bar{\sigma}_i$ system is simply the representative of the elastic energy due to the discontinuities of the stress at the grain boundaries, we can understand that a mechanical energy concentrated on so small a space is likely to disintegrate into heat movement of the molecules and that this must happen so much more easily if the energy of the microstresses is bigger.

It is obvious that the Equation [3a] has to be replaced by another one introducing the disintegration of energy according to Maxwell:

$$\frac{d\bar{\sigma}_i}{dt} = 2H \cdot \frac{d(\epsilon_i - \epsilon)}{dt} - \frac{\bar{\sigma}_i}{T} \ldots\ldots\ldots\ldots [4]$$

Now if we want to embody the results of Deutler, Nadai, and Soderberg in our theory, we have only one choice for the relaxa-

[6] Compare, also, A. Nadai, "Plasticity," chaps. 25 and 38.

tion time T. It must depend on the intensity of stress in the $\bar{\sigma}_i$ body. We must have:

$$T = T_0 \frac{\omega|\bar{\sigma}_r|}{e^{\omega|\bar{\sigma}_r|} - 1} \quad [4a]$$

T_0 is the relaxation time for small values of ω, $1/\omega$ has the dimension of a stress and is a new important constant.

A simple model of such an elastic-plastic system would be a common iron test piece with a rubber skin glued to the surface. Plastic deformation of the inner test piece would be accompanied by elastic extension of the rubber skin.

On account of the big difference in the elastic moduli, the unloading would release only a small percentage of the stress in the rubber. If now we were using raw rubber, relaxation would come into play, and after some days the stress would have disappeared in the rubber also.

We see that the Equations [1] to [4] form a suitable and usable scheme for the study of the mechanics in the inelastic states of matter. Every new coefficient introduced has a clear mechanical meaning.

Equation [1] applied to different stress systems yields different numerical coefficients.

A number of interesting problems concerning power-press operations can be studied and the experimental work can be simplified considerably through the use of Equation [1].

II—Some Applications of the Equations of Plasticity and Creep

The material is considered incompressible. We are leaving out the indices for the stresses which must not lead to confusion with $\sigma = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3)$, the symbol of the hydrostatic part of the stresses.

(1) *The amount of mechanical energy needed to change the form of a test piece.*

Let us consider first the simple tensile and compression test. For the uniaxial strain we use the symbol λ. σ = stress. $\sigma_0 = \sqrt{3/2}\,P$ = the uniaxial limit of elastic stress.

Our equations simplify to $\sigma = 3G \cdot \lambda$, in the elastic region; $\sigma = \sigma_0 + \bar{\sigma}$, in the plastic region.

$$\frac{d\bar{\sigma}}{dt} = 3H \cdot \frac{d\lambda}{dt} - \frac{\bar{\sigma}}{T} \quad [1]$$

$$T = T_0 \frac{\omega|\bar{\sigma}|\sqrt{2/3}}{e^{\omega|\bar{\sigma}|\sqrt{2/3}} - 1} \quad [1a]$$

For the sake of simplicity we write simply ω instead of $\omega \cdot \sqrt{2/3}$, and obtain:

$$T = T_0 \frac{\omega|\bar{\sigma}|}{e^{\omega|\bar{\sigma}|} - 1} \quad [1b]$$

If one end of the test piece is fixed and the other moves with the speed v, this velocity cannot be constant if we wish to have stationary flow.

For stationary flow we have $d\bar{\sigma}/dt = 0$ and $d\lambda/dt$ = constant. With the length l_0 at time $t = 0$ and speed $v = v_0$, l at time t, and $v = dl/dt$, we get:

$$\frac{d\lambda}{dt} = \frac{d}{dt}(ln\,(l/l_0)) = \frac{dl}{dt} \cdot \frac{1}{l} = \frac{v}{l}$$

whereas $v_0/l_0 = v/l$

as a condition of stationary flow.

Combining [1] and [1b] and remembering that in formula [1b] the absolute value has to be introduced, we get:

$$\bar{\sigma} = \pm 1/\omega \cdot ln\,\{1 + 3H \cdot \omega \cdot v_0 \cdot T_0/h_0\} \quad [2]$$

where + = tension and — = compression.

The behavior of the material according to the assumed law of creep is perfectly symmetrical with respect to tension or compression, but the end of the test piece has to be accelerated in the case of tension and retarded in the case of compression in order to get v/l constant.

If F is the instantaneous cross-section, the work will be $W \cdot V = \int (\sigma_0 + \bar{\sigma}) \cdot F \cdot \delta l$, and with $F \cdot l = V$ = constant:

$$W = (\sigma_0 + 1/\omega\, ln\,[1 + 3H\omega v_0 T_0/h_0]) \cdot ln(l/l_0) \quad [3]$$

This equation can be used to define a measure of ductility. We take a constant amount of W and compare the corresponding strains. Applying the energy W in form of kinetic energy and solving Equation [1] for the case of impact, we get a measure of dynamic ductility or malleability.

In general we must emphasize that the use of any proportionality between stress and strain velocity is very objectionable. To prove that, we assume the simpler case of small ω. Maxwell's law is then:

$$\frac{d\bar{\sigma}}{dt} = 3H \cdot \frac{d\lambda}{dt} - \frac{\bar{\sigma}}{T_0} \quad [4]$$

Let us assume a velocity v is rapidly decreasing, so that $d\lambda/dt = v_0/l_0 \cdot e^{-t/T_0}$. Introducing this into [4], we have the equation to solve:

$$\frac{d\bar{\sigma}}{dt} + \frac{\bar{\sigma}}{T_0} = \frac{3H \cdot v_0}{l_0} e^{-t/T_0} \quad [4a]$$

and the solution is:

$$\bar{\sigma} = e^{-t/T_0}\left(\bar{\sigma}_0 + \frac{3H \cdot v_0}{l_0} \cdot t\right)$$

with $\bar{\sigma} = \bar{\sigma}_0$ for $t = 0$; or using the value of $d\lambda/dt$:

$$\bar{\sigma} = \left(\frac{\bar{\sigma}_0 v_0}{l_0} + 3Ht\right)\frac{d\lambda}{dt} \quad [4b]$$

In this formula we have the so-called coefficient of friction as a function of the time, showing clearly that in general a friction analogous to viscosity in liquids does not exist, if we assume relaxation.

To come back to our tensile and compression test in the plastic region, we would like to know if the law of friction as it is given for stationary flow in Equation [2] can be approximately applied even in case the speed does not satisfy the condition $v_0/l_0 = v/l$. Most of our testing machines are built so that the end of the test piece has a constant speed. In this case $l = l_0 + v_0 \cdot t$; $d\lambda/dt = v_0/l$; and $dl = v_0 \cdot dt$.

Introducing $x = l/v_0T_0$ as a new variable instead of t and $\bar{\sigma} = 3H\Sigma$ to extract the dimensional quantities, Equation [4] becomes:

$$\frac{d\Sigma}{dx} + \Sigma = \frac{1}{x} \quad [5]$$

The solution of this equation leads to a new function, the integral logarithm.[6] The symbol of this function is:

[6] Compare Jahnke-Emde, "Funktionentafeln," pp. 19–23, 1909.

$$Ei(x) = \int_{\infty}^{x} \frac{e^x}{x}\, dx$$

The solution of [5] gives:

$$\Sigma = e^{-x}\left[+ \frac{e^{+x_0}}{x_0} + Ei(x) - Ei(x_0)\right] \ldots\ldots [6a]$$

for tension, and:

$$\Sigma = e^{+x}\left[- \frac{e^{-x_0}}{x_0} + Ei(-x) - Ei(-x_0)\right] \ldots\ldots [6b]$$

for compression. Equation [2] would yield, with $\omega = 0$, $\sigma = 3H \cdot v_0 T_0/l$.

In the new notations therefore:

$$\Sigma = 1/x \ldots\ldots [6c]$$

For the sake of comparison we give the values of Σ corresponding to [6a], [6b], and [6c]; [6c] corresponds to the law of friction used in hydrodynamics:

Tension			Compression		
x	Σ [6a]	Σ [6c]	x	$-\Sigma$ [6b]	$-\Sigma$ [6c]
1.0	1.0	1.0	2.0	0.5	0.5
1.2	0.99	0.84	1.8	0.51	0.55
1.4	0.99	0.72	1.6	0.52	0.63
1.6	0.97	0.63	1.4	0.55	0.72
1.8	0.94	0.55	1.2	0.59	0.84
2.0	0.91	0.50	1.0	0.65	1.00

The comparison shows the deviations from the fluid viscosity very strongly. Naturally for higher values of x, [6a] and [6b] merge asymptotically into $1/x$. But only for values $x \geqq 17$ equality is reached approximately.

The use of $1/x$ would lead to calculations of the amount of work which would be too small for tension and too large for compression, whereas the use of our equations would yield results comparable with the experiment and therefore also suggesting new experiments.

As the relaxation time depends on the intensity of stress, the stress must be applied in as concentrated a form as possible so as to get the greatest effect with the smallest amount of energy. This is also the reason why in rolling mills of more recent construction small cylinders are used in direct contact with the plastic material. To hinder any bending, these rollers are backed up by bigger ones. It is true that the rolling-mill experts have found out these things without the direct aid of the mathematical theory, but this shows only that a number of improvements could be made even in the manufacturing processes by determined application of the laws of plasticity and creep.

(2) *The tensile test with metal wires.*

Developing a mathematical theory of plastic deformation means the amassing of a great amount of information, considering even such a trivial thing as a simple tensile test.

We want now to find out what happens if we load a wire so that the plasticity limit is surely passed by the stress when we then leave the wire to itself, with the load hanging on.

There is a dynamical problem involved also, because of the mass acceleration of the load, but on account of the slow movement we can neglect this influence.

We have in the elastic region, as before

$$\sigma = 3G \cdot \lambda \ldots\ldots [1]$$

and at the same time the hardening stresses

$$\bar{\sigma} = 3H \cdot \lambda \ldots\ldots [2]$$

and the total stress $\sigma + \bar{\sigma} = 3(G + H) \cdot \lambda$ in the elastic region. After having passed the plasticity limit, we have the stress $\sigma_0 + \bar{\sigma} = \sigma_0 + 3H \cdot \lambda$ up to a certain critical intensity of the hardening stress $\bar{\sigma}'$. If that stress is passed also, relaxation sets in.

With $\bar{\sigma}'$ as this limit, the law of relaxation will be expressed by

$$\frac{d\bar{\sigma}}{dt} = 3H \cdot \frac{d\lambda}{dt} - \frac{\bar{\sigma} - \bar{\sigma}'}{T} \ldots\ldots [3]$$

$$T = T_0 \frac{\omega|\bar{\sigma}|}{e^{\omega|\bar{\sigma}|} - 1} \ldots\ldots [3a]$$

The introduction of a limiting intensity of the hardening stresses is hypothetical and has to be justified. But this can be done easily. All elastic constants are functions of the temperature, and we know that temperature is only an indirect manner of measuring the vibrational energy of the molecules. But we have seen that the stress intensity of the hardening stresses is likewise only an equivalent to the elastic energy of these microstresses. The mechanical energy on its way to disintegrate into heat can assume an intermediate level in the form of elastic microenergy. In relation to macromechanical energy, this elastic energy of the microstresses in the grain boundaries comes into account only statistically, and *the intensity of these stresses* as defined by us *is a scalar quantity of the same character as the temperature.* Physically, our stress intensity is a sort of "cold" temperature. As quite a considerable amount of energy is, in solid bodies, frozen in in the form of elastic energy, we cannot build up the mechanics of the inelastic state without these two parameters—the temperature and the stress intensity.

But let us come back to our example. The problem is properly a two-dimensional one, because λ is a function of the place as well as of the time; but in stretching the wire under a constant load, we have with F as instantaneous cross-section $F(\sigma_0 + \bar{\sigma}) =$ constant; therefore, differentiating, we get:

$$(\sigma_0 + \bar{\sigma})\ \delta F + F \cdot \delta\bar{\sigma} = 0$$

But because of the incompressibility of the material assumed

$$\delta(F \cdot l) = F \cdot \delta l + l \cdot \delta F = 0$$

Combining these two equations gives

$$\delta\bar{\sigma} = (\sigma_0 + \bar{\sigma}) \cdot \delta l/l = (\sigma_0 + \bar{\sigma}) \cdot \delta\lambda \ldots\ldots [4]$$

and after integration

$$\sigma_0 + \bar{\sigma} = (\sigma_0 + \bar{\sigma}_0)e^{\lambda - \lambda_0} \ldots\ldots [4a]$$

where

$$\lambda_0 = \frac{\sigma_0 + \bar{\sigma}_0}{3(G + H)} \cong \frac{\sigma_0}{3G} \ldots\ldots [4b]$$

Introducing [4] into Equation [3], we get an important relation which allows us to calculate a limiting strain. If this strain limit is reached, the wire will no longer elongate uniformly, but will show a sudden reduction in cross-section somewhere, and will break.

The combination of [4] and [3] yields

$$\frac{d\bar{\sigma}}{dt} = \frac{(\bar{\sigma} - \bar{\sigma}')(\sigma_0 + \bar{\sigma})}{T \cdot [3H - (\sigma_0 + \bar{\sigma})]} \ldots\ldots [5]$$

This equation is meaningless for $\bar{\sigma} < \bar{\sigma}'$, but if this limit is passed, the increase in stress becomes infinite for

$$3H = \sigma_0 + \bar{\sigma} = (\sigma_0 + \bar{\sigma}_0)e^{\lambda - \lambda_0} \text{ (using [4a])} \ldots\ldots [5a]$$

or

$$e^{\lambda} = e^{\lambda_0} \cdot \frac{3H}{\sigma_0 + \bar{\sigma}_0} \cong 3H/\sigma_0 \ldots\ldots\ldots\ldots [5b]$$

The critical strain is therefore independent of the speed $\lambda_{critical} = ln(3H/\sigma_0)$.

The strain reached until reduction of the cross-section sets in allows us to calculate H if σ_0 is known. We see that under all circumstances $3H > \sigma_0$.

The integral of Equation [3] can be expressed by a series of integral logarithms, but it is simpler to use numerical integration.

The critical stress $\bar{\sigma}'$ can be found by precise measurements of the creep rate, which has to be zero at this limit.

The only hypothetical part in our theory is the assumption of the same law of elasticity for the microstresses as for the elastic stresses. But even if we shall find here any deviation, we shall nevertheless continue to use the linear law. Even so, the mathematical difficulties of space problems are enough.

(3) *The moving of a cylinder in a plastic mass and the depth to which the zone of plastic deformation can penetrate.*

The depth to which the zone of plasticity can penetrate is important for the design of manufacturing machines for metal forming. The limiting surface between the plastic and the elastic region is weaker than the elastically strained part, and the forming of such surfaces of separation must be restricted as much as possible. In the extruding of metals we would have dead corners for the plastic movement, mostly there where we would have eddies in the case of a fluid.

A great aid for the solution of plastic-flow problems is that the flow lines can be calculated as if we had a viscous liquid. Only for the relations between stress strain and strain velocity the laws of viscous fluids are not applicable. In general, one cannot treat in Euler coordinates the movement of a plastic-elastic body, because the elastic energy is connected with the moving mass and not with the space element at which it happens to be for a moment.

However, the case of a cylinder moving in a plastic mass is an exception and can be treated by classical methods, because the flow lines are circles and the deformation is constant along such a circle.

Let us assume $-\tau_0$ as the limiting shearing force of the plastic material and $\bar{\tau}$ as the strain-hardening influence. The equation of equilibrium alone determines the stress distribution. It becomes, using polar-coordinates:

$$\frac{d(-\tau_0 + \bar{\tau})}{dt} - \tau_0 + \bar{\tau} = 0 \ldots\ldots\ldots\ldots [1]$$

We shall denote with
a = radius of cylinder
r = radius of an element
r_0 = radius of the boundary between the elastic and the plastic part.

Putting $r = a \cdot \rho$ to concentrate the dimensional quantities, we get the solution:

$$\bar{\tau} = -\tau_0 [(\rho_0/\rho)^2 - 1] \ldots\ldots\ldots\ldots [2]$$

ρ_0 is unknown and can be found only when the formula for the velocity is established. The only velocity which a point can have is perpendicular to the radius. With v as velocity at r and v_a at $r = a$, we get the strain velocity

$$\gamma = \frac{dv}{dr} - \frac{v}{r} \ldots\ldots\ldots\ldots [3]$$

and for stationary flow from $\frac{d\bar{\tau}}{dt} = G \cdot \gamma - \frac{\bar{\tau}}{T}$, with $\frac{d\bar{\tau}}{dt} = 0$:

$$\bar{\tau} = GT \cdot \gamma \ldots\ldots\ldots\ldots [4]$$

where

$$T = T_0 \frac{\omega|\bar{\tau}|\sqrt{2}}{e^{\omega|\bar{\tau}|\sqrt{2}} - 1} \ldots\ldots\ldots\ldots [4a]$$

Combining [2], [3], [4], and [4a], we get the differential equation:

$$\frac{dv}{d\rho} - \frac{v}{\rho} = -\frac{a}{G\omega T_0\sqrt{2}} \left(e^{\tau_0\omega\sqrt{2}\left[\left(\frac{\rho_0}{\rho}\right)^2 - 1\right]} - 1 \right) \ldots [5]$$

The solution is given by

$$v = \rho \left[v_a - \frac{a}{G\omega \cdot T_0 \cdot \sqrt{2}} \int_1^{\rho} (e^{\omega\tau_0\sqrt{2}((\rho_0/\rho)^2 - 1)} - 1) \frac{d\rho}{\rho} \right]. [5a]$$

We see immediately that the condition $v = v_a$ is fulfilled for $\rho = 1$. The integral can easily be reduced to the integral logarithm.

Denoting again with $Ei(y)$ the integral $\int_{\infty}^{y} e^y \frac{dy}{y}$, we get the solution of [5a] in the form:

$$v = a\rho \left(\frac{v_a}{a} + \frac{ln\,\rho}{G \cdot \omega \cdot T_0\sqrt{2}} - \frac{e^{-\omega\tau_0\sqrt{2}}}{2G\omega T_0\sqrt{2}} \left[Ei(\beta) - Ei\left(\frac{\beta}{\rho^2}\right) \right] \right)$$

$$\beta = \omega\tau_0\sqrt{2}\rho_0^2 \ldots\ldots [6]$$

For $\rho = \rho_0$, we get an equation in which ρ_0 is the only unknown quantity:

$$\frac{Ei(\omega\tau_0\sqrt{2}\rho_0^2) - Ei(\omega\tau_0\sqrt{2})}{2e^{\omega\tau_0\sqrt{2}}} - ln\,\rho_0 = \frac{v_a}{a} \cdot T_0\omega G \cdot \sqrt{2} \ldots [7]$$

For large values of $\omega\tau_0\sqrt{2}$, it is comparatively easy to solve this transcendental equation numerically. For instance, for $\omega\tau_0\sqrt{2} = 20$, $\frac{v_a}{a} T_0\omega G\sqrt{2} = 1000$, we get $\rho_0 = 1.22$.

Amplitudes of Non-Harmonic Vibrations[1]

By J. P. DEN HARTOG,[2] CAMBRIDGE, MASS.

IN THE usual theory of the vibration of an undamped single-mass system, the spring is assumed to have a linear characteristic, i.e., the force-deflection diagram is represented by a straight line through the origin. It is known that the free as well as the forced vibrations of such a system can be completely calculated in all detail. This is entirely different when the spring characteristic ceases to be linear. Then only the *free* vibrations of the system can be determined for a given starting condition by a process of graphical or numerical calculation. Though this is rather complicated and generally requires a considerable amount of work, at least the solution can be obtained with any desired degree of accuracy, according to the simple rule "the more work, the greater accuracy."

The results thus found are by no means as general as those for the case of linear springs, because the natural frequency comes out to be dependent on the amplitude. Moreover, the principle of superposition ceases to be valid, so that each particular case has to be solved by itself.

When steady-state *forced* vibrations are considered, the situation becomes even worse. Here not only is there no superposition, but even the golden rule of "the more work, the greater accuracy" is no longer true. An approximate solution exists, originated by Martienssen, on the analogous electrical problem of the alternating current in a circuit containing a condenser and an iron-cored inductance in series. This solution was later applied to mechanical problems by Duffing and by Rüdenberg. For the special cases of spring characteristics represented by an ordinary or by a cubic parabola, Duffing in his book gives a method whereby this result can be improved by successive approximations. An exact solution was obtained by S. J. Mikina and the author for spring characteristics made up of three sections of straight lines. For that case (the only one for which an exact solution exists so far) a comparison was made with the approximation of Martienssen, showing that under unfavorable circumstances this approximation may be 75 per cent off or more.

In this paper it is pointed out that Martienssen's original graphical solution follows a somewhat arbitrary procedure in that he satisfies only the condition of equilibrium between the various forces at the end of the stroke and thus necessarily violates other conditions. The solution can be modified by satisfying some other condition—for instance, the energy relation during a quarter cycle of the motion. When this is done the condition of equilibrium at the end of the stroke is violated. This "quarter cycle energy method" gives results which are no better than those of the Martienssen solution.

Another graphical solution has been worked out whereby two conditions are satisfied simultaneously. These two were chosen to be the equilibrium of the forces at the end of the stroke ($\omega t = 90°$) and also at another point somewhere between the neutral middle position and the end of the stroke ($\omega t = 60°$). This method naturally gives results which are considerably more accurate than those of Martienssen. They can be obtained by a rather simple graphical construction described in the paper.

The numerical results of the various methods are compared with each other for the case of the broken-straight-line characteristic for which the exact solution is available.

Stress-Concentration Phenomena in Fatigue of Metals

By R. E. PETERSON,* EAST PITTSBURGH, PA.

This paper consists of two parts: (I) General Considerations, which is a brief review of available data on the effect of holes, fillets, grooves, etc., on endurance strength; and (II) Some Observations Concerning Fatigue Fractures, wherein notes on crack propagation as related to stress-concentration phenomena are presented.

THE effect of stress concentration[1] on the endurance of metals subjected to alternating stresses is of importance to engineers, since stress concentrations are invariably present in machines owing to fillets, grooves, holes, threads, keyways, etc., in their parts. It is proposed in this paper, first, to review briefly some of the significant results of value to the engineer and, second, to present certain observations concerning fatigue fractures. The paper deals primarily with the rotating-beam fatigue test (alternating bending), but one section is devoted to alternating torsion tests.

I—GENERAL CONSIDERATIONS

1—Terminology[2]

In mathematical analyses of stress concentration based on the theory of elasticity, the results are usually stated in terms of a "theoretical stress-concentration factor"

$$K = \frac{\text{maximum stress}}{\text{average nominal stress}}$$

(The average nominal stress $S_n = P/a$ = load/net area, or in bending, $S_n = M/(I/c)$ = moment/net section modulus.)

Similarly, the results of fatigue tests of fillets, holes, grooves, etc., are stated in terms of a "fatigue stress-concentration factor"

$$k = \frac{S_e}{S_e'} = \frac{\text{ordinary endurance limit (without stress concentration)}}{\text{endurance limit with stress-concentration effect (fillet, hole, etc.)}}$$

Sometimes it is of value to express the percent decrease (c) of endurance strength due to stress concentration.

$$c = \frac{S_e - S_e'}{S_e} \times 100$$

It is apparent that $c = (1 - 1/k)100$. As a measure of fatigue stress-concentration effect in comparison with the corresponding theoretical value, a "stress-concentration index" may be used:

$$q = \frac{k - 1}{K - 1}$$

The value of q ranges from zero (when $k = 1.0$, as for certain tests of cast iron) to unity (should the fatigue stress-concentration factor k attain the theoretical value K; up to the present, however, no cases of this seem to be on record).

2—Material as a Variable

While theoretical stress-concentration factors are independent of the material (in so far as it conforms to Hooke's law), test data show that fatigue stress-concentration factors (k) are *not*. Although insufficient data are available at present, it seems that the variation of k for similar test pieces of different materials cannot be correlated completely with any of the ordinary properties of materials, such as ductility,[3] hardness, etc. For steels a possible relation exists between fatigue stress-concentration factors and ultimate strength. Fig. 1 shows the variation of k for a variety of steels of different ultimate strengths, all specimens having a 60-deg sharp groove 0.1 mm deep.[4] A similar relation is indicated by Fig. 2. Tests of cast iron have shown little or no fatigue stress-concentration effect,[5] the reason apparently being that the flakes and pores inherent in cast iron produce considerable stress concentration so that the effect of an imposed discontinuity is largely masked. It has been suggested that materials having small stress-concentration effect in fatigue are also materials having large internal damping,[6] and vice versa.

3—Effect of Size of Discontinuity

If the material and size of a specimen are kept constant and the size of a discontinuity (such as a hole) is varied, theoretical stress-

* Manager, Mechanics Division, Westinghouse Research Laboratories. Assoc-Mem. A.S.M.E. Mr. Peterson received his B.S. in mechanical engineering from the University of Illinois in 1925, and one year later his M.S. in theoretical and applied mechanics from the same institution. In September, 1926, he entered the employ of the Westinghouse Company in the railway-motor engineering department, and in January, 1928, was transferred to the research department. During 1926–1929 he also was part-time instructor in analytical mechanics and strength of materials at Carnegie Institute of Technology. In 1930 he was made section engineer in charge of strength of materials, Westinghouse Research Laboratories, and in 1931 was appointed to his present position.

[1] For general discussions of stress concentration see Timoshenko, "Strength of Materials," vol. ii, chap. vi (Van Nostrand); also Seely, "Advanced Mechanics of Materials," part iii (McGraw-Hill).

[2] The German investigators use expressions corresponding to those mentioned in this section. *Formziffer* (α_k) is the same as "theoretical stress-concentration factor" (K); *Kerbwirkungszahl* (β_k) corresponds to "fatigue stress-concentration factor" (k); and *Kerbempfindlichkeit* is equivalent to "stress-concentration index" (q). See, for instance, Thum and Buchmann, "Dauerfestigkeit und Konstruktion" V.D.I. Verlag (1932).

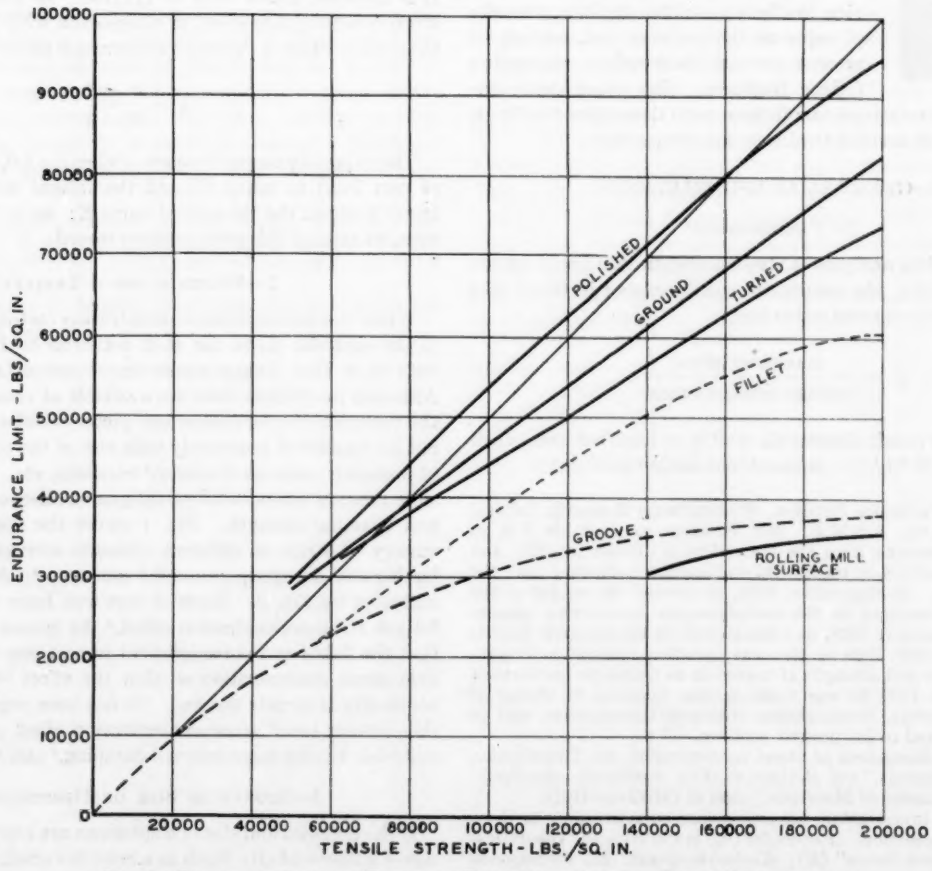

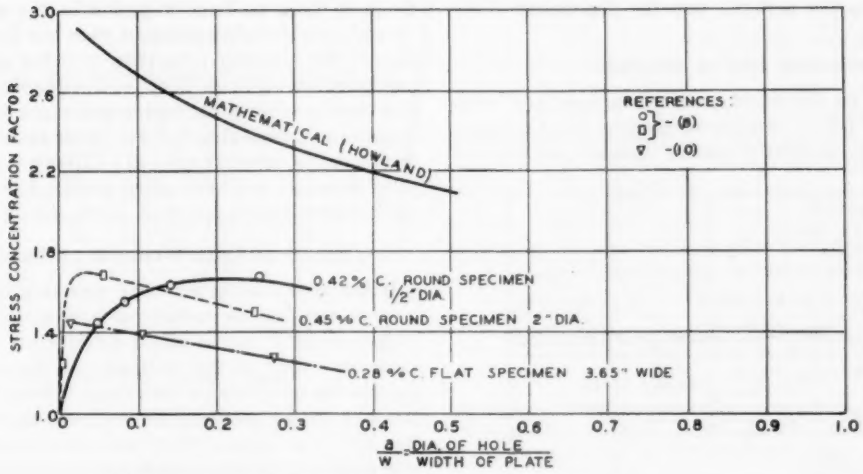

FIG. 2 EFFECT OF SURFACE FINISH ON ENDURANCE LIMIT OF STEEL SPECIMENS

concentration factors[7] increase as the size decreases. [Fig. 3(*a*).] Fatigue stress-concentration factors[8,9] show a similar tendency except for a marked decrease for very small discontinuities (but not necessarily small values of a/w). This is shown by plotting the data of Fig. 3(*a*) in terms of size of hole, as in Fig. 3(*b*). The upper curves of Fig. 3(*b*), representing data obtained with rotat-

(b) PLOTTED IN TERMS OF HOLE DIAMETER

FIG. 3 STRESS-CONCENTRATION FACTORS FOR HOLES

ing cantilever specimens of about the same material, indicate that for very small holes the fatigue stress-concentration factor may depend on the hole diameter regardless of the specimen size (except for very small specimens, since a/w must also be small).

Curves of fatigue stress-concentration factors for specimens having grooves tend also to have the same general form as the curve of theoretical factors.[10] However, as in the case of hole tests, the fatigue stress-concentration factors tend to approach unity for small grooves, the limiting case being fine scratches, which do not alter the endurance limit nearly as much as do deeper grooves.[11] (See also Fig. 1.) Different degrees of cold work due to the machining of different-sized discontinuities may be an important variable affecting the results, particularly in the case of small discontinuities.

Corresponding data for fillets are shown in Fig. 4. Here again the fatigue stress-concentration factors[8,12,13,14] follow the same tendency as the theoretical (photoelastic) stress-concentration factors,[15] although the former are lower than the latter. In general, it can be stated that fatigue stress-concentration factors are lower than theoretical stress-concentration factors, the devia-

tion depending upon the material and the dimensions of the specimen.

4—Effect of Size of Specimen

Fatigue-test data on size effect are very meager, and much remains to be done before definite conclusions can be drawn. In a few tests of geometrically similar fatigue specimens of different sizes, no large variation in the endurance limit was found[16] provided the specimens were free from stress concentration at the breaking zone (Fig. 5). For geometrically similar specimens having holes, fillets, and artificial cracks, it was found[17] that small specimens had higher endurance limits (lower values of k) than large ones (Figs. 6, 7, 8). Here again the cold work of the machining process may enter as a variable. A discussion of other possible causes has been given previously.[17] As stated before, further investigation is needed on the size-effect problem.

(0.45 per cent C steel.)

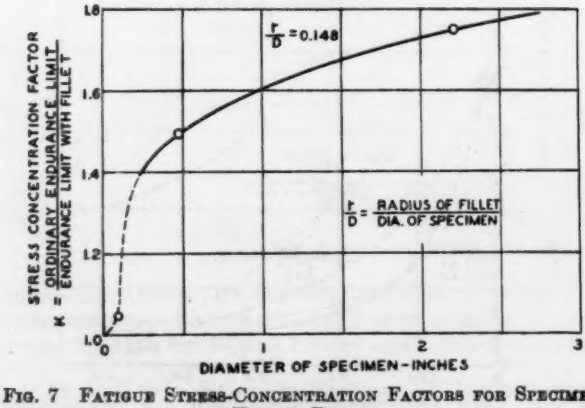

Fig. 7 Fatigue Stress-Concentration Factors for Specimens Having Fillets
(0.57 per cent C steel, heat treated.)

5—Effect of Cold Working on Fatigue Properties

It has been demonstrated by several investigators[18,19,20] that by cold working the surfaces of fatigue specimens the ordinary endurance limit can be raised considerably (as much as 30 per cent, depending on the material and degree of working). An indentation made with a center punch (conical end) into the surface of a fatigue specimen did not lower the endurance limit, the fracture occurring away from the indentation.[20] A hole of similar size made with a countersink reamer (conical end) reduced the endurance limit considerably (21 to 35 per cent, depending on the material). In the former case considerable plastic deformation took place. Apparently the beneficial effect of cold working is also operative in cases where stress concentration is present.

screw threads as compared with specimens having a single groove of screw-thread form.[3]

Rotating-beam fatigue tests of specimens with keyways[21] have shown higher strength for sled-runner keyways (cut with an ordinary milling cutter of same width as keyway) than for profiled keyways (cut with an end mill of same diameter as width of keyway). In these tests failure occurred at the end of the keyway.

Data are needed on the fatigue occurring at the edges of fitted members, such as at gear and pulley hubs. A general investigation of fatigue phenomena occurring in press fits would be of considerable value.

7—Alternating-Torsion Fatigue Tests

Tests have shown that the ratio of the endurance limits of ordinary specimens (no stress concentration) in alternating bending and alternating torsion is substantially the same in the case of fillet specimens.[22] These results seem to indicate that for certain cases the stress-concentration factors may be the same in bending and in torsion.

Tests have been made of model crankshafts in alternating torsion.[23] The effect of holes and fillets on the torsional endurance limit has also been investigated.[20]

8—Data and General Remarks

In addition to the data presented in Figs. 1–7, further fatigue stress-concentration factors are given in Tables 1–4. Additional references covering these data are given below.[24–34]

The notations used in Tables 1–4 are those discussed in Sec. 1 (Terminology). It will be noted that in all cases the stress-concentration index (q) is less than unity, i.e., fatigue stress-concentration factors are less than the corresponding theoretical stress-concentration factors.

It is clear that much work, practically of routine character, remains to be done before satisfactory systematic data for design purposes will be available. Further investigations must also be made of certain problems of fundamental character, as indicated by the indefiniteness of some of the conclusions of the foregoing sections.

II—SOME OBSERVATIONS CONCERNING FATIGUE FRACTURES

1—Effect of Stress Concentration on Mode of Failure

The examination of a large number of specimens broken in fatigue tests has led to some rather interesting observations concerning the appearance of the fracture. In ordinary fatigue specimens where stress-concentration effects are not present, the crack usually begins at one place and progresses across the speci-

men, so that the area of final rupture has a segmental appearance (Fig. 9). If, however, a stress-concentration effect is present (such as, for instance, in a specimen having a small fillet or

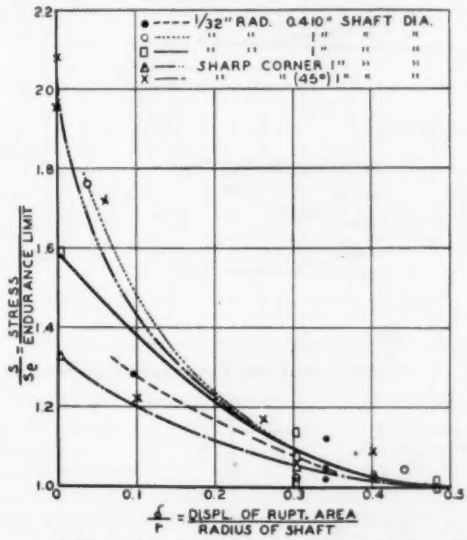

FIG. 11 SHIFT OF RUPTURE AREA AS A FUNCTION OF STRESS
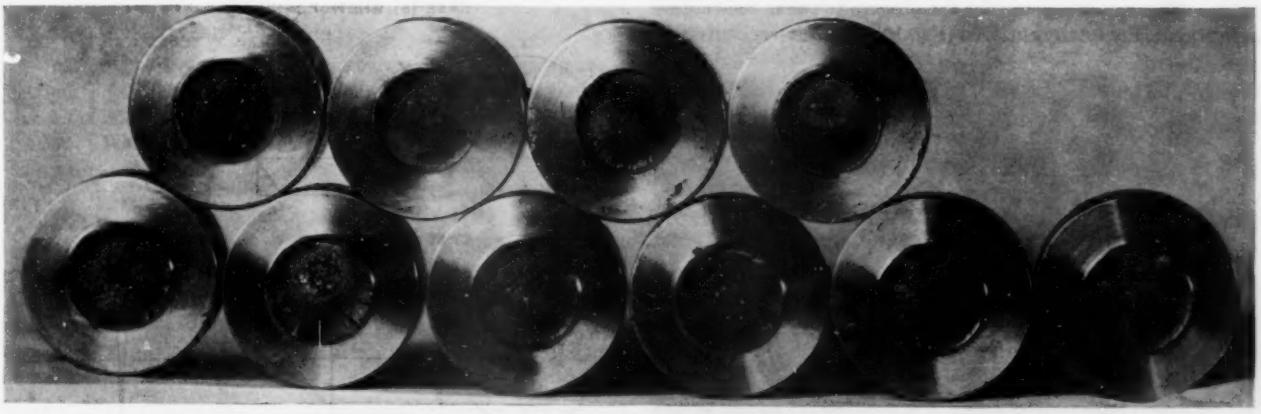
(0.20 per cent C steel specimens.)

fatigue strength of individual grains might be such as represented schematically in Fig. 13(*b*). At a high stress the condition corresponding to (*S'*) could exist, and if stress concentration is present, as in Fig. 13(*a*), failure would be localized in one plane and would progress from all around the periphery and finally rupture with a concentric area, as in Fig. 10(*b*).

Initial failure at many points is evidenced by the presence of radial ridges, called "beach marks" by several fatigue investigators.[34] These radial ridges are formed by the initial cracked portions meeting each other as the test progresses. [Fig. 10(*b*).] Such markings are not likely to occur in specimens uniformly stressed (no stress concentration) since it is improbable that the weakest grains would be located in the same transverse section. "Beach marks" together with a concentric rupture area are generally characteristic of relatively high stress and stress concentration.

Even in the case of severe stress concentration (such as due to a small fillet), the different cracks do not all follow exactly the plane of highest stress, or there would be no steps as evidenced by "beach marks." Several possible explanations can be offered. First, if a cantilever specimen having a fillet be considered, the stress may not vary greatly over a portion of a fillet, since the increase in diameter (causing decrease of stress) can be partly offset by the increase in moment arm (causing increase of stress). Second, cracks might start in adjacent scratches and, in joining, cause beach marks to form.[4] Third, it has been observed that in



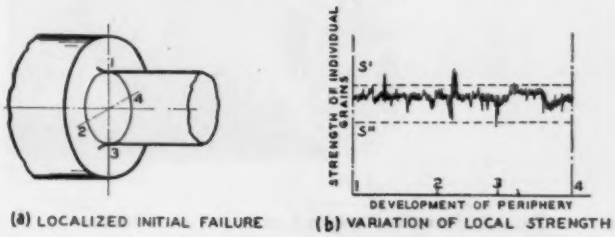


FIG. 12 SHIFT OF RUPTURE AREA
(0.20 per cent C steel.)
(UPPER ROW: Sharp-cornered specimens; stresses, respectively, 19,200, 15,200, 14,900, and 14,000 lb per sq in., reading from left.
LOWER ROW: Fillet radius 1/32 in.; stresses, respectively, 23,800, 17,100, 16,200, 15,100, and 14,900 lb per sq in., reading from left.)

groove), the rupture area will generally be totally enclosed and within the boundary of the cross-section (Fig. 10). The position of the rupture area within the cross-section seems in general to vary with the stress, being centrally located for high stresses and displaced from the center as the stresses are decreased toward the endurance limit.[35] In Fig. 11 are shown data for a low-carbon steel. The shift of the rupture area was also apparent in tests of copper and of chrome-nickel-steel specimens. A medium-carbon steel showed similar results, although not as clearly. A heat-treated carbon steel showed erratic results with respect to this type of measurement.

Fig. 12 shows a series of fractures of low-carbon-steel specimens (sharp corner and 1/32 in. radius). The displacement of the rupture area as related to the applied stress and the degree of stress concentration might be explained as follows: The variation in

(a) LOCALIZED INITIAL FAILURE (b) VARIATION OF LOCAL STRENGTH

FIG. 13

cantilever specimens cracks progress around the periphery in a helical manner. In Fig. 14, reproduced from a previous publica-

[35] A similar observation was made by Dr. J. A. Goff, of the University of Illinois, a number of years ago.

[36] After the manuscript of this paper had been prepared, Professor Bacon, of Swansea, England, sent the author a preprint copy of "Cracking and Fracture in Rotary Bending Tests" to be published in *Engineering* (London). Professor Bacon uses the term "ratchet-faced fracture" to denote what is here called a "beach-marked" surface.

tion,[37] cracks started at each of the holes and progressed helically until they joined midway between the holes, where the outer crack curved in abruptly to meet the inner crack. The helical movement evidently depends on the lateral curvature of the cantilever specimen, due to internal friction.[38] Since the direction of lateral curvature depends on the direction of rotation, the helix should change from right hand to left hand (using screw rotation) with a change of direction of rotation. Experiments have shown this to be the case.[39]

The foregoing remarks have been concerned with a case in which the stress is relatively high. At a lower stress, say, slightly above the "endurance strength of the specimen," a condition corresponding to S'' in Fig. 13(b) could exist, so that failure starts at one place and progresses slowly around the periphery and across the section simultaneously, resulting in a displaced rupture area. In this case the appearance of the displaced rupture area [Fig. 9 or 10(a)] depends on whether or not stress concentration due to form of specimen is present.

If stress concentration is present, the ratio of the rate of crack growth around the periphery as compared with the rate of crack penetration across the section will be higher than if stress concentration is not present, because of the difference in stress fields as shown in Fig. 15. The diagrams of constant-stress lines [Fig. 15(b, d)] represent the original stress fields (not the progress of the crack). It seems reasonable that a stress field such as Fig. 15(d) would be more conducive to relatively rapid crack growth around the periphery than would a stress field such as in Fig. 15(b). This would account for the observation that the rupture area is generally totally enclosed (Fig. 10) for stress-concentration specimens; and is of segmental form for specimens without stress concentration.

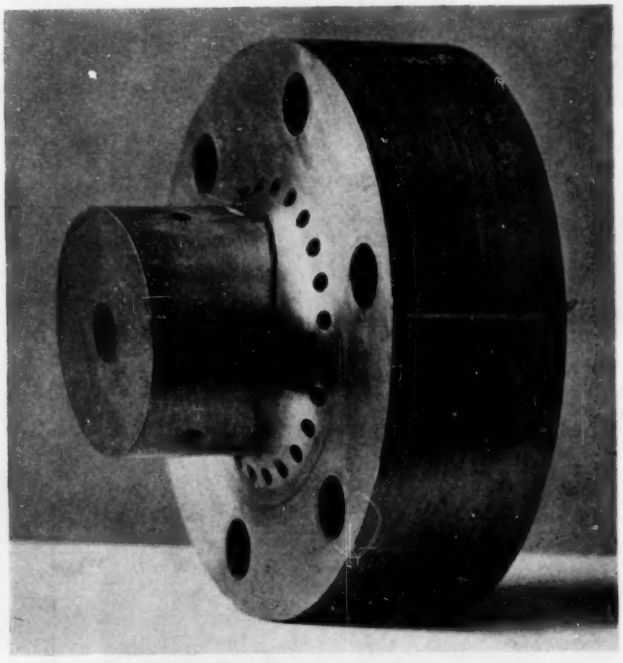

FIG. 14 HELICAL FATIGUE CRACK IN ROTOR MODEL

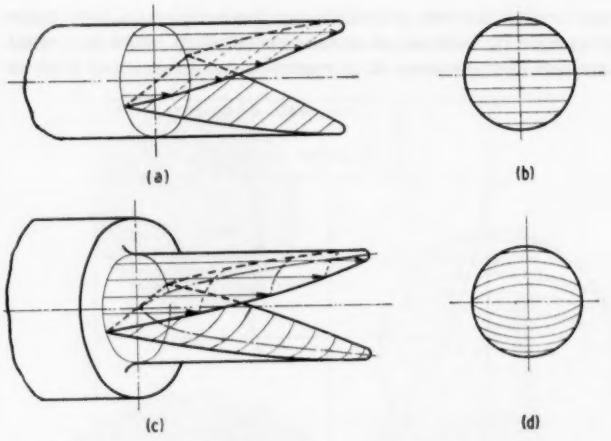

FIG. 15 STRESS FIELDS FOR ROTATING-BEAM SPECIMENS

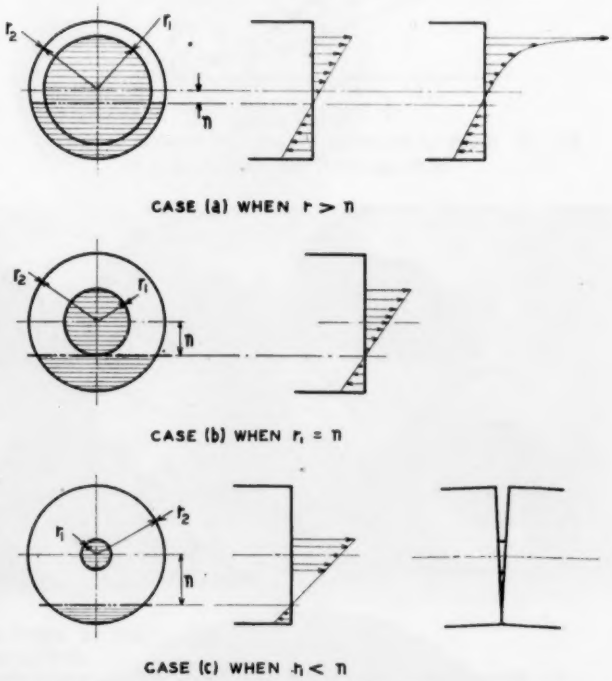

FIG. 16 STRESS DISTRIBUTION FOR CONCENTRICALLY CRACKED SPECIMENS

In connection with the latter type of failure mentioned in the foregoing, a mathematical analysis[40] has been made of the shape of the bottom of the crack at different stages of penetration. It was concluded that the bottom of the crack during penetration tended to conform to a series of elliptic curves.[41] The analysis should be carried further, and should include conditions at the rupture stage and also take account of the cracked area carrying compressive stresses.

[37] Peterson, R. E., "Fatigue Tests of Model-Turbo-Generator Rotors," *Mechanical Engineering*, vol. 53 (1931), p. 211.

[38] Mason, W., "Mechanics of the Wöhler Rotating Bar Fatigue Test," *Engineering* (London), 1923, p. 698.

[39] Professor Bacon (see footnote no. 36) states: "It appears to be a law that the arrowhead defining rotation meets the steep sides of the ratchet face." A check of our specimens confirms Professor Bacon's observations as far as filleted specimens are concerned, but for the specimens with holes, the direction was opposite in all cases.

[40] Bacon, F., "Fatigue Stresses With Special Reference to the Breakage of Rolls," Proc. So. Wales Inst. Engrs., vol. 47 (1931), no. 2, p. 141.

[41] In Professor Bacon's paper (see footnote no. 36) the progress of cracking is followed by ingenious methods. While the course of cracking is different from that indicated by the mathematical analysis[40] (see also Fig. 9), the above comments on the effect of stress concentration are apparently unaffected.

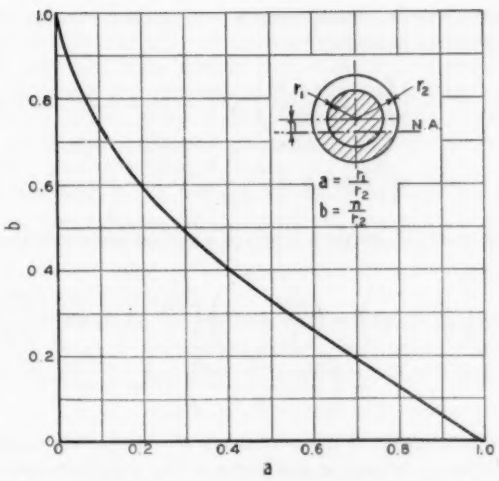

FIG. 17 POSITION OF NEUTRAL AXIS FOR CONCENTRICALLY CRACKED SPECIMEN

A study of fractures is not only of scientific interest, but of immediate practical value as well. In examining broken shafts and parts sent to us we have been able to reach a number of conclusions concerning the degree of stressing and the nature of failure.

2—NOTES ON CONCENTRIC CRACK PROPAGATION

As pointed out in the foregoing section, concentric cracking is produced by relatively high stress and stress concentration. In the following analysis of stress conditions in terms of crack penetration, it will be assumed that: (1) the stress distribution is linear (as in ordinary bending) during the progress of crack penetration. While this assumption is not correct due to stress concentration at the bottom of the crack, it is thought that the stress peak is quite narrow [Fig. 16(*a*)] so that the position of the neutral axis will not be changed greatly and the stress phenomena will be represented as essentially correct from a qualitative point of view; (2) that the cracked portion of the bent specimen carries compressive stresses, but not tensile stresses [Fig. 16(*a*)].

The position of the neutral axis is found as follows:

$$n = \frac{\int y\,dA}{\int dA}$$

$$n = \frac{\displaystyle\int_{-r_2}^{-n} y\sqrt{r_2^2 - y^2}\,dy + \int_{-n}^{0} y\sqrt{r_1^2 - y^2}\,dy + \int_{0}^{r_1} y\sqrt{r_1^2 - y^2}\,dy}{\displaystyle\int_{r_2}^{-n} \sqrt{r_2^2 - y^2}\,dy + \int_{-n}^{0} \sqrt{r_1^2 - y^2}\,dy + \int_{0}^{r_1} \sqrt{r_1^2 - y^2}\,dy}$$

$$n = \frac{-\frac{2}{3}\left[\sqrt{(r_2^2 - n^2)^3} - \sqrt{(r^2 - n^2)^3}\right]}{\left(n\sqrt{r_1^2 - n^2} - \sqrt{r_2^2 - n^2}\right) + r_1^2 \sin^{-1}\left(\frac{n}{r_1}\right) - r_2^2 \sin^{-1}\left(\frac{n}{r_2}\right) + \frac{\pi}{2}\left(r_1^2 + r_2^2\right)}$$

The solution for the position of the neutral axis can be expressed independently of size by taking $a = r_1/r_2$ and $b = n/r_2$, whence the above equation can be simplified to

$$(2a^2 + b^2)\sqrt{a^2 - b^2} - (b^2 + 2)\sqrt{1 - b^2} + 3b\left(a^2 \sin^{-1}\frac{b}{a} - \sin^{-1} b + \frac{\pi}{2}a^2 + \frac{\pi}{2}\right) = 0 \quad \ldots\ldots [1]$$

By using a trial-and-error method and plotting results graphically, the position of the neutral axis can be found to three decimal places in a comparatively short time. The moment of inertia is found as follows:

$$I = \int y^2 dA$$

$$I = 2\int_n^{r_2} (y-n)^2\sqrt{r_2^2 - y^2}\,dy - \int_n^{r_1} (y-n)^2\sqrt{r_1^2 - y^2}\,dy + \frac{\pi r_1^4}{8} - \frac{\pi r_1^2}{2}\left(\frac{4r_1}{3\pi}\right)^2 + \frac{\pi r_1^2}{2}\left(n - \frac{4r_1}{3\pi}\right)^2 + \frac{\pi r_1^4}{8} - \frac{\pi r_1^2}{2}\left(\frac{4r_1}{3\pi}\right)^2 + \frac{\pi r_1^2}{2}\left(n + \frac{4r_1}{3\pi}\right)^2$$

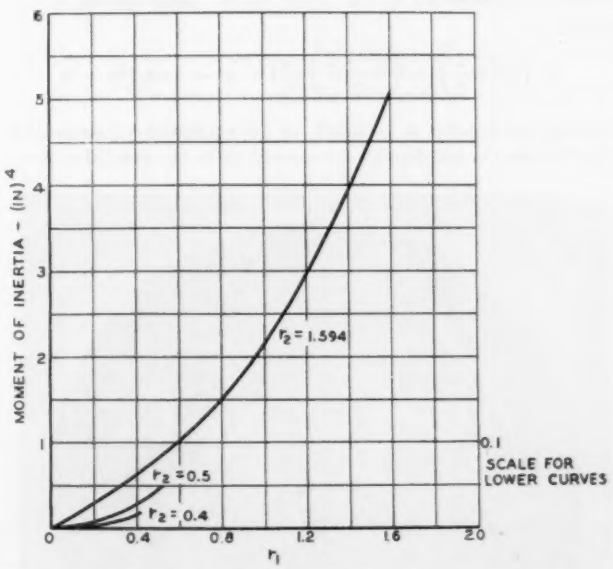

FIG. 18 MOMENTS OF INERTIA OF CONCENTRICALLY CRACKED SPECIMENS

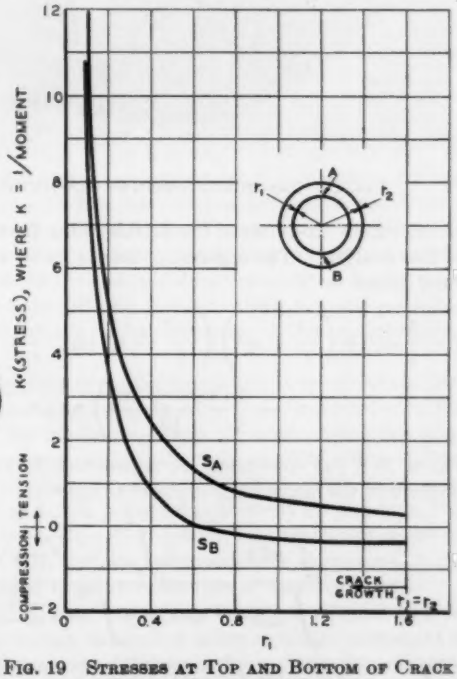

FIG. 19 STRESSES AT TOP AND BOTTOM OF CRACK DURING GROWTH OF CRACK
(For r_2 = 1.6 in.)

$$I = \left(\frac{r_1^2}{4} + n^2\right)\left(\frac{\pi r_1^2}{2} + r_1^2 \sin^{-1}\frac{n}{r_1}\right) + \left(\frac{r_2^2}{4} + n^2\right)\left(\frac{\pi r_2^2}{2} - r_2^2 \sin^{-1}\frac{n}{r_2}\right) + \left(\frac{13nr_1^2 + 2n^3}{12}\right)\sqrt{r_1^2 - n^2} - \left(\frac{13nr_2^2 + 2n^3}{12}\right)\sqrt{r_2^2 - n^2} \quad [2]$$

The foregoing equations are valid for $n \leqq r_1$. For $n = r_1$ the condition represented in Fig. 16(*b*) exists. Substituting $b = a$ in [1],

$$\pi a\left(a^2 + \frac{1}{2}\right) - \left(\frac{a^2 + 2}{3}\right)\sqrt{1 - a^2} - a \sin^{-1} a = 0$$

Solving graphically, $a = 0.397$, or approximately, four-tenths. The "critical crack depth" corresponding to the condition mentioned will be six-tenths of the outside radius for the assumptions of this analysis. The moment of inertia for $n = r_1$ becomes by substitution in [2]

FIG. 20 FRACTURED SPECIMEN (ARTIFICIAL CRACK)

$$I = \frac{5}{4}\pi r_1^4 + \left(\frac{r_2^2}{4} + r_1^2\right)\left(\frac{\pi r_2^2}{2} - r_2^2 \sin^{-1}\frac{r_1}{r_2}\right) - \left(\frac{13r_1r_2^2 + 2r_1^3}{12}\right)\sqrt{r_2^2 - r_1^2} \quad [3]$$

For $n > r_1$ the conditions are represented in Fig. 16(*c*). The position of the neutral axis is found as follows:

$$n = \frac{\int y\,dA}{\int dA} = \frac{2\int_n^{r_2} y\sqrt{r_2^2 - y^2}\,dy}{\pi r_1^2 + 2\int_n^{r_2}\sqrt{r_2^2 - y^2}\,dy}$$

$$\pi n\left(r_1^2 + \frac{r_2^2}{2}\right) - \left(\frac{2r_2^2 + n^2}{3}\right)\sqrt{r_2^2 - n^2} - nr_2^2 \sin^{-1}\frac{n}{r_2} = 0$$

Dividing by r_2^2 and substituting $b = n/r_2$ and $a = r_1/r_2$ a dimensionless equation results:

$$\pi b\left(a^2 + \frac{1}{2}\right) - \left(\frac{2 + b^2}{3}\right)\sqrt{1 - b^2} - b \sin^{-1} b = 0$$

$$a = \sqrt{\frac{1}{\pi}\sin^{-1} b + \frac{2 + b^2}{3\pi b}\sqrt{1 - b^2} - \frac{1}{2}} \quad [4]$$

The moment of inertia is found in a manner similar to the foregoing:

$$I = \pi r_2^4\left(\frac{r_1^2}{4} + n^2\right) + \left(\frac{r_2^2}{4} + n^2\right)\left(\frac{\pi r_2^2}{2} - r_2 \sin^{-1}\frac{n}{r_2}\right) - \left(\frac{13nr_2^2 + 2n^3}{12}\right)\sqrt{r_2^2 - n^2} \quad [5]$$

The displacement of the neutral axis is given by b in terms of a (independently of size) in the curve of Fig. 17 drawn according to Equations [1] and [4]. The moment of inertia is not independent of size and requires a separate curve for each outside diameter as in Fig. 18. Equations similar to the foregoing have also been derived for displaced fracture areas, but these equations are not essentially different and are omitted because of space limitations.

If stress concentration is neglected, the stress variation during crack penetration can be plotted as shown in Fig. 19.

$$S_A = \frac{M}{I}(r_1 + n) \quad [6a]$$

$$S_B = \frac{M}{I}(r_1 - n) \quad [6b]$$

When the crack has penetrated to the "critical crack depth" $0.6r_2$ (for the assumptions of this analysis), the condition $r_1 = n$ exists, so that $S_B = 0$. For greater crack penetration the central zone becomes entirely in tension.

One might expect the above condition to reveal itself in the surface markings; before the "critical crack depth" is reached the crack opens and closes once per revolution, and in the closed position carries compressive stresses, the entire action resulting in the usual smooth, battered, and somewhat corroded surface; below the "critical crack depth" the bottom of the crack is not subjected to compression at any time [Fig. 16(*c*)] and consequently should not show a battered appearance. A number of fractured specimens were examined, and in some cases three zones were evident. (Fig. 20.) Although the "critical crack depth" was generally indistinct, measurements of a few fractures did not show it to be 0.6 r_2 in accordance with the foregoing analysis.[42]

However, if the analysis offers a qualitative explanation, it may be considered to be of some value.

The stresses acting on the central zone (Fig. 19) can also be resolved into a variable stress S_v and a steady stress S_0 as in Fig. 21. At the outset the stress is all S_v, but at the time of failure is largely S_0.

It was thought that it would be possible to calculate the size of the fracture area by using this method,[43] but computations

[42] Professor Bacon (see footnote no. 36) has found by means of an etching procedure that the crack does not close as completely as assumed in the foregoing analysis, due to slight plastic flow at the crack bottom. This would cause the "critical crack depth" to be less than that found by analysis, a condition borne out by observations.

[43] The above-mentioned discovery by Professor Bacon would also explain the lack of quantitative check in the case of size of rupture area.

did not generally agree with measurements. Data are needed on the tensile strength of specimens having circumferential cracks, also data from bending tests. The procedure for calculating the size of the fracture area does not seem unreasonable.

In order to test a severe case of stress concentration, specimens were made with artificially produced circumferential cracks.[44] A very narrow V-bottomed groove was turned in a bar, which latter was heated and compressed axially to close the groove. The bar was subsequently annealed and machined into a test piece having a circumferential crack. The material used was a 0.44 per cent C steel.[17] The appearance of a fractured specimen is shown by Fig. 20.

The results of the fatigue tests of the cracked specimens are given in Table 5, the computations being made according to Equations [1], [2], and [6a]. The stress-concentration factors

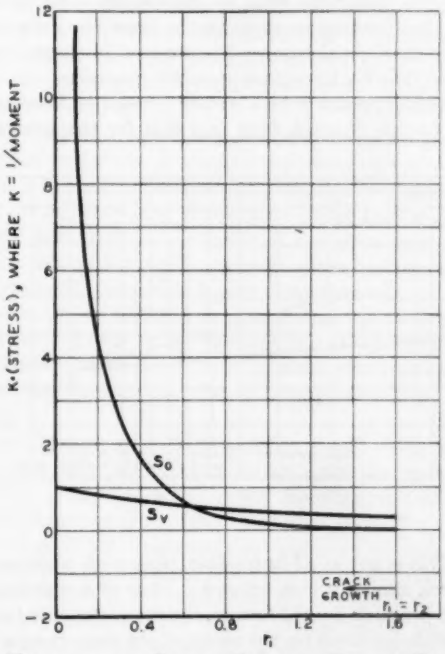

FIG. 21 VARIABLE AND STEADY STRESSES DURING GROWTH OF CRACK
[For r_2 = 1.6 in. (See Fig. 19.)]

are found by dividing 31,700 (which is the endurance limit without stress concentration) by the crack-endurance limits (Table 5). The stress-concentration factors as a function of size are shown in Fig. 8.

TABLE 5 FATIGUE OF SPECIMENS HAVING ARTIFICIAL CRACKS—SUMMARY OF DATA

	Endurance limits* lb per sq in.	Stress-concentration factor, k
Without crack	31,700	..
r_2 = 1.60; r_1 = 1.18	7,900	4.00
r_2 = 0.40; r_1 = 0.297	11,200	2.83
r_2 = 0.40; r_1 = 0.160	4,700	6.75

* Based on Equations [1], [2], and [6a].

ACKNOWLEDGMENTS

The author is indebted to Mr. F. Cassel for considerable assistance in the collection of data for Part II; and to Dr. S. Timoshenko and Messrs. J. M. Lessells and I. W. Chubb for their interest and support of research on mechanics of materials.

[44] The method was suggested by Mr. P. G. McVetty, of the Westinghouse Research Laboratories.

Discussion

JOHN A. GOFF.[45] In section 2 of the paper there are certain observations regarding fatigue fractures, and, in particular, the author points out that when a stress-concentration effect such as that produced by a small fillet or groove is present in the specimen being tested, the final rupture area is generally totally enclosed within the boundary of the cross-section at which failure occurs. Moreover, the author states that the location of this final rupture area seems to vary with the nominal stress imposed upon the specimen and that it appears to be centrally located for high nominal stresses, but displaced toward the circumference for stresses approaching the endurance limit for the given stress-concentration effect.

FIG. 23

In a footnote there is a reference to some unpublished data obtained by the writer at the University of Illinois in 1921. At that time the writer was working under the direction of Profs. H. F. Moore and J. B. Kommers to determine the effect of fillets on the resistance of steel to repeated stress by reversed bending as a part of the work of the joint investigation of fatigue of metals. The principal results on lowering of endurance limit due to stress concentration by the different fillets studied have been published in Bulletins 124 and 142 of the University of Illinois Experiment Station.

Early in the investigation just mentioned, it was observed that two of the fillets studied exhibited the features described in the paper; that is, the final rupture area (or bright crystalline area) was totally enclosed within the cross-section where failure occurred. These fillets are referred to as the V-notch and square-shoulder fillets, and their principal dimensions are shown in Fig. 22. The steel was 0.49-carbon sorbitic, heat treated as described in Bulletin No. 124, and the specimens were those used at the time in the Farmer rotating-beam type of machine.

In almost every case the rupture area was distinct and its boundary sharp enough to admit of rather careful measurement of its principal dimensions. Consequently a little jig was con-

[45] University of Illinois, Urbana, Ill. Assoc-Mem. A.S.M.E.

structed for holding the fractured specimen in front of a Brinell hardness telescope, and in this way dimensions A, B, C, and G (Fig. 23) were easily read to one-tenth millimeter.

After miscellaneous attempts to correlate the measurements obtained in this manner with other data such as number of repetitions of stress etc., the writer finally hit upon the idea of plotting on logarithmic coordinate paper the displacement of the center of the rupture area from the center of the specimen (dimension F, Fig. 23) against the nominal stress S, and in this way obtained the representation of Figs. 24 and 25.

One of the most striking and unusual features presented by Figs. 24 and 25 is the fact that to each fillet belongs a pair of distinct straight lines. For the square-shoulder fillet, for example, this means that a specimen loaded with a nominal stress of

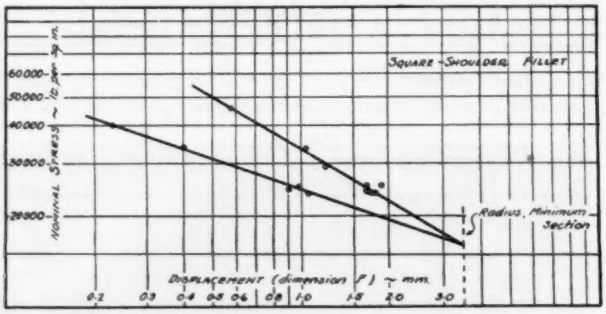

Fig. 24

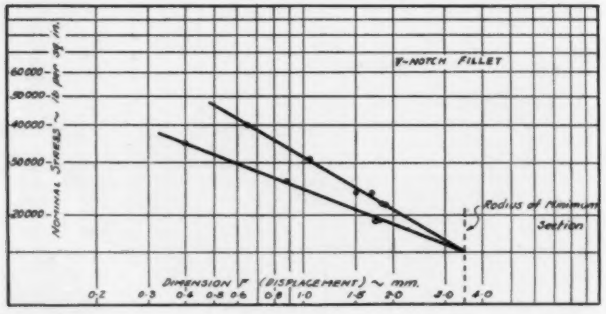

Fig. 25

40,000 lb per sq in. will break in either one of two possible ways; that is, the center of its final-rupture area will be displaced either 0.23 mm or 0.74 mm from the center of the cross-section.

Again, it is quite conspicuous how, for either fillet, the two straight lines intersect at a common value of F very near to 3.5 mm; but 3.5 mm is almost exactly the radius of the minimum cross-section of the fillet. Hence such a displacement, if possible, would place the center of the rupture area right on the circumference of the minimum cross-section.

From the distribution of test points on the pair of straight lines for either fillet, it would appear that neither mode of failure is more probable than the other. The grouping of points near the endurance-limit stress is explained by the fact that a relatively large proportion of specimens broken were loaded with nominal stresses in this region, the primary object of the experiments being to determine the endurance limit for each fillet as accurately as possible.

The data present in Figs. 24 and 25 confirm the author's observation that the location of the rupture area seems in a general way to depend upon the nominal stress; but at the same time they indicate a kind and order of dependence which might never be suspected from an examination of his Fig. 11. The way in which the test points fall along the straight lines of Figs. 24 and 25 would seem to argue that the mechanism of fatigue failure in a specimen having sufficient stress-concentration effect to insure that the final rupture area is totally enclosed within the cross-section is not such a random phenomenon as it is sometimes imagined to be.

Yet another interesting feature of the results is brought to light by an examination of the measurements for the square-shoulder fillet, Fig. 23. In the table of Fig. 23, the specimens are grouped according as their displacements F and nominal stresses S place them on the upper or on the lower straight line. Comparing dimensions D and G, then, shows very clearly that the fractures on the lower line are nearly circular, while those on the upper line are decidedly oval in shape. The measurements for the V-notch specimens seem to exhibit the same peculiarity—namely, that the rupture areas on the lower line are nearly circular, while those on the upper line are oval in shape, but less decidedly so than for the square-shoulder specimens.

There also appears to be a certain correlation between the pair of lines for the V-notch fillet and that for the square-shoulder

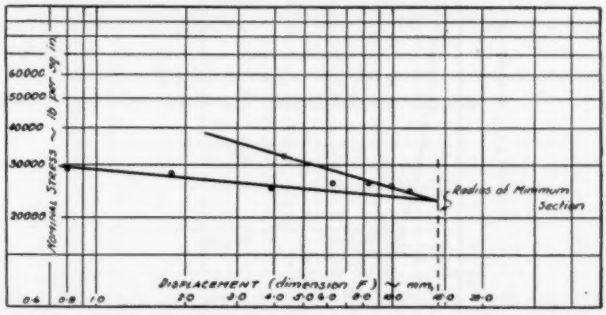

Fig. 26

fillet. This is not at all impossible, since both were made in the same steel, similarly heat treated. Thus at a nominal stress of 24,720 lb per sq in. for the former, the radial distance between the two possible locations for the center of the rupture area is greater than that at any other stress. For the square-shoulder specimen this greatest radial distance is found at almost exactly the same nominal stress—namely, 24,850 lb per sq in.

Corroborating these results described are similar measurements furnished the writer in 1925 by Mr. J. Muller, who at that time was engaged with the joint investigation of fatigue of metals. At the writer's request, Mr. Muller kindly measured the rupture areas of larger cantilever-type specimens which were being tested for endurance limit. These specimens were made with a square-shoulder fillet whose small diameter was in every case $1^1/_8$ in. (28.6 mm). This shoulder determined the critical section and introduced sufficient stress-concentration effect to insure that the rupture areas were totally enclosed within the critical cross-sections.

The results of measurements on the cantilever-type specimens are shown in Fig. 26, which again exhibits the characteristic pair of straight lines on logarithmic coordinate paper, intersecting at a common value of F very nearly equal to 14.3 mm—just half the diameter of the minimum cross-section. A check on the principal diameters of the rupture areas, however, fails to yield the interesting conclusions regarding shape of rupture area which obtain for the V-notch and square-shoulder fillets as described.

The writer offers the foregoing data without any attempt at physical explanation. It would be gratifying to him, however, to have these data attract the attention of those actively inter-

ested in the study of fatigue of metals to the extent possibly of influencing their views on the mechanism of fatigue failure. It seems not unreasonable to suppose that the ultimate theory of fatigue must include an explanation of the results presented herewith.

R. Eksergian.[46] The author's tests and interpretation on stress concentration as affecting fatigue are very interesting, and his introduction of a "fatigue stress concentration factor," with his discussion of its variation as a function of different physical properties of materials and for fillet sizes, is an important contribution.

It has been known that stress-concentration effects on endurance are lower than would be expected from the estimating of endurance from calculated or photoelastic data, and the tests of Haigh and Wilson for holes in flat plates indicate a marked reduction with mild steel plates. The comparison of grooved specimens with ordinary fatigue specimens shown in the author's Fig. 1 also shows that with mild steels the effect of stress concentration is greatly reduced.

This opens up a very interesting question, inasmuch as on the one hand ductility appears to play an important role in reducing the effect of dimensional stress concentrations on endurance and on the other hand it has been consistently shown that endurance limits appear essentially only a factor of the ultimate strength. Furthermore, we know that the range of stress becomes greatly reduced when oscillating about higher mean stresses.

It appears to the writer that some explanation can be offered by considering the ultimate stress concentration to be divided into two components: (1) an intermolecular stress concentration and (2) a dimensional stress concentration arising from fillets, holes, notches, etc.

Both would be expected to be reduced by ductility due to local plastic flow in a redistribution and spreading of the local stress concentration. With the more brittle materials the effect of stress concentration becomes more emphatic.

If now we regard the endurance limit governed by stress concentration, the relative ductility, and the yield point rather than the ultimate strength, it would be necessary to explain the effect of these factors in maintaining with a simple fatigue specimen the apparent constant percentage on the ultimate strength where ordinary steels of various carbon contents are used. Raising the carbon contents raises the tensile strength, increases the ratio of yield to ultimate, and reduces the ductility. On the other hand, the molecular stress concentration would increase with decreasing ductility. With mild steels, the molecular stress concentration due to the plastic-flow spreading action would be small, so that the endurance should approximate the yield value. With decreasing ductility the molecular-stress-concentration factor would be anticipated to increase, lowering the endurance with respect to the yield value. But since the ratio of the yield to ultimate strength increases with decreasing ductility, the ratio of the endurance with respect to the ultimate would tend to maintain a constant ratio. On this basis, therefore, we would anticipate that by the use of an alloy steel, by raising the ratio of the yield to ultimate but maintaining very good ductility, the endurance with respect to the ultimate strength would be raised. It is further likely with mild steels having good ductility, with the beginning of the spreading action of the local stress concentration; likewise local cold working takes place during the first few cycles, raising the yield and resulting in understressing.

With dimensional stress concentrations the effect of ductility in reducing the importance of stress concentration would likewise be anticipated. With increasing tensile values shown in Fig. 1, the effect of dimensional stress concentration would be more pronounced, and with very brittle materials an approach to the photoelastic values would be anticipated. This condition is indicated in the author's Fig. 4 for Si steel. The discrepancy of the endurance based on photoelastic or calculated fillet stresses appears to show that endurance limits are really dependent on the peak stress going into the yield with some spreading action even with small ductility.

The writer recently had some experience with failures of hypercompressor crankpins occurring at the fillet. The pin and web assimilated more of a curved-beam characteristic than the symmetrical construction shown in Fig. 4. For this reason the stress concentration resulting from the fillet joining the web was calculated, and a comparison was made with stress-concentration factors obtained by Timoshenko and Dietz on a symmetrical construction shown in Fig. 4. This comparison is shown in the accompanying Fig. 27. Some weight was given to the greater tendency toward the curved-beam action, but at best the stress was far below the ideal endurance values. The fillets were located at the center core of the forging, and the forging was of massive dimensions. Proper working of the forging was impossible in the vicinity of the fillet. For this reason both the local ductility and grain structure were likely poor. The molecular stress concentration, accentuated by the dimensional stress concentration, or in other words the writer's "fatigue-stress-concentration factor," was of high order, and with possible internal stress superimposed could account for the failure. This is characteristic of the mass feature of a forging.

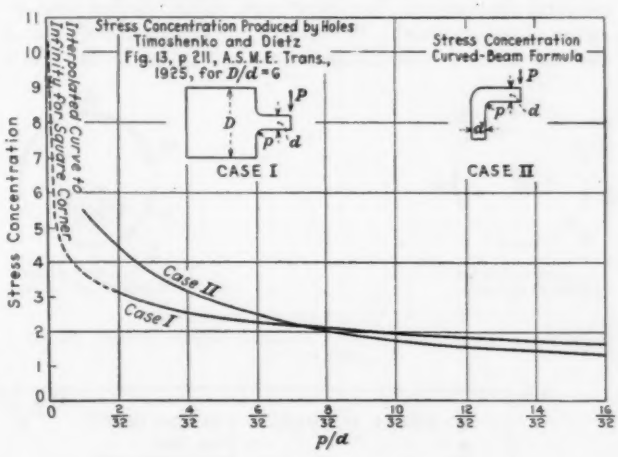

Fig. 27

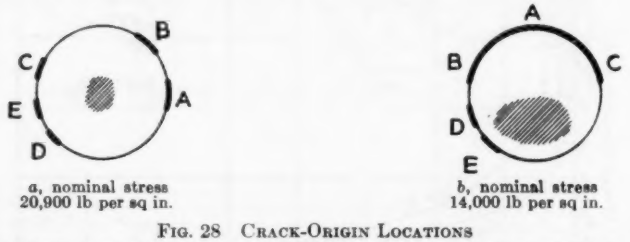
In locomotive axles failure usually occurs at the fillet connecting the axle with the hub fit which is stepped up in the wheel center. With axles in the order of 12 to 14 in., fillets with $^1/_4$-in. radius and even up to $^1/_2$ in. are likely to fail. Such failures occur mostly on the main axle where the maximum loading is due to piston thrusts. The author has shown in the very interesting test, Fig. 8, that the stress-concentration factor, with a severe stress concentration, increases with the size of specimen. It would be anticipated, therefore, that the stress concentration factor shown in Fig. 4 for fillets would increase considerably with massive forgings as in axles. Therefore, until tests on large forgings have been made, the data shown in Fig. 4 should not be used for interpreting the effect of fillet stresses on endurance for large forgings.

The effect of mass size and fatigue with stress concentrations is a very important matter, and aside from the cost and difficulties for carrying on such tests, the matter is greatly tied up with the large variations in the conditions of forgings. Cut-out test

[46] Consultant, Engineering Department, E. I. du Pont de Nemours & Co., Wilmington, Del. Mem. A.S.M.E.

specimens are entirely misleading and in no way indicate the true conditions in a forging itself. But the important point is that the data supplied by the author for estimating stress concentrations are hardly applicable for assimilating the conditions in a massive forging. Statistical experience indicates that sharp fillet ratios are much more severe, resulting in higher stress concentration factors with large forgings than are indicated by such results as shown by the author's Fig. 4.



The writer would suggest that a cooperative test program under the supervision of a committee sponsored by the A.S.M.E. be established for planning some suitable tests for large forgings with typical fillet conditions. The survey plan would first gather as much statistical data as possible before planning a series of tests and the cost for them.

Author's Closure

Dr. Goff has found that for a series of fatigue tests of "stress-concentration specimens" two modes of failure may occur, one resulting in a round rupture area and the other resulting in an elliptical rupture area, the latter being shifted farther from the center of the specimen. A check of our specimens does not reveal the striking relationships shown in Figs. 24 to 26. However, some of the observations mentioned in the paper in connection with "stress-concentration" specimens are not incompatible with Dr. Goff's data. The idea was put forth that, at high stresses, cracking started from numerous sources around the periphery and progressed concentrically to form a centrally located circular rupture area. This is illustrated by the following log of a test run of a $^1/_{32}$-in. fillet, 1-in.-in-diameter specimen at relatively high stress (see Fig. 28*a*):

43,000 cycles, very tiny crack at *A*
48,000 cycles, *A*, 0.19 in., cracks appear at *B* and *C*
50,000 cycles, *A*, 0.19 in.; *B*, 0.18 in.; *C*, 0.05 in.; crack at *D*
52,000 cycles, same
54,000 cycles, *A*, 0.19 in.; *B*, 0.40 in.; *C*, 0.05 in.; *D*, 0.08 in.
56,000 cycles, *A*, 0.31 in.; *B*, 0.40 in.; *C*, 0.23 in.; *D*, 0.08 in.
58,000 cycles, *A*, 0.31 in.; *B*, 0.40 in.; *C*, 0.23 in.; *D*, 0.08 in.; *E*, crack appeared
60,000 cycles, *A*, 0.31 in.; *B*, 0.40 in.; *C*, 0.23 in.; *D*, 0.08 in.; *E*, crack appeared
64,000 cycles, *D* and *E* merged, very fine hairlike crack from *A* to *D*
68,000 cycles, same
78,000 cycles, *B* and *C* merged, *C* and *E* merged
80,000 cycles, *A* and *B* merged
398,000 cycles, failed

It was further proposed that at relatively low stresses (just above the endurance limit), cracking starts at one place, corresponding to the weakest point on the periphery (see Fig. 13), and then develops in a manner, described in the paper, so as to result in a displaced elliptical rupture area. This type is illustrated by the following log of a test run of a specimen similar to that above, but at relatively low stress (Fig. 28*b*).

a, nominal stress 20,900 lb per sq in. *b*, nominal stress 14,000 lb per sq in.

(0.20C steel; $^1/_{32}$-in. fillet; 1 in. in diameter; endurance limit, 13,700 lb per sq in.)

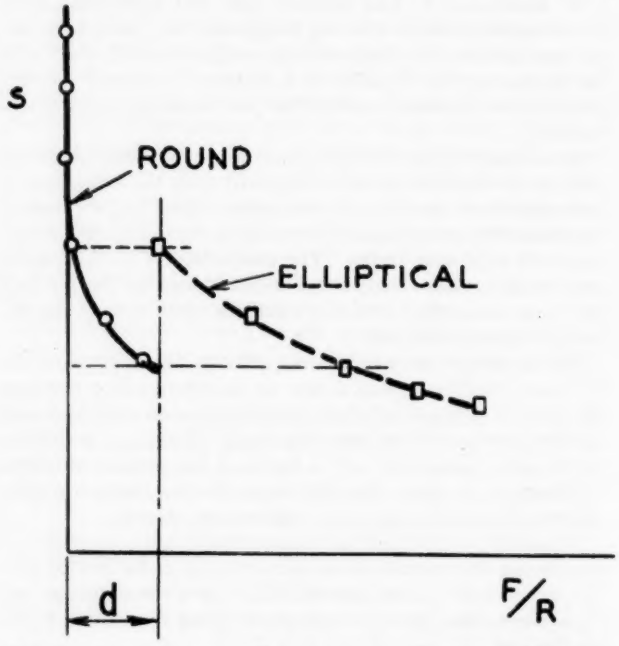

Fig. 30 Illustration of Explanation of Different Modes of Failure

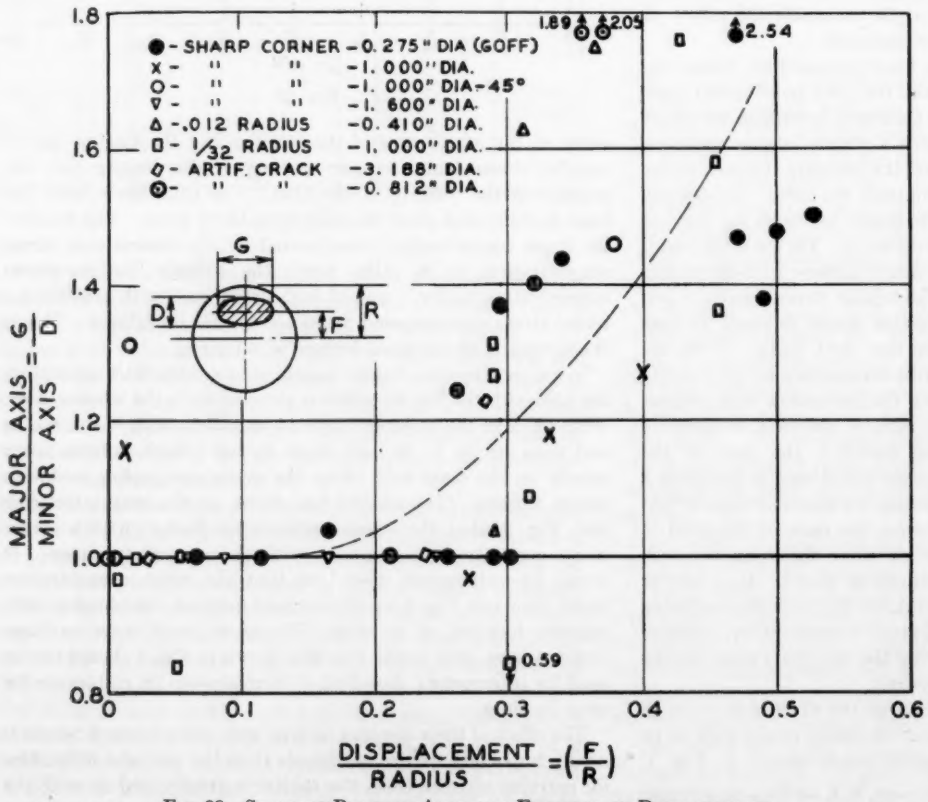

Fig. 29 Shape of Rupture Area as a Function of Displacement

2,871,000 cycles, crack 0.5 in. long discovered at *A*
3,094,000 cycles, crack *A*, same; approx. 0.2 in. from *A*, crack *B*, 0.15 in. long
3,183,000 cycles, *A* and *B* same; approx. 0.15 in. from *A*, crack *C*, 0.1 in. long
3,256,000 cycles, *A*, 0.55 in.; *B*, 0.27 in.; *C*, 0.20 in.
4,005,000 cycles, *A*, *B*, *C* merged, 1.3 in. long
6,459,000 cycles, *A*, *B*, *C* 1.67 in. long; approx. 0.15 in. from *A*, *B*, *C*, crack *D*, 0.17 in. long; approx. 0.1 in. from *D*, crack *E*, 0.1 in. long
7,094,000 cycles, failed

It is suggested that between the above-mentioned extremes a transition range may occur where for any given stress failure may be either concentric or eccentric, depending on the "point-by-point" strength distribution around the periphery (Fig. 13) for the individual specimens. That the elliptical rupture areas are farther displaced than the round areas is shown in Fig. 29, which also includes Dr. Goff's data. One might expect as a consequence of the foregoing remarks, some such diagram as shown in Fig. 30. Then at a displacement d one might have either round or elliptical areas. Perhaps the region near the vertical line at $0.3\ F/R$ in Fig. 29 represents such a condition. Or it may be that the transition from round to elliptical rupture areas is more gradual, following a general trend indicated by the dotted curve of Fig. 29. The wide scattering of points makes it difficult to draw conclusions without a large number of tests.

It appears to the author that much light can be thrown on the foregoing questions concerning the mode of failure by carefully recording crack progress and also simultaneously recording crack penetration by periodic insertion of some type of coloring medium or by some other suitable method of attaining the same end.

Mr. Eksergian has contributed some interesting remarks, particularly with regard to locomotive axles. The author agrees that direct data on the fatigue strength of fillet specimens of 12 to 14 in. diameter are not available. The largest specimens of this type which have been tested are $2^1/_8$ in. in diameter. Considerable extrapolation of uncertain character must be done in order to estimate what happens for large sizes. Mr. Eksergian apparently realizes the difficulty in making tests on large specimens; his suggestion of a cooperative test program under the supervision of a committee sponsored by the A.S.M.E. seems like a worth-while move.

APM-55-20

Working Stresses for Columns and Thin-Walled Structures

By S. TIMOSHENKO,[1] ANN ARBOR, MICH.

In metallic structures such as airplanes, airships, ships, bridges, etc. slender bars, thin webs, and thin-walled tubular members are very often used. In choosing working stresses for such structural elements, not only the mechanical properties of the material but also the elastic stability of these elements should be considered. The method of choosing working stresses for such structures is illustrated in this paper by several examples.

1—Introduction

IN METALLIC structures such as airplanes, airships, ships, bridges, etc. we very often use slender bars, thin webs, and thin-walled tubular members. In choosing working stresses for such structural elements, not only the mechanical properties of the material but also the elastic stability of these elements should be considered. Take, for instance, a centrally compressed column (Fig. 1). In this case the failure may occur at a comparatively low direct stress, and the magnitude of this stress then depends not on the strength of the material, but only on its modulus of elasticity and on the slenderness of the column. The failure occurs not as a result of crushing of the compressed material, but as a result of lateral buckling of the column. We may have analogous conditions in the case of thin plates subjected to the action of compressive or shearing forces in their middle plane, and, in general, in the case of thin-walled structures. The methods of choosing working stresses for such structures will now be illustrated by several examples.

2—Prismatic Columns

Let P = compressive force
E = modulus of elasticity
σ = normal stress
$\sigma_{y.p.}$ = yield-point stress
l = length of the column
r = least radius of gyration of the cross-section
A = cross-sectional area
I = smallest moment of inertia of the cross-section
S = section modulus
$m = S/A$
$k = \sqrt{(P/EI)}$
n = factor of safety
h = thickness of the plate
τ = shearing stress
μ = Poisson's ratio
R = radius of a cylindrical tube.

In the case of a slender column, the *critical* value of the centrally applied compressive force P_{cr} at which lateral buckling occurs is given by Euler's well-known formula:

$$P_{cr} = \frac{\pi^2 EI}{l^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The corresponding critical compressive stress is

$$\sigma_{cr} = \frac{P_{cr}}{A} = \pi^2 E \left(\frac{r}{l}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots [2]$$

in which r is the least radius of gyration of the cross-section and l the length of the column. The ratio l/r is usually called the "slenderness ratio" of the column.

In Fig. 2 the curve AB represents the critical stress σ_{cr} as a function of the slenderness ratio calculated from Equation [2] for steel ($E = 30.10^6$ lb per sq in.).

The derivation of Equation [1] is based on Hooke's law, and the curve AB can be used only if σ_{cr} does not exceed the proportional limit of the material. Taking, for instance, in our example a proportional limit equal to 30,000 lb per sq in., we find that Euler's formula can be used only if the slenderness ratio l/r is not less than 100.

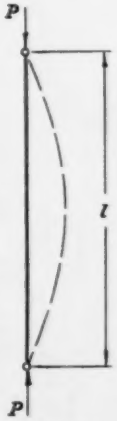

FIG. 1

Further investigations have shown that the application of Equation [2] can be extended also to shorter columns, in which σ_{cr} is above the proportional limit of the material, by substituting, instead of the constant modulus E, a reduced modulus E_1 varying with the slenderness ratio of the column. This reduced modulus can be determined from the compression stress-strain diagram of the material. Investigations made with structural steel show that for comparatively short columns ($l/r < 60$) the critical stress σ_{cr} can be taken equal to the yield point of the material, and for intermediate slenderness ($60 < l/r < 100$) it can be assumed that σ_{cr} varies from the yield point to the proportional limit following a linear law. Taking, for instance, a yield point of the material equal to 40,000 lb per sq in. and the proportional limit equal to 30,000 lb per sq in., we obtain in Fig. 2 the line DCB, which, together with Euler's curve, determines the values of σ_{cr} for any value of the slenderness ratio of a column.

In discussing working stresses for a column we must consider the critical stress given by the diagram $ABCD$ (Fig. 2) in the same way as ultimate strength in the case of simple tension. A compressive stress equal to the critical stress brings the column to failure, and the working stress must be much less than this stress. The magnitude of the factor of safety depends on the

---

[1] Professor of Mechanical Engineering, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E. Dr. Timoshenko was educated in Russia and was called to the Polytechnic Institute of Kiev to occupy the chair of applied mathematics. For five years he was professor of applied mechanics in various engineering schools of St. Petersburg, and professor of applied mechanics at the Polytechnic Institute in Zagreb, Jugoslavia. In 1923 he entered the research department of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., leaving there in 1927 to assume his present position.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

possible errors in the magnitude of the load P (Fig. 1), and also on the possible errors in the central application of the load and on possible initial crookedness. The simplest assumption is to take a certain constant factor of safety. Taking, for instance, a factor of safety of 2.5 and using the critical stresses from Fig. 2, we obtain the diagrams $ABCD$ in Figs. 3(*a*) and 3(*b*) which give working stresses for columns of various slenderness ratios.

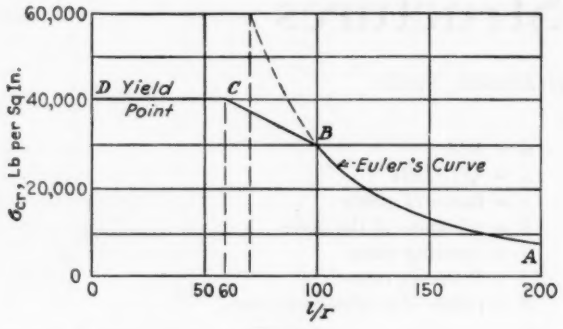

FIG. 2

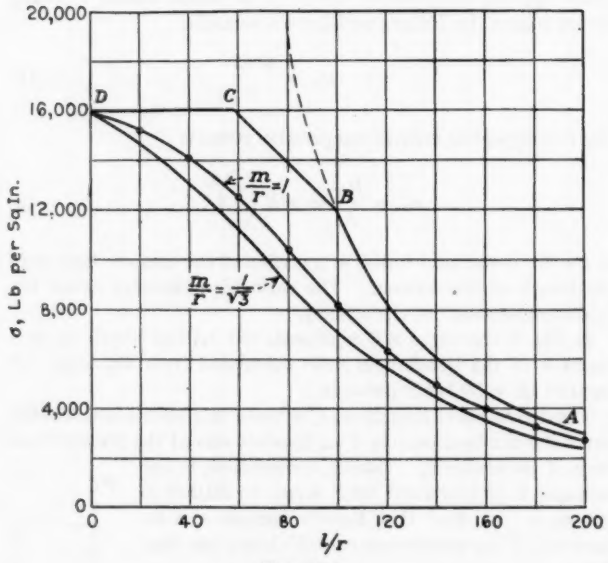

FIG. 3(*a*)
($\sigma_{y.p.}$ = 40,000 lb per sq in.; n = 2.5; e = l/400.)

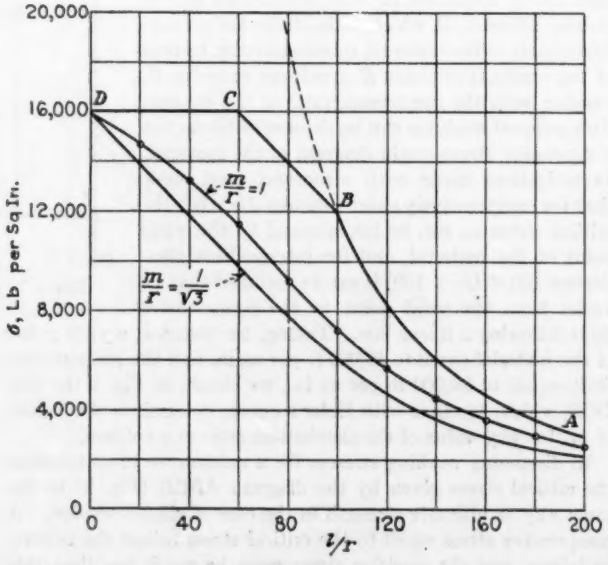

FIG. 3(*b*)
($\sigma_{y.p.}$ = 40,000 lb per sq in.; n = 2.5; e = l/250.)

Experiments show that errors in application of the load and the magnitude of initial deflection of the column usually increase with an increase in the slenderness ratio. This justifies the use of a variable factor of safety which increases with the slenderness of the column. German specifications for bridges assume, for instance, a factor of safety of 3.5 for slender structural-steel columns ($l/r > 100$) and 1.7 for very short columns. In the interval $0 < l/r < 100$ the factor of safety varies according to a linear law. In this manner a table of working stresses for columns of various degrees of slenderness can be established.

3—Eccentrically Loaded Columns

To give some theoretical justification to the practice of using a variable factor of safety, let us consider the case of a column subjected to a load having an eccentricity e at both ends (Fig. 4).

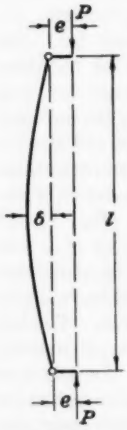

FIG. 4

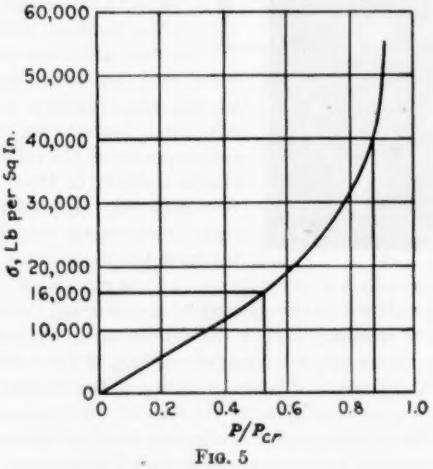

FIG. 5

In this case there is no question of critical load because the column begins to bend once the load is applied. The maximum deflection at the middle is

$$\delta = \frac{e\left(1 - \cos\frac{kl}{2}\right)}{\cos\frac{kl}{2}} \quad \ldots\ldots\ldots\ldots\ldots [3]$$

in which

$$k = \sqrt{\frac{P}{EI}} \quad \ldots\ldots\ldots\ldots\ldots [4]$$

The maximum bending moment is

$$M_{max} = P\,(\delta + e) = Pe \sec\frac{kl}{2} \quad \ldots\ldots\ldots\ldots [5]$$

and the maximum compressive stress,

$$\sigma_{max} = \frac{P}{A} + \frac{Pe}{S} = \frac{P}{A}\left(1 + \frac{e}{m}\sec\frac{kl}{2}\right) \quad \ldots\ldots\ldots [6]$$

in which S = section modulus

$m = S/A$ = core distance of the cross-section.

Remembering that k is a function of P (Equation [4]), it can be concluded from Equation [6] that in this case the stress is not proportional to the load. The relation between the load and the

stress σ_{max} can be represented by a curve which has a vertical asymptote, corresponding to the Euler load (Fig. 5). From such a curve we can see at once that in designing the column we cannot proceed as in the case of simple bending, and determine the safe dimensions from Equation [6] by substituting in it $\sigma_{max} = \sigma_{y.p.}/n$, where n is the factor of safety. Assuming, for instance, $\sigma_{y.p.} = 40{,}000$ lb per sq in. and $n = 2.5$, we find that the load producing the maximum stress, equal to $40{,}000/2.5 = 16{,}000$ lb per sq in., is larger than half of the load producing yield-point stress; i.e., by substituting in Equation [6] for σ_{max} the quantity $\sigma_{y.p.}/2.5$ the factor of safety for the load P becomes less than 2. In order to ascertain a given factor of safety n for the load P, we must take such cross-sectional dimensions of the column that the substitution of nP for P in Equation [6] will give us σ_{max} equal to $\sigma_{y.p.}$ Then the equation for the design of the column becomes

$$\sigma_{y.p.} = \frac{nP}{A}\left(1 + \frac{e}{m}\sec\frac{l}{2}\sqrt{\frac{nP}{EI}}\right) \quad [7]$$

This equation derived for columns compressed by a load with a given eccentricity can be used also in the case of centrally loaded columns. Due to imperfections in manufacturing we must always expect some eccentricity in the application of the load, and also some initial deflection. It can be assumed that such deviations from perfect conditions increase in the same proportion as the length of the column, and that their effect on the maximum stress is the same as that of an eccentricity e proportional to the length. Assuming for the ratio e/l a certain value, we can, for a given $\sigma_{y.p.}$ and for a given factor of safety n, calculate from Equation [7] the values of safe average stress P/A for any slenderness ratio. The results of such calculations[2] made for

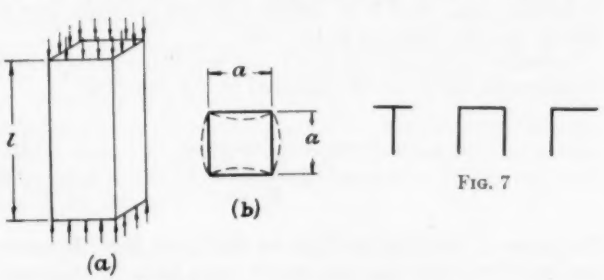

FIG. 6

FIG. 7

$e/l = 1/400$ and $e/l = 1/250$ are given in Figs. 3(*a*) and 3(*b*). The calculations are made for a built-up section with $m/r = 1$ and also for a solid rectangular section for which $m/r = 1/\sqrt{3}$. In all cases $\sigma_{y.p.}$ is taken equal to 40,000 lb per sq in., and the factor of safety $n = 2.5$. Comparing these results with the ordinates of the diagram in Fig. 2 we find that the factor of safety with respect to the critical stress in the case of the eccentricity $e = l/400$ [Fig. 3(*a*)] and for a built-up cross-section ($m = r$) varies in the inelastic region ($l/r < 100$) from 2.5 to 3.7. For a larger eccentricity, $e = l/250$ [Fig. 3(*b*)], the same factor varies from 2.5 to 4.2. Thus the discussion gives some justification for the use of a variable factor of safety in calculating working stresses for columns (see Art. 2). It also shows that the design of columns on a basis of critical stress can be replaced by designing on a basis of the yield point of the material if a suitable choice of the factor of safety n and the eccentricity ratio e/l is made.

If the eccentricities of the application of the load are known, as in the case of compressed members of trusses for which the end moments can be calculated, we derive the deflection curve on a basis of these known eccentricities and finally arrive at an equation of the same kind as Equation [7], from which the proper cross-sectional dimensions of the column can be obtained.[3]

4—Buckling of Walls of Tubular Members

In the previous discussion we have considered the buckling of the column as a whole. If the column is built up of thin plates, the walls of the column may buckle before the column buckles as a whole. Take, for instance, a thin tube of square cross-section and uniformly compressed (Fig. 6). The side plates may buckle as shown in Fig. 6(*b*), and each side can be considered as a long plate simply supported along the edges and uniformly compressed in the longitudinal direction. The critical compressive stress for a comparatively long plate ($l/a > 3$) is

$$\sigma_{cr} = \frac{\pi^2 E h^2}{3(1-\mu^2)a^2} \quad [8]$$

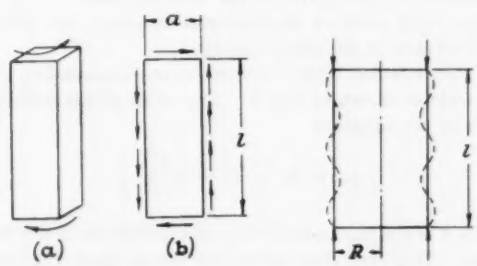

FIG. 8

FIG. 9

in which h is the thickness of the plate and μ is Poisson's ratio. For steel, for instance ($E = 30 \times 10^6$ lb per sq in., $\mu = 0.3$), taking $h = 0.01a$,

$$\sigma_{cr} = 10{,}900 \text{ lb per sq in.}$$

For any other ratio between the thickness and the width of the plate the critical stress is obtained from the equation:

$$\sigma_{cr} = 10{,}900\,\frac{10^4 h^2}{a^2} \text{ lb per sq in.} \quad [9]$$

It is seen that for steel plates, the thickness of which is one-hundredth of the width, buckling occurs at a stress which is far below the proportional limit. Substituting $\sigma_{y.p.}$ for σ_{cr} in [9] and taking $\sigma_{y.p.} = 40{,}000$ lb per sq in., the corresponding value of the ratio is found to be

$$\frac{a}{h} = 51$$

For thicker plates Equation [9] is not applicable and we can assume that σ_{cr} is equal to the yield-point stress of the material.

The question of the buckling of plates arises also in the case of such cross-sections as those shown in Fig. 7.[4]

If a square tube is subjected to the action of twist (Fig. 8), each side of the tube is in a condition of pure shear and may buckle if the shearing stress exceeds a certain critical value. Regarding this critical value we have the following information: If the length of the plate is large ($l > 4a$) and the edges can be considered as simply supported, the critical value of the shearing stress is given by the equation:

$$\tau_{cr} = 5.35\,\frac{\pi^2 E}{12(1-\mu^2)}\,\frac{h^2}{a^2} \quad [10]$$

[2] These calculations were kindly made for the author by D. H. Young, Instructor in Engineering Mechanics at the University of Michigan.

[3] Calculations of this kind were made by D. H. Young, see International Association for Bridge and Structural Engineering Memoirs, vol. 1 (1932), p. 507.

[4] Several formulas for calculating critical stresses in this case are given in the author's book, "Strength of Materials," see p. 604.

If the edges are built in, the critical stress is

$$\tau_{cr} = 8.98 \frac{\pi^2 E}{12(1-\mu^2)} \frac{h^2}{a^2} \quad [11]$$

If the plate cannot be considered as long and the edges are simply supported, the value of the critical stress is given by the equation

$$\tau_{cr} = \alpha \frac{\pi^2 E}{12(1-\mu^2)} \frac{h^2}{a^2} \quad [12]$$

in which α, a numerical factor depending on the ratio between the length and width of the plate, can be taken from the following table:

l/a =	1	1.2	1.4	1.5	1.6	1.8	2.0	2.5	3.0	∞
α =	9.4	8.0	7.3	7.1	7.0	6.8	6.6	6.3	6.1	5.35

If Equations [8]–[12] give for the critical stress a value greater than the yield point of the material in shear, the yield point should be taken as the critical stress.

If a thin circular tube is subjected to compression, the wall may buckle as shown in Fig. 9. The value of the critical stress is given by the equation

$$\sigma_{cr} = \sqrt{1/3(1-\mu^2)}\, E \frac{h}{R} \quad [13]$$

in which h is the thickness of the wall and R the mean radius of the tube. It is seen that within the elastic limit, buckling may occur only in the case of very thin tubes.

5—Long Circular Tubes Submitted to Uniform External Pressure

Another problem in which the question of elastic stability is of great practical importance is the case of a long circular tube submitted to uniform external pressure (Fig. 10). It is well known that if the pressure p exceeds a certain value p_{cr} the circular form of the tube becomes unstable and the tube collapses, as shown in Fig. 10 by the full line. The critical value of the external pressure is given by the equation:[5]

Fig. 10

$$p_{cr} = \frac{E}{4(1-\mu^2)} \cdot \frac{h^3}{R^3} \quad [14]$$

and the corresponding value of the compressive stress in the circumferential direction is:

$$\sigma_{cr} = \frac{p_{cr} \cdot R}{h} = \frac{E}{1-\mu^2} \frac{h^2}{4R^2} \quad [15]$$

in which h is the thickness of the wall and R the radius of the tube.[6] Assuming $E = 30 \times 10^6$ lb per sq in. and Poisson's ratio $\mu = 0.3$ and plotting σ_{cr} against $2R/h$, we obtain a curve AB (Fig. 11) giving the critical stress for steel tubes of various proportions. This curve represents the actual critical stress only if the magnitude of this stress does not exceed the proportional limit of the material. Beyond this limit the curve gives exaggerated values of the critical stress. To get the true values of this stress we must proceed in the same manner as in the case of a column, and work with a reduced modulus of elasticity. In this manner it can be shown that for materials with a pronounced yield point, this yield-point stress must be taken as the critical stress for thicker tubes. Taking, for instance, a steel with yield point $\sigma_{y.p.} = 40{,}000$ lb per sq in. and proportional limit $\sigma_p = 30{,}000$ lb per sq in., we find that the smallest value of $2R/h$ for which Equation [15] can be used is about 33. This corresponds to point B on the curve AB. For thicker tubes ($2R/h < 20$)

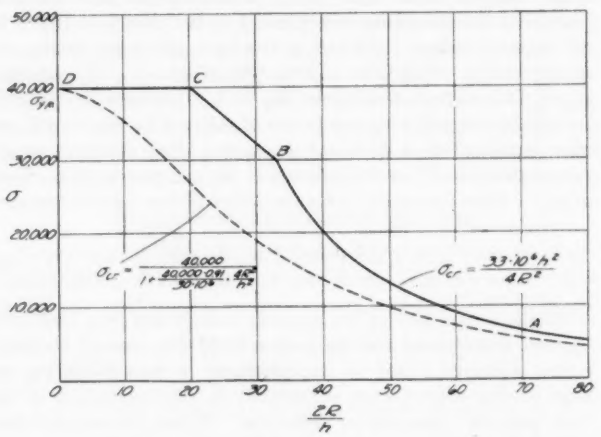

Fig. 11

the horizontal line DC giving $\sigma_{cr} = \sigma_{y.p.}$ can be used. For intermediate thickness ($20 < 2R/h < 33$) we can use, as in the case of columns, the straight line CB for determining the critical stress. Thus the line $ABCD$ gives the critical values of compressive stress for all proportions of the tubes, and if a factor of safety is decided upon, there is no difficulty in each particular case in finding the safe thickness of the tube.

Instead of the broken line $ABCD$, it is sometimes useful to have a continuous curve, as the one given by the equation:[7]

$$\sigma_{cr} = \frac{\sigma_{y.p.}}{1 + \frac{\sigma_{y.p.}(1-\mu^2)}{E} \cdot \frac{4R_2}{h^2}} \quad [16]$$

This curve is shown in the figure by the dotted line. It can be seen that for thick tubes the critical stress given by this curve approaches $\sigma_{y.p.}$, and for thin tubes it approaches the critical stress given by Equation [15]. For usual proportions the curve gives much lower stresses than those given by the line $ABCD$. This additional safety introduced by Equation [16] can be considered as compensating for the effect of any initial ellipticity of the tube which always can be expected in practice.

Let us consider now the effect of an initial ellipticity on the magnitude of maximum stress in a uniformly compressed tube. The deviation of the shape of the tube from a perfect circular form can be defined by the initial radial displacements u_o (Fig. 12). A very simple solution of the problem can be obtained by assuming that u_o is given by the equation:

$$u_o = \delta \cos 2\theta$$

in which δ is the maximum initial radial deviation from the circle and θ is the central angle to the point in question. When θ is varying from 0 to $\pi/2$, the radial deviation is changing from $+\delta$ to $-\delta$, and the general shape of the tube is as shown in Fig. 12 by the full line.

Under the action of external uniform pressure p, there will be an additional flattening of the tube. The corresponding radial

[5] This equation was obtained by M. Levy, *Journal d. Math. pure et Appl.* (Iiouville), ser. 3, vol. 10, p. 5, 1884. The derivation of the equation can be found in the author's "Strength of Materials," vol. 2, p. 598, 1930.

[6] The thickness of the wall is assumed small, and the external radius and mean radius are assumed to be the same.

[7] Such a curve was proposed by R. V. Southwell, *Phil. Mag.*, vol. 29, p. 67, 1915.

displacements will be represented by u. Then to determine u we can use the differential equation:[8]

$$\frac{d^2u}{d\theta^2} + u = -\frac{12(1-\mu^2)}{Eh^3} MR^2 \quad [17]$$

in which M is the bending moment, taken positive when it produces a decrease in the initial curvature of the tube. Following

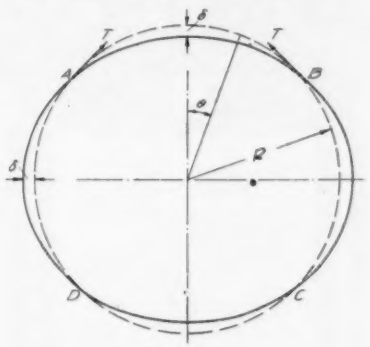

FIG. 12

this rule, we conclude that in the portions AB and DC there will be produced by a uniform external pressure a positive bending moment and in the portions AD and BC a negative bending moment. At points A, B, C, and D the bending moment is zero, and the actions between the parts of the tube are represented by forces T tangential to the circle representing the ideal shape of the tube. This circle can be considered as the funicular curve for the external pressure. The compressive force along this curve remains constant and equal to T. Thus the bending moment at any cross-section is obtained by multiplying T by the total radial displacement $u_o + u$ at this cross-section. Taking an elementary ring from the tube of a width, in the direction perpendicular to the plane of the figure, equal to unity, the compressive force T is obtained from conditions of static equilibrium to be equal to pR. Then the bending moment at any cross-section of the ring is

$$M = pR(u + u_o) = pR(u + \delta \cos 2\theta)$$

Substituting in Equation [17], we obtain

$$\frac{d^2u}{d\theta^2} + u = -\frac{12(1-\mu^2)}{Eh^3} pR^3(u + \delta \cos 2\theta)$$

or

$$\frac{d^2u}{d\theta^2} + u\left(1 + \frac{12(1-\mu^2)}{Eh^3} pR^3\right) = -\frac{12(1-\mu^2)}{Eh^3} \delta pR^3 \cos 2\theta$$

The solution of this equation satisfying the conditions of continuity at the points A, B, C, and D is

$$u = \frac{\delta p}{p_{cr} - p} \cos 2\theta \quad [18]$$

in which p_{cr} is given by Equation [14]. It is seen that at points A, B, C, and D, u and $d^2u/d\theta^2$ are zero. Hence the bending moments at these points are zero, as was assumed above. The maximum bending moment occurs when $\theta = 0$ and $\theta = \pi$. At this cross-section:

$$M_{max} = pR\left(\delta + \frac{\delta p}{p_{cr} - p}\right) = pR\delta \frac{1}{1 - (p/p_{cr})} \quad [19]$$

[8] This equation was established by J. Boussinesq, *Comptes Rendus*, vol. 97, p. 843, 1883. The derivation of this equation can be found in the author's "Strength of Materials," vol. 2, p. 457, 1930.

It is seen that for small values of the ratio p/p_{cr} we can neglect the change in the ellipticity of the tube due to pressure p and multiply the compressive force pR with δ in calculating the maximum bending moment. When the ratio p/p_{cr} is not small, the change in the initial ellipticity should be considered and Equation [19] must be used in calculating M_{max}.

The maximum compressive stress is now obtained by adding to the stress produced by the compressive force pR the maximum compressive stress due to bending moment M_{max}. Thus we find:

$$\sigma_{max} = \frac{pR}{h} + \frac{6M_{max}}{h^2} = \frac{pR}{h} + \frac{6pR}{h^2} \frac{1}{1 - (p/p_{cr})} \quad [20]$$

The pressure p at which yielding of the material begins is found from the foregoing equation by substituting $\sigma_{y.p.}$ for σ_{max}. Then

$$\sigma_{y.p.} = \frac{pR}{h} + 6p \cdot \frac{R^2}{h^2} \frac{\delta}{R} \frac{1}{1 - (p/p_{cr})} \quad [21]$$

Using the notation

$$\frac{R}{h} = m; \qquad \frac{\delta}{R} = n \quad [22]$$

the equation for calculating p becomes

$$p^3 - \left[\frac{\sigma_{y.p.}}{m} + (1 + 6mn)p_{cr}\right] p + \frac{\sigma_{y.p.}}{m} p_{cr} = 0 \quad [23]$$

It should be noted that the pressure p determined in this manner produces a stress equal to $\sigma_{y.p.}$ only in the weakest spot. This pressure is smaller than the pressure at which the collapsing of the tube occurs, and it becomes equal to the latter only in the case of a perfectly round tube. Hence the use of Equation [23] for calculating critical values of p is on the safe side. Without any difficulty a curve analogous to the dotted curve in Fig. 11 can be constructed for any value of δ/R. Having a series of such curves for various values of initial ellipticity, the determination of the necessary thickness of the tube can be easily made in each particular case.

We have given here only a few examples of buckling of thin-walled structures. More problems of this kind are discussed in the author's paper in the Reports of the Third International Congress for Applied Mechanics, Stockholm, 1930. The literature on the subject is given there also.

Discussion

GEORGE E. BEGGS.[9] Since the experiments on buckling of wrought-iron compression members were made in connection with the design of the Britannia and Conway bridges over eighty years ago, no equally thorough tests have been conducted to guide bridge engineers in selecting a proper plate thickness for cellular compression members of steel having one or more squares in their cross-section. [See Fig. 13 (*b*) and (*c*)]. The most elaborate tests of this character in recent years are the web plate compression tests made at the U. S. Bureau of Standards and reported in its Technologic Paper No. 327. In the writer's opinion, these tests do not exhibit accurately the structural behavior of a cellular column, nor do the test results support the mathematical formula for critical buckling stress, as will be explained below. The best approach to the mathematical solution of the problem

[9] Professor of Civil Engineering, Princeton University, Princeton, N. J.

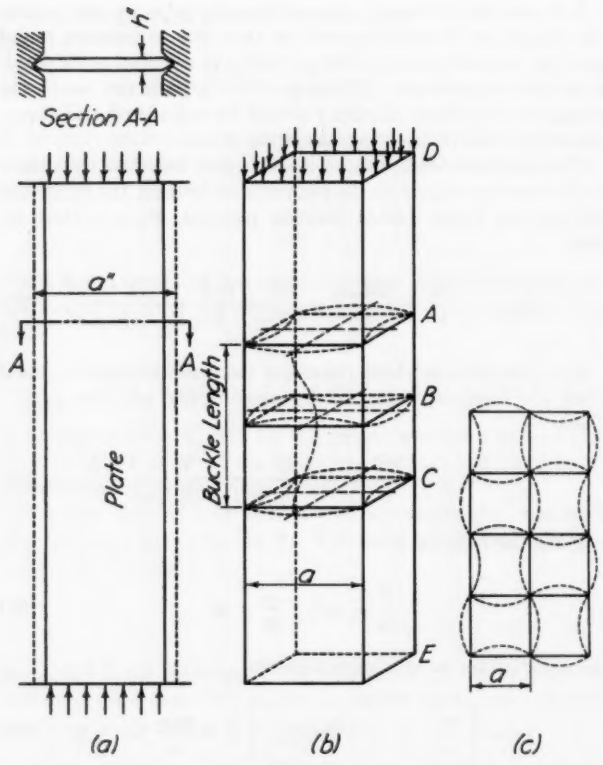

FIG. 13

of plate buckling was made originally by George H. Bryan (Proc. Lond. Math. Soc., vol. 22, pp. 54–67), in which will be found Equation [8] of the paper, being the same as the one quoted in Fig. 15.

Bryan assumed a truly flat and perfectly elastic plate of infinite length, supported freely along its longitudinal edges and loaded in compression, as indicated in Fig. 13 (*a*). He developed for this ideal case a formula giving the maximum unit stress that this plate would carry without starting to become crooked. The resulting expression and Euler's column formula are strikingly similar:

Bryan's Web-Plate Buckling Formula:

$$\sigma_{cr} = [\text{constant}]\pi^2 E/(a/h)^2$$

Euler's Column Formula:

$$\sigma_{cr} = [\text{constant}]\pi^2 E/(l/r)^2$$

The plotted curve for Bryan's formula (Fig. 15) is closely similar to Euler's curve in Fig. 2 of the paper. The criticisms of the application of Euler's formula to the design of columns of usual slenderness ratios seem to apply to the general use of Bryan's formula in designing web plates of usual thinness ratios. By reason of the ever-present initial crookedness of web plates, it appears that Bryan's formula is inapplicable for an accurate computation of buckling resistance, particularly when the critical stress found by this formula has a value near the yield point of the material. Bryan's formula tells only the maximum load that a single truly flat plate [Fig. 13 (*a*)] will carry before starting to buckle. The engineer desires a formula that will give him the buckling resistance of a plate or assemblage of plates of steel, all of which have initial Bryan buckles in them due to cooling at the rolling mill or irregularities due to handling. From published data about such initial crookedness of web plates, the writer has observed that these plates may be expected to have initial buckles of the Bryan type with the crests of the buckles $a/350$ above the dents (Fig. 13). It is suggested that the mathematician assume this degree of initial crookedness of the plates, the yield point, and other properties of the material, and derive a practical formula or curve for the buckling resistance of a square tube or cellular column in compression.

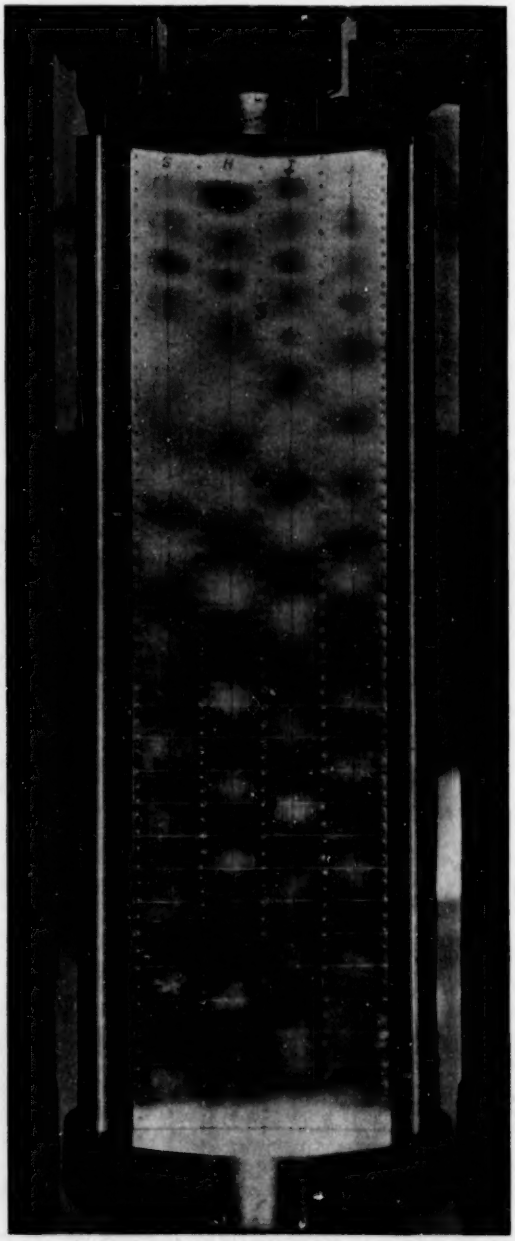

FIG. 14

Fig. 14 shows a cellular column under load. The cross-section consists of eight cells [see Fig. 13 (*c*)]. The buckling load has a value such that the column yields without added load at an average unit stress well below the yield-point value of the material. The crests and dents of the buckles alternate both vertically and around the cross-section. The vertical distance center to center of buckle dents (Fig. 14) averages 1.38 times the full width of a partition, as was noted for all partitions of this and a similar

specimen, whereas Bryan's theory indicates that the buckle length should not exceed the full width of partition. The pattern of the buckles became apparent at a unit stress about $^3/_4$ of that indicated by Bryan's formula for a single plate. [Fig. 13 (*a*).] Nature's tendency to produce a buckle pattern was so strong that several initial dents reversed their curvature and became crests, in order to accommodate the prevailing pattern. At one elevation, as at *A*, Fig. 13 (*b*), the plates bent in and out around the tube, as shown by the dotted line. At a lower elevation, as at *B*, a similar but opposite order of dents and crests occur around the sides of the square cell. The reversal from dents to crests at successive elevations evidently subjects each long corner, as *ABC*, of the square cell to a torsion, alternately clockwise and counterclockwise in plan. If the partitions are joined by steel angles in the corners of the cell, these angles will be subjected to an alternating torsional strain and will offer some resistance thereto. However, since angle sections have extremely little

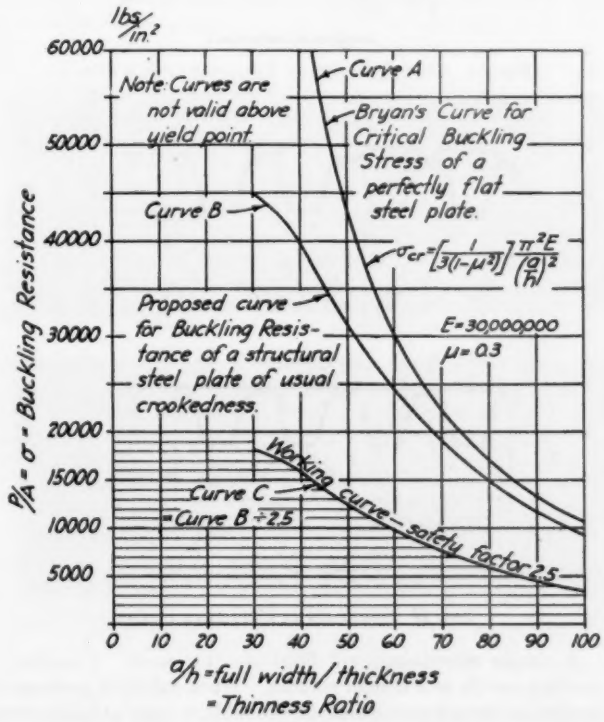

FIG. 15

torsional resistance, they would afford no great support against the buckling of the web plate. In the web-plate compression tests at the U. S. Bureau of Standards (Tech. Paper 327), this natural alternating torsional movement at the two vertical edges of a web plate was prevented by the attachment of heavy steel stiffeners to the flange angles of the tested partition, with the result that the natural buckling of the webs was hindered. In the one test where these stiffeners were not very tightly attached, failure occurred at a comparatively low stress. These tests therefore give results on the unsafe side, even though the actual structure is safeguarded by an ample safety factor. A further criticism of the test report referred to is that the conclusions there given support a misquoted formula of Bryan instead of the correct one. This misquoted formula is incorrect by 25 to 30 per cent on the unsafe side, this estimate depending on the value taken for Poisson's ratio.

Just as mathematicians have developed formulas and curves to predict the actual capacity of columns of usual crookedness and eccentricity, so should they also give their attention to deriving similar ones to predict the buckling resistance of thin, but somewhat initially crooked, web plates of cellular compression members. Engineers should also carry out buckling tests with cellular columns of steel comparable to the experiments made by Fairbairn with wrought-iron cellular columns. Only by such studies can a reliable guide be found for the efficient design of the webs of such members. Until then, part of the factor of safety will remain a factor of ignorance.

In the absence of adequate theory and tests, the writer proposes curves *B* and *C* of Fig. 15 as a guide in selecting thickness of webs for cellular compression members of structural steel, Curve *B* fits reliable test data more safely than curve *A*, but such data are meager.[10]

The writer hopes that the author may be able to extend the excellent studies he has made of the ideal behavior of plates subject to buckling and to modify the plate-buckling theory so as to allow for some specified initial crookedness of the plates. A practical formula or design curve taking such initial crookedness into account will be of value.

R. EKSERGIAN.[11] The choice of suitable working stress is governed essentially by such factors as eccentricity of loading, degree of constraints at the ends, initial deflections, etc., and the writer feels that to provide for such contingencies reference to full-size tests approximating actual conditions is always desirable when possible.

In choosing a factor of safety, the preliminary limits are shown by the boundary curve of Fig. 2 which extends over two regions, one the yield limit for low values of l/r since in this region the critical stress exceeds the yield value, and the other the column-stability region where the limiting stress depends upon the critical column stress. The former region is dependent upon the physical properties of the material, i.e., the yield value, while the latter is independent of all except the modulus of elasticity E. Now in any actual column eccentricities must exist, and such eccentricities introduce a transition curve from the yield-limit region into the column-stability region. Equation [7] represents this transition curve, and it will be noted the peak stress, after a suitable factor of safety on the load is used, is limited to the yield value. At first glance we might conclude there is some inconsistency since with the boundary-curve idea for the higher values of l/r, the stress is totally independent of any yield limit, whereas the column equation for any value of l/r appears to always depend on the yield value as well. A little study of the equation, however, will show that for the higher values of l/r, the working stress P/A is very little affected by large changes in yield values, or, in other words, the ratio of the critical stress to the working stress, i.e., the factor of safety on the column stability, is little affected by any choice of yield value for the higher values of l/r. For instance, if we write Equation [7] in the form,

$$\sigma_{y.p.} = n\sigma\left(1 + \frac{e}{m}\sec\frac{l}{2}\frac{n\sigma}{\sigma_{cr}}\right), \quad \sigma_{cr} = \frac{2E}{(l/r)^2}$$

and assume $n = 2.5$ and $l/r = 200$ for a slender column, and $m/r = 1$, with $e/l = 1/400$, then when $\sigma = 2500$ lb/per sq in., $\sigma_{cr.} = 7400$ lb per sq in., $\sigma_{y.p.} = 2.5 \times 2500\,(1 + 1/2\sec 82.8°) = 31{,}200$ (lb per sq in.), and $n' = 7400/2500 = 2.96$; and when

[10] A safety factor of 2.5 was used to obtain curve *C* from curve *B* only because this factor was used by the author in obtaining his working curve for columns. However, if further tests and study show that curve *B* approximates closely the true ultimate buckling resistance of commercial web plates, a smaller factor of safety between 1.5 and 2.5 may be chosen, depending on conditions and individual judgment.

[11] E. I. du Pont de Nemours & Co., Wilmington, Del. Mem. A.S.M.E.

σ = 2700 lb. per sq in., $\sigma_{y.p.}$ = 2.5 × 2700 (1 + 1/2 sec 82.2°) = 57,800 (lb per sq in.) and n' = 7400/2700 = 2.74.

Thus nearly doubling the yield value changes n' by only $7^1/_2$ per cent. For this reason, with the higher values of l/r, raising the yield value has very little effect on increasing the allowable working stress.

In the case of rods subjected to alternating or cyclic stresses, as connecting rods in engines, it would seem that the endurance limit should replace the yield value in the boundary curve *DC* in Fig. 2, and likewise in the column Equation [7].

In the design of rods for high-speed engines, particularly locomotive rods, due to the bending caused by centrifugal whip action, the rods are either of I- or rectangular section with a large depth of section in the plane of reciprocation. In the latter the rod acts as an ideal pin-connected column, while in the lateral plane, due to the bearing constraint of the pins, it approaches a column with fixed ends. Due to the inertia bending action, the depth of the rod with rectangular sections is never less than 2 and frequently from 3 to 4 times its width. Thus if b is the width and h the depth of the rod, the critical compression stresses σ_v for the plane of reciprocation and σ_h for the lateral plane have the relation, $\sigma_h/\sigma_v = 4b^2/h^2$, so that when $h = 2b$, failure can only occur by lateral buckling perpendicular to the plane of reciprocation. It is to be noted that maximum compressive loadings occur at low speeds where the inertia forces can be neglected.

Some years ago the late Professor Lanza conducted at the Massachusetts Institute of Technology a series of tests on full-sized locomotive rods having various values of l/r. Up to a value of l/r = 160, which the writer believes was the limiting value used in the test, failure occurred practically at the yield value, around 38,000 lb per sq in. A fully constrained column would give a compressive stability with l/r = 160 and with $E = 30 \times 10^6$ equal to 47,000 lb per sq in. Since the rods failed at the yield value rather than by actual column instability, these tests assure us that at least the effect of the lateral bearing at the pins gives sufficient constraint to approximate over $^3/_4$ the stability of a fully constrained column, which is equivalent to a pin column of length 0.58 l. Professor Lanza recommended an allowable working compressive stress at 8000 lb per sq in. with l/r = 160. In practice stresses up to 10,000 lb per sq in. have been used with this value. This corresponds to a factor n = 3.5. The fact that the lateral constraint of the pin bearing is very effective is evident from the fact that with side rods, bearing centers may have considerable eccentricity with no allowance for this eccentricity.

J. M. Frankland.[12] One aspect of instability in elastic systems not discussed in the paper, seems to the writer of practical importance in present-day construction of thin-walled structures.

Owing to a certain rather widespread misconception of Euler's theory of buckling, it has unfortunately been extended into a range for which it was never intended. This may best be illustrated by referring to Fig. 16, where P is the load and d the deflection at the end of the strut. From O up to A the load is less than the critical Euler load and the strut remains straight. At A the critical load P_{cr} is reached. Now the statement is often made that at this load the strut becomes unstable and that any deflection greater than or equal to d_{cr} is possible; in other words, the column should continue to deflect along AB at constant load until it folds up completely. But the correct interpretation of the theory is that the strut begins to bend at the critical load and the deflection begins to increase more rapidly along some such curve as AC. This means that there is a perfectly definite deflection for each load, even when the load exceeds the critical value. Provided that the combined stresses due to bending and direct compression nowhere exceed the elastic limit, the strut can be loaded above the critical point A without producing any permanent deformation, the column becoming straight again as soon as the load is reduced below the critical value.

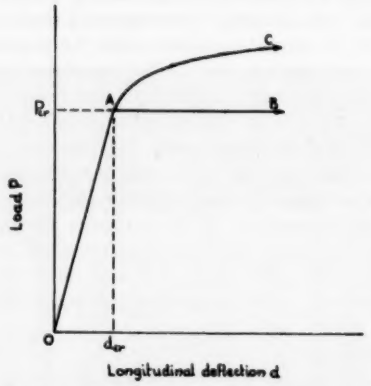

Fig. 16 Load-Deflection Relations for a Strut

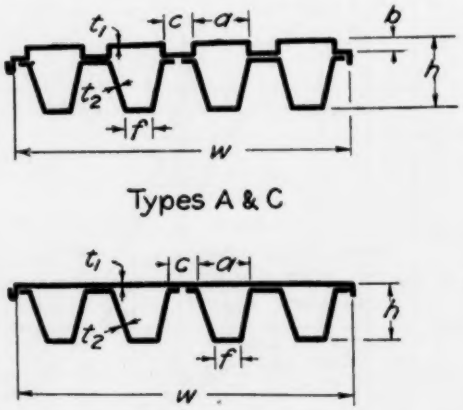

Fig. 17 Sections of Cellular Beams

A simple experiment will illustrate this point. Consider a knitting needle as a slender column. When sufficient pressure is applied at the top as it stands on the table, a large lateral bowing is produced, the amount being quite definite for each pressure exerted. That the needle has only been elastically deformed is obvious, for it becomes quite straight when the pressure is removed. It is perhaps unfortunate that this relatively stable state of affairs should be known as "elastic instability."

There is consequently in slender members a range of loads above the Euler critical load for which the structure receives no permanent deformation. This range, of course, will increase with the slenderness ratio. It is obvious that little use can be made of this characteristic property when dealing with columns such as are customarily used in construction, since in none of their parts is the slenderness ratio high and the added range of loads is negligible. There are, however, certain types of structures coming into increasing use today in which the necessity for economizing weight has led to the use of slender parts—in particular, sections built from sheet metal. The author's box column is an example. Given a sufficiently thin wall, considerable elastic buckling can develop before crippling or permanent buckling occurs. The theoretical analysis of such conditions is difficult and edge conditions are so important that it is hard to apply

elastic theory to structures of this kind. Experimental investigation will probably yield more satisfactory results. With Prof. H. L. Whittemore of the Bureau of Standards the writer has recently been engaged in making mechanical tests of a structure[13] which brought these points vividly to our attention. It is a cellular beam of sheet steel intended to be used in floor construction. Fig. 17 shows some typical sections. The beam is assembled from light-weight corrugated sheets and made into panels 2 ft wide and of the desired span length. The depth h is $5^5/_8$ in. The thickness of the steel in the experimental panels ranged from 0.05 in. to 0.11 in. (U. S. Standard gages 18 to 12), various combinations of gages being used to obtain the necessary range of section properties. The panels were tested as beams, so the tops of the sections were in compression. Buckling occurred only in the portion labeled a. Now the only reason to fear elastic buckling in the cell tops was that it might possibly increase the transverse deflection of the beam. The tests showed, however, that there is no sensible effect on the deflection until permanent buckles begin to appear.

22,000 lb per sq in. and the other with a yield point of about 43,000 lb. That is to say, the high yield point had increased the stress range of elastic buckling by about 10,000 lb per sq in. This occurs for a/t_1 equal to 52, which the author has shown to give a relatively stiff wall in a box column. Such an increase in the crippling strength is by no means to be neglected; in fact, the increased yield point has practically doubled the crippling strength. The theory of elastic buckling would indicate the same allowable working load no matter what the yield point was. Such a section after testing is shown in the lower part of Fig. 18. Earlier stages of buckling showed much greater uniformity. What Fig. 18 shows is a late stage in failure.

The flat-top section with a/t_1 equal to 62 showed permanent buckling at stresses about 50 per cent of the yield point.

The author's formula for the secondary elastic buckling of a box column does not apply to the case of these cellular beams, since here the stresses are more complicated, there being shear as well as compression in the top of the cell. Also one cannot assume that the compressive stresses are uniform across the width

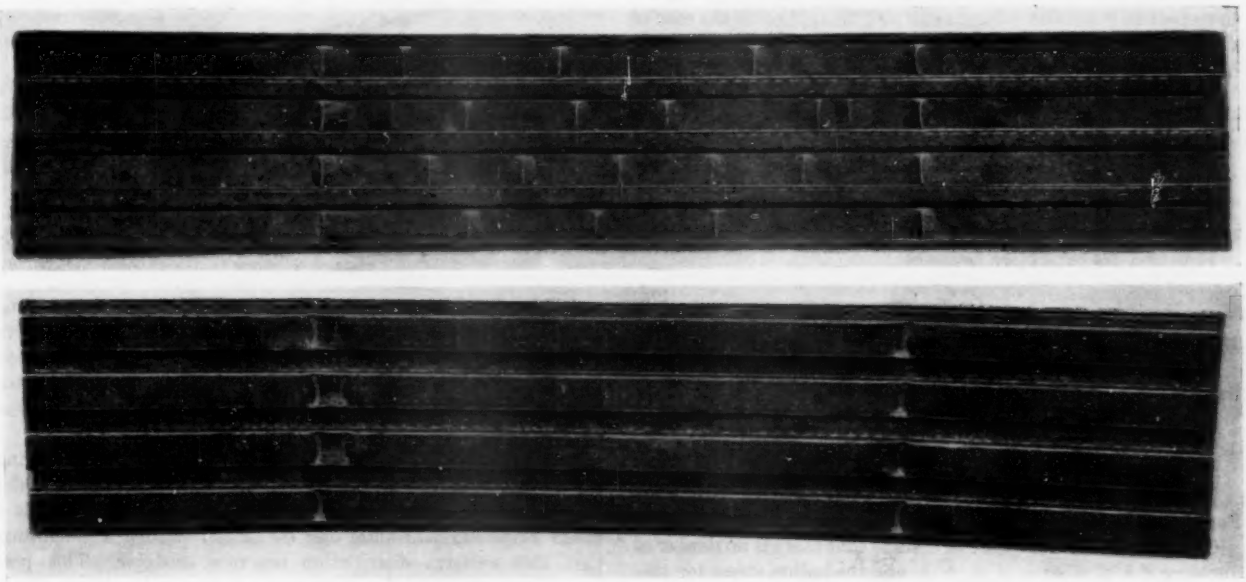

FIG. 18 TOP VIEW OF CELLULAR BEAMS AFTER TESTING

As seen in Fig. 17, the section is not symmetrical about a horizontal axis, the neutral axis being 33 to 40 per cent of the depth below the top of the beam. This gives a range of maximum compressive stresses from 50 to 67 per cent of the maximum tensile stresses. The values of a/t_1 ranged from 36 to 62. At the lowest ratio of 36 in a specimen with a corrugated top, there was little buckling of the cell tops and the compressive yield point of the material was developed. The upper half of Fig. 18 shows the top surface of such a specimen after testing. The dents at the quarter-points mark the places where the load was applied. Strain lines in the mill scale at 45 deg to the axis of the panel can be seen in the cell tops, which indicates a simple compressive yield. When a/t ranged from 52 to 62 in a corrugated-top type and the compressive stress was 60 per cent of the tensile stress, compression crippling began at about the same loads that developed the yield on the tension side. It was found for this type of section and for these values of a/t_1 that permanent buckling took place at stresses about 55 per cent of the yield point. This was true for two materials, one with a yield point of about

[13] Research Paper 463, Bureau of Standards *Journal of Research*, vol. 9 (1932), p. 131.

of the cell top. This, no doubt, explains why buckling was obtained with such low values of a/t_1. Further details of these tests can be found in the report published in the August, 1932, number of the Bureau of Standards *Journal of Research*.

The points the writer wishes to emphasize are:

1 There exists in general a range of elastic buckling before crippling occurs. Experiment shows that in certain cases the load range may be considerable.

2 The upper limit to this load range is set by the yield point, the lower limit by the critical load for elastic buckling. This latter is determined by the slenderness ratio and the modulus of elasticity. Thus slender members in high-strength steel and in duralumin should show this effect to a pronounced degree.

3 The general phenomenon is, however, characteristic of all cases of buckling in one degree or another, so that its consideration need not be restricted to design in sheet metal. It is suggested that these considerations might play a part in the design in stiffeners in plate-girdle webs (though they probably would not apply to stiffeners under the points of concentrated load). It may often be possible for the designer to use this range of loads up to the point of crippling to increase the economy of his struc-

ture without sacrificing the safety, particularly when using sheet metal in which local buckling can occur.

G. H. MacCullough.[14] In the present paper, the author has utilized the results of some European investigators showing that Euler's column analysis can be extended[15] into the region beyond the proportional limit and the results of this logical extension are very closely approximated by the line *ABCD* of Fig. 2. He also gives a theoretically correct formula for the design of eccentrically loaded columns. Perhaps his Equation [7] ought to be supplemented by further investigation whenever the axis about which the bending moment acts is not the axis about which resistance to bending is least. The danger of buckling as in pure column action about the other axis (the axis of least radius of gyration) with the load P treated as a centrally placed load should also be considered. The actual stress P/A in this case should not exceed the allowable stress given by the line *ABCD* of Fig. 3 with l/r based on the least radius of gyration.

Markus Reiner.[16] The reasoning which the author applies in respect to prismatic columns can also be applied to the case of the buckling of walls of tubular members. Equation [8], originally due to G. H. Bryan, can be written as

$$\sigma_{cr} = \frac{\pi^2 E}{3(1-\mu^2)}\left(\frac{h}{a}\right)^2 \quad [24]$$

The expression $\pi^2E/3(1-\mu^2)$ is a constant (c) of the material. The ratio a/h, put equal to α, is analogous to the slenderness ratio and may be called the "thinness ratio."

Equation [24] therefore becomes

$$\sigma_{cr} = c/\alpha^2 \quad [25]$$

which is the equation of a third-order hyperbola.

Equation [25] is not valid for stresses above the proportional limit ($\sigma_{p.l.}$). The limiting thinness ratio is therefore

$$\alpha_B = \sqrt{\frac{c}{\sigma_{p.l.}}} \quad [26]$$

For thicker plates Bryan's equation is not valid.

On the other hand it is safe to assume that there is no danger of buckling if $h \leqq a$, or $\alpha \leqq \alpha_c = 1$, and the failure stress for this condition is therefore equal to the yield point.

Substituting the values for E, $\sigma_{p.l.}$, $\sigma_{y.p.}$, and μ given in the paper,

$$c = \frac{3.14^2 \times 30 \times 10^6}{3(1-0.09)} = 1.083 \times 10^8 \quad [27]$$

and

$$\alpha_B = 10\sqrt{\frac{1083}{30}} = 60 \quad [28][17]$$

Plotting σ_{cr} against α in Fig. 19, we get, using the above values, the parts of the graph between points D and C and between B and A. Between points B and C a theoretical law could be derived in a way similar (but more complicated) to that in which Engesser and Kármán derived their law for short prismatic columns. However a straight line connecting points B and C is on the safe side and probably a sufficient approximation, and a linear law

$$\sigma_{cr} = C_1 - C_2\alpha \quad [29]$$

is therefore proposed instead of Bryan's law for plates thicker than $h_B = a/60$, or, more generally, $h_B = a\sqrt{(\sigma_{p.l.}/c)}$.

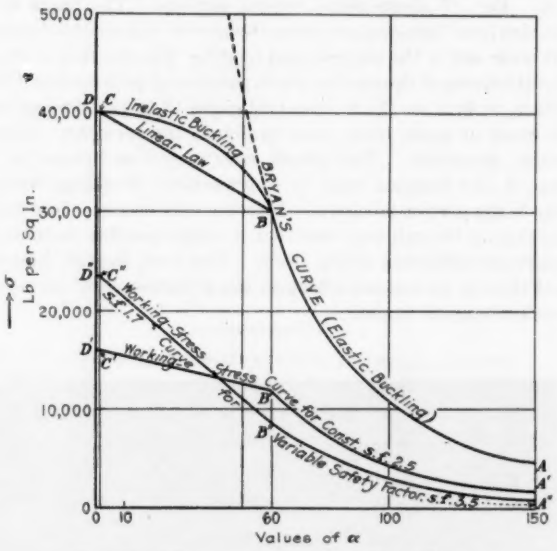

Fig. 19 Buckling of Column Web Plates
(E = 30,000,000; μ = 0.3; $\sigma_{p.l.}$ = 30,000; $\sigma_{y.p.}$ = 40,000; α = width of plate ÷ thickness.)

If we assume a constant factor of safety of 2.5, the working stresses for different thinness ratios are given by the curve $A'B'C'D'$. However, it is better practice, for reasons explained by the author in detail in this paper, to assume a variable factor of safety of from 1.7 to 3.5. The working stresses are then given by the curve $A''B''C''D''$.

It may, however, be doubted whether the concept of buckling failure can be applied at all to the failure of column plates under thrust as occurring in actual practice. The buckling stress is a stress *uniformly distributed over the section* of such a magnitude that this uniform distribution becomes unstable. This presupposes in the case of a plate that the plate is perfectly plane. However, it is well known that large plates exhibit considerable initial crookedness. The stresses in such plates under thrust are therefore not uniformly distributed from the beginning, and failure will occur after the maximum stress has reached the yield value. In order to determine the working stresses in a column web plate, an analysis of the stresses developed in a *curved plate* is therefore necessary. The design of such plates would have to proceed on a basis of the yield point, the factor of safety, and a suitable choice of an initial crookedness of the plate.

Apart from the theoretical difficulties of the problem, there is that of the choice of the initial crookedness, which seems to offer infinite possibilities. If, however, the initial web-plate contours, which have been very carefully measured up by R. S. Johnston,[18] are inspected, distinctive regularities can be noted, which may find their explanation from the process of rolling the plates.

The writer has in hand a theoretical investigation along these lines, the results of which he hopes soon to publish elsewhere.

Author's Closure

In writing the paper on thin-walled structures for the symposium on working stresses, the author had in mind only to bring

[14] Professor of Engineering Mechanics, Worcester Polytechnic Institute, Worcester, Mass. Mem. A.S.M.E.

[17] The author gives for the limiting ratio a value of 51 by using $\sigma_{y.p.}$ instead of $\sigma_{p.l.}$ as a criterion.

[18] Technologic Papers No. 321, Bureau of Standards (1926).

the attention of designers to the cases in which not only the strength of the material but also the stability of the structure should be considered in determining the allowable stresses. The problems of columns, thin plates, and thin shells were briefly discussed as examples without going into details.

Prof. G. E. Beggs, in his discussion, gives an interesting example of a cellular column buckled under the action of uniform compression. He states that buckling started at a load three-fourths of that indicated by Bryan's formula for a single plate. Such a discrepancy can be explained if we keep in mind that certain initial crookedness of thin plates is always present at the very beginning of experiments and by application of a compressive load further increase of this initial crookedness is produced. This makes it difficult to establish experimentally the magnitude of the critical load. To eliminate this difficulty, the writer and several other experimenters, who worked with stability of thin plates, used the method in which deflections of the plate are measured and curves are plotted representing deflections as functions of the load. These curves have the form of hyperbolas, and by drawing asymptotes to these curves critical loads can be determined with a better accuracy than can be done by simply observing when buckling begins.

Professor Beggs mentions also that the length of waves in which the buckled sides of the column are subdivided was equal to 1.38 the width of a partition, "whereas Bryan's theory indicates that the buckle length should not exceed the full width of partition." It should be noted that if the measurements were taken between two consecutive crests, the distance, following Bryan's theory, should be twice the width of a partition. If Professor Beggs has found shorter distances, it can be explained only by the stiffening action of steel angles in the corners of the cell. It is theoretically proved that any fixity of the edges results in a decrease of wave length.

The author agrees completely with Professor Beggs that the theory of thin-walled columns is not sufficiently developed and that further theoretical and experimental investigations of thin-walled structures are necessary.

Mr. J. M. Frankland, in his discussion, mentions that the Euler load does not represent the maximum load which a compressed slender bar can carry and that to produce an increase in the deflection of a buckled compressed bar certain increase of the load is necessary. This is a very well-known fact. It is also known that the relation between the load and deflection will be represented by a curve which is very different from the curve AC of Mr. Frankland. The true curve is of such a kind that for an increase of the load of 1 per cent above Euler's value, the deflection becomes of the amount of 9 per cent of the length of the bar. Practically, a slight increase of the load above Euler's load produces complete failure in a column of usual proportions.

The Euler load is called critical and indicates instability, because if the column is compressed above this load the two forms of equilibrium are possible—one straight form, which is unstable, and the other curved, which is stable.

Progress in Fuels

Fuels and Fuel Utilization in 1932

THE last year has been characterized by a general slackening of technical progress in the fuel industries, a condition which has not been unexpected. Industrial research in most branches has been confined principally to operating problems, and much caution has been observed toward new developments. The trends of recent years have for the most part continued in the same direction, although some changes are noticeable.

Of particular importance has been the increased competition between solid, liquid, and gaseous fuels. This intense competition has created an economic problem difficult of solution. Overproduction and competition within the separate branches of the industry have been serious enough, and the present situation is causing considerable concern on the part of fuel producers. The availability of fuel oil and natural gas at prices competitive with solid fuel has been responsible for a number of technical developments, chief of which is the demand for combination burners that can handle any of the fuels. Installation of these burners permits changing from one fuel to another as the relative prices fluctuate.

Activity in the domestic field has been greater than usual, due partly to the competition between fuels and partly to the greater stability of the domestic market as compared with the industrial.

As in all industries, employment conditions in the fuel industries are unsatisfactory. Because of the almost complete suspension of new construction, there is practically no demand for designing or construction engineers. Industrial research has been drastically curtailed, and even university research has been reduced considerably. There are a few openings from time to time for operating engineers, particularly for those having behind them records of reduced operating costs. The outlook for the future, however, is hopeful. The depression has brought a keener realization of the importance of fuel economy, and increased efforts in this direction may be expected.

Natural Fuel Production

Bituminous-coal-mining statistics indicate the unsatisfactory economic condition of the industry. The situation has been bad for some years, but it has been aggravated by the general curtailment of industrial activity. In the first eight months of 1932 there were mined 184,910,000 tons of bituminous coal, a decrease of 26.1 per cent from the 1931 production in the same period.

Differences in production costs in the various mining sections, due partly to a lack of standardization of wages according to the union or non-union character of the labor,[1] an absence of any agency to equalize these differences, and a diminishing market have been responsible for an orgy of price cutting. Much of the coal produced has been offered for sale at prices far below the cost of mining.[2]

The effect on those producers who have survived has been to compel the adoption of cheaper production methods and the preparation of a more salable product. Reduction of mining costs is being accomplished by closing high-cost mines and by further mechanization of operations. During 1931 the tonnage loaded by machines increased by 1.3 per cent in spite of a large decrease in total tonnage. A better product is being obtained by increased use of cleaning methods and more uniform sizing.[3,4]

Some short-sighted purchasers of fuel have been pleased with the present situation in the bituminous-coal industry, resulting as it has in a better fuel at a lower price. To the extent that the condition of the industry has forced the preparation of a better product and the adoption of lower cost methods, the results have been beneficial, not only to the consumers, but to the producers. Where the result has been the sale of coal below the cost of production, no permanent benefit can accrue even to the consumer. The reestablishment of the bituminous-coal industry in a position where reasonable profits are possible is of vital importance to producer and consumer alike.

Remedial measures proposed are directed toward the regulation of production and better controlled marketing methods. A majority of operators would welcome some regulative agency provided it is not governmental. The proposed mechanism of the Davis-Kelly bill was actively opposed by most operators, although favored by the labor group. It is generally believed that changes in the anti-trust laws will be necessary before any cooperative regulation within the industry can be effected.[5]

The decline in anthracite production has been slightly less than that in bituminous. Production figures for the first eight months of 1932 indicate a tonnage of 30,653,000, a drop of 23 per cent from the 1931 figure for the same period.[6] This branch of the industry has attempted to solve its own internal problems. A large group of operators have formed a marketing organization which, being attacked by the government on the grounds of restricting free competition, is serving as an experiment which the entire coal industry is watching carefully. Its success would open the way for more organizations of a similar type.

In the face of competition from fuel oil and gas, the anthracite industry is making a strong effort to conserve its market. Through research and development of new equipment, attempts are being made to endow anthracite with the same attributes of cleanliness, convenience, and efficiency possessed by fuel oil and gas. The efforts in this direction have been decidedly successful. It appears that before very long comparisons between the fuels must be made solely on the basis of costs.[7,8] The increased use of automatic equipment has created a greater demand for the smaller sizes of anthracite and has established a better balance between supply and demand for the various sizes produced.[9]

In New England foreign anthracite is a serious competitor. Under existing rates coal can be and is brought by boat from Wales, Germany, and even Indo-China to compete with that sent by rail from Pennsylvania. The foreign coal enjoys all the benefits of the research and development carried on by domestic producers to increase the demand for anthracite without contributing to its support.[10]

Research is under way in an attempt to find uses for anthracite

other than as fuel. These other uses, if developed, will be of importance to the fuel industries to the extent that they divert a portion of the anthracite production from the fuel markets. It is reported that anthracite fines have been found superior to sand in water-softening beds, and an investigation is under way to determine the possibility of using anthracite as electrode carbon.[11]

The last year has witnessed an improvement in the position of crude petroleum resulting from the rigid production control set in operation in the fall of 1931. Strict enforcement of the proration laws in the East Texas area has overcome the demoralizing influence which this field exerted on the whole mid-continent territory. The producers now find themselves in the unusual position of enjoying a greater net return from a smaller volume of production.[12]

During the first seven months of 1932, 463,500,000 bbl of crude were produced, as compared with 498,600,000 in the same period of 1931. The result has been a very desirable reduction of crude in storage, although this has been achieved partly by the not so desirable increase in stored refined products. Considerable drilling activity has been manifest, and in these seven months 8464 wells were completed, an increase of 15 per cent. Better prospecting methods reduced the percentage of dry wells from 33 per cent to 23 per cent of the total completed.[13]

While the figures indicate a better statistical position, concern is felt for retaining the gains. Illegal production under the proration laws is hard to prevent and tends to depress prices. The maximum permissible production per well in the East Texas field has been raised recently, and there is some question as to whether the increase can be properly absorbed. The subject of proration has entered the realm of politics, which causes some uneasiness, but it is probable that the benefits are sufficiently evident to insure retention of some form of restriction of output.

"The Impelling March of Natural Gas," as one important series of articles dealing with this subject was entitled, has continued throughout the last year.[14] The changeover from manufactured to natural gas was carried through in the Chicago district. Although statistics indicate a drop in natural-gas sales of about 8 per cent, the extension of pipe lines and distribution systems has continued hardly undiminished.

Natural gas is becoming so widespread in its distribution that there is scarcely a section of the country that has not been influenced by either its advent or its approach. It is now a factor to be reckoned with in all branches of fuel utilization. It has affected the trends in boiler and industrial-furnace design. It has affected the solid-fuel market to such an extent that the Interstate Commerce Commission has given the railways authority to meet competition of Texas natural gas by reducing rates on industrial coal in the Middle West.[15] Such a move is without precedent. It has become so cheap in the Far West that water power has reversed its position, becoming a standby for steam generated by natural gas. Southern California Edison has abandoned some of its hydro sites and has evidenced a willingness to relinquish part of its share of the projected power from Boulder Dam.[16]

The realization that the economics of pipe-line transportation requires a high load factor has put natural gas in the position of usually carrying the base load. It has therefore been necessary to have available a substitute for it that has the same physical characteristics and that can be produced with high flexibility to carry the peaks. This demand has resulted in some new processes. Foremost is the "refractory-screen oil-gas process," which cracks low-grade oils on a refractory bed in a converted water-gas set. Deposited carbon is intermittently burned to supply the necessary heat.[17] There are also two catalytic processes, one continuous and the other intermittent, which utilize butane for the same purpose.[18,19]

The removal of hydrogen sulphide from natural gas is obtained in a new method by scrubbing with a solution of salt and lime. This process is of especial interest, since it has been shown that the addition of relatively small amounts of chemicals to oil-field water produces the equivalent composition of the salt-lime solution and permits elimination of the hydrogen sulphide at a relatively low cost.[20]

Coal Carbonization and Gas Manufacture

There have been few engineering developments in the manufacture of coke because of the uncertainty in that industry. By-product coke production has suffered severely due to decreased blast-furnace output. Likewise the carbonization of coal primarily for the production of gas has felt the effects of the expanding networks of natural-gas transmission lines. Improvements have been in operation rather than in design, since there has been little new construction. In some ovens flue gas is being recirculated in the heating flues to produce a longer flame and provide more uniform heating. There is a trend toward the utilization of blast-furnace gas for heating the ovens, where it is available. The successful utilization of coke breeze by recharging to the ovens has been reported.[21]

The gas industry in general has not been so adversely affected by the depression as have most industries. The decrease in total gas sales has been small and has been due principally to lessened sales of gas for industrial purposes. There have been actual increases during the year in the production of both oil-gas and reformed refinery gas. Both of these, however, still constitute a small percentage of the total.

The by-product situation, which has such an important effect on the economics of coal carbonization, is generally unsatisfactory. New markets are needed for the benzol, ammonia, naphthalene, and tar, the importance of which have been diminished by synthetic ammonia, new anti-knock fuels, and non-phenolic plastics. Some progress has been made toward finding new uses. One example is the comparatively new fertilizer produced by mixing ammonia liquor with superphosphate fertilizer. A use has been discovered for the ammonia thiocyanate, a recently developed by-product formed during the removal of cyanogen from the gas. It has been found that the application of this material to soil results in immediate sterilization, with the destruction of weed growth, but the subsequent decomposition of the material provides a latent fertilizer which prepares the soil for fresh vegetation.

Some interesting experiments are being carried out by the Detroit Edison Company on the carbonization of coal by electricity. The principal appeal of such a process is that it would furnish an outlet for off-peak power. A public utility producing both electricity and gas might find the process profitable if it becomes technically successful.[22]

The United States Bureau of Mines in cooperation with the American Gas Association has recently completed a comprehensive test program on the gas, coke, and by-product making proper-

ties of American coals. The results of this investigation will be of inestimable value to the carbonization industry.[23]

Steam Generation

Probably the major development in the field of steam generation is the increased competition between fuels, particularly between coal, oil, and nat ral gas, and the determination of operating engineers to use the cheapest fuel available at all times, whether it be one of the three mentioned or some fuel available locally—as, for example, petroleum coke or acid sludge. Fluctuating prices of the various fuels relative to one another has created a strong demand for combination burners that will handle coal, oil, or gas with few or no changes necessary when changing from one fuel to another. The demand for combination burners has not been limited to pulverized-coal installations. It has been found to be a comparatively simple matter to install combination oil-and-gas burners in stoker-fired furnaces, and a number of such installations have been made.

The trend in burner design has been toward larger capacity. Burners that will handle up to 100,000,000 Btu per hr using coal, oil, or gas are in successful operation. Improvements have been made to decrease draft loss across both natural-draft and forced-draft burners. This permits a higher capacity for a given draft with natural-draft burners or a reduction in power consumption for a given capacity in the case of forced-draft installations.

An important development in pulverized-coal firing has been a modification in the design and operation of ball mills to eliminate lag, thus making it possible to handle sudden changes in boiler output when these mills are used with the unit-fired system, without an appreciable change in boiler pressure.

Burners for refinery waste fuels such as acid sludge have been greatly improved. Suitable materials have been found, which together with changes in design permit the atomizer parts to give several thousand hours of continuous service without replacement, where formerly a hundred hours was about the best performance.

A new pneumatic transport system for pulverized coal or other pulverulent material has been developed during the past year and appears to have a number of decided advantages. Claims made for it are ease of installation, low first cost, negligible maintenance charges, and entirely automatic operation. It may be installed for any capacity or distance, using small-diameter standard pipe, and requires no more air per ton of material at low than at high capacity according to the statements of the manufacturer.

The trend toward the unit system of pulverized-coal firing continues. In the first nine months of the year 68 orders for unit pulverizers for steam generation were reported, with no reported orders for the central system.[24,25]

Several improvements in stoker design are noteworthy. Additional installations provided with zoned air control have been made, this system having demonstrated its usefulness and practicability under actual operating conditions. In one of the plants using zoned air control, it has been possible to operate at rates of firing up to 90 lb per sq ft per hr for long periods of time with air temperatures as high as 570 F.

A modification has been made in the design of multiple retort stokers permitting continuous discharge of the ash without the use of a clinker grinder or crusher. This design is especially applicable where head room is limited, since it requires less space than either the dump grate or clinker grinder. The general trend in ash handling is toward a finer clinker, partly for ease of handling the ash hydraulically and partly because of the greater use being made of ash for purposes other than fill. Clinker grinders to meet this requirement have been developed.

Improvements have been made in stoker drive mechanisms, both mechanical and hydraulic, so that it is now possible to obtain almost an infinite variation of speeds within the limits practicable for stoker operation. Stoker sizes continue to increase. The average capacity of those ordered during 1932 was 305 hp, compared with the 1931 average of 252 hp.

During the last few years there has been a decided renewal of interest in stokers, which may be attributed to several causes. First and most important is the enormous progress that has been made in their design to permit higher rates of combustion, larger sizes, and greater flexibility, and to insure greater reliability. A second factor is the realization that the advantages of pulverized coal have in many cases been overemphasized, due perhaps to the more or less revolutionary character of this method of firing and the glamor connected with the earlier stages of its application to steam generation. Still another reason for the increased popularity of stokers is the attention that is being focused on the elimination of stack discharge. Pulverized coal has certain advantages over stokers, particularly for the combustion of coals having a high ash content or a low fusing ash, and there is no danger that this method of firing will be displaced. It is probable, however, that the choice between stokers and pulverized coal in future installations will be made on the basis of sounder engineering judgment and with more attention being paid to the real merits of the two systems.

Several research projects of particular importance have been reported during the last year. The Bureau of Mines completed a study of the use of fluxes in slag-bottom furnaces and is continuing work on the problem of determining the types of coal satisfactory for successful operation.[26] Several excellent papers on the combustion of pulverized coal were presented at the Third International Coal Conference last winter which gave the results of important research in progress.[27] The Bureau of Mines is studying the combustion on grates of coal ignited from the top in an effort to clarify the principles involved in firing with underfeed stokers. The results of these investigations completed and in progress should be of great value in the design and operation of steam-generating equipment.

Industrial Furnaces and Kilns

During the last year the use of luminous flames for the dual purpose of increasing the rate of heat transfer and providing a non-oxidizing atmosphere has grown in popularity. This development has been facilitated by the extension of natural-gas distribution and the availability of liquefied petroleum gases, both of which are admirably suited to this type of combustion. Luminous-flame burners are being used for annealing sheet steel, heating copper billets, normalizing, and many other heating and treating operations.[28]

Important research on luminous flames is under way, and one paper on the determination of true temperature and radiation of luminous flames has been published within the year.[29]

There are no new important developments in fuel application in steel making or in cement manufacture. Efforts are being made, however, in the latter industry to increase the efficiency of rotary kilns—in some instances by preheating combustion air and the raw mixture, by supplying a drier mixture from a slurry filter, by spray feed, and by waste-heat boilers.

There have been some changes from pulverized-coal to natural-gas firing.[30]

Marine and Locomotive Developments

Probably the item attracting the most attention in the marine field is the use of colloidal fuel by the Cunard liner *Scythia* on one of her trips. Colloidal fuel was a development of the oil-conservation activities during the war, but not much has been done with it since then. It is not truly colloidal, but consists of finely pulverized coal suspended in heavy oil in the ratio of 40 parts coal to 60 parts oil. It has a heating value per pound intermediate between the two, and per unit volume a 3–6 per cent increase over oil. Because of the coal, the flame is highly luminous, while the operating ease of oil is retained. The marine field has always been considered its sphere of greatest applicability. It is reported that the trial was very satisfactory.[31]

Of interest also is the boiler installation planned for the proposed super-liners of the United States Lines. The boilers are believed to have greater unit output than any now afloat, yet the number of boilers is such that ample flexibility of power is possible. Rated power is developed with two of the 18 boilers out for cleaning. The total steam demand will be 1,650,000 lb per hr. The installation follows the trend ashore of fewer and larger steam-generating units.[32]

There have been no new developments in the railway-fuel situation. The railroads are continuing their efforts toward higher efficiencies, and the yearly figures will probably show a further reduction in coal per unit output. In 1931 there was about a 2 per cent efficiency gain in both freight and passenger services.

Motor Fuels

Developments in gasoline production have progressed steadily in the direction of better knock rating, increased volatility, and reduction of gum content.

The better knock rating has been obtained chiefly by increasing the percentage of cracked gasoline. In 1931 cracked gasoline constituted 39.8 per cent of the total produced, which increased to 42.4 per cent for the first half of 1932. So great has been the demand for cracked gasoline that additional cracking capacity has been installed, although refining operations in general are at somewhat less than two-thirds of capacity. In the new cracking installations the trend has been, as it has in many fields, toward larger units. One unit of 20,000 bbl per day capacity has been completed.[33]

The hydrogenation of petroleum, which has been mentioned in previous reports, has progressed considerably. Two large-scale commercial plants are in operation and are apparently entirely satisfactory. In April of this year one of the plants completed a run which had been in continuous progress for a year.[34]

The Knowles coking process for the carbonization of heavy petroleum residuals seems to be finding favor. Removal of the coke from the Knowles stills or ovens is by means of a mechanical pusher similar to that used for the removal of coke from by-product ovens. The product is an excellent domestic fuel, having a low volatile content and an ash content of around 1 per cent. It can be manufactured at a price to compete with anthracite.

Among new processes is that of treating with boiling zinc-chloride solution. The process is countercurrent with the oil in the vapor phase. The resulting product has high color stability and low sulphur and gum content. Costs are said to be quite low, and commercial application seems to be successful.[35]

The most important Diesel-fuel development is the production by several leading refiners of anti-knock oils. Surprising as it may seem, conditions which prevent knock in gasoline engines produce knock in the Diesel engine. The usual types of knock inhibitors are therefore harmful rather than beneficial in a Diesel fuel. Progress is being made in determining oil characteristics of importance to good operation, with special attention being paid to "ignitibility." There is still a need for satisfactory tests and specifications for Diesel fuels.[36]

Domestic Heating

Probably in no branch of the fuel industry has there been greater activity during the last year than in the field of domestic heating. Although a large percentage of the total fuel produced is consumed for this purpose, domestic furnaces have been permitted to languish at a low state of efficiency and convenience for many years. Increased competition between solid, liquid, and gaseous fuels and a belated realization that the domestic fuel market is the least affected by periods of low business activity have brought this field to the attention of both producers of fuel and equipment manufacturers.

The attempt of the anthracite industry to retain its hold on the domestic market by the development of automatic equipment has already been mentioned. Stokers have been developed for bituminous coal also, and there are now over 60 manufacturers of household stokers. There is no complete report available of the number of stokers sold, but a major manufacturer of feed-screws reports a 120 per cent increase in sales.

Oil burners have shown considerable improvement during the past year. Completely automatic burners which will handle the heaviest grades of fuel oil have been designed and should find application in apartment houses and office buildings. Several self-contained oil burners and furnaces have made their appearance. The construction of burner and furnace as a unit has permitted the incorporation of some desirable features which are not possible when the burner is designed to be used in a boiler previously fired with coal. Combined with the desirable technical features is a neatness of appearance which should insure their popularity.

One reputable manufacturer has ready for market a pulverized-coal unit for domestic boilers. Some 20 of these units were in operation during the winter of 1931–1932.

The American Gas Association reports an increase of 4 per cent over 1931 in the number of customers using gas for house heating and an increase of 2.8 per cent in gas sold during the first six months of 1932 as compared with the corresponding period in 1931. Installations include completely new units especially designed for gas and conversion burners which are used to adapt coal-fired boilers to gas firing.

A development which may completely change the economic situation of the fuel industries is the conditioning of air for homes, including cooling and dehumidifying during the summer as well as heating and humidifying during the winter. Since the increased demand for fuel would come during the summer, when activity in most lines of the fuel industry is now at a minimum, the new load would be of inestimable value. All branches of the fuel industry in addition to equipment manufacturers are actively engaged in exploring this new field. Some equipment is already on the market, and the predictions are that before many years

have passed, summer air conditioning for homes will be considered as essential as heating during the winter.

Of interest in the heating field is the application of the refrigeration principle, or heat-pump action, to furnish heat in winter and cold in summer to a Los Angeles office building. The same equipment does both jobs, apparently with economic satisfaction. The possibilities of this application are greatest in localities where the seasonal fluctuations are small.[37]

Smoke and Dust Abatement

The work of smoke elimination is being carried on. There are no outstanding developments in this field, but the continued watch on stacks and on the installation of new equipment is slowly effecting an improvement in conditions. Atmospheric pollution from dust and sulphur fumes is still a serious problem, and extensive research, hampered somewhat by the economic situation, is being carried on for its elimination.

The electrical precipitator has been found the best agent for dust removal, but its operation is expensive. Scrubbing methods, not yet entirely satisfactory, show promise of success. With these, corrosion is a very serious handicap, so that much of the research on scrubbers consists in studies of the life of materials of construction. The work on sulphur fumes, which are responsible for most of the corrosion, has not yet given much indication that they can be properly eliminated. There is, rather, a growing conviction that preparation of the coal is a more fertile field for the solution of the sulphur problem than is scrubbing the stack gases.

The question of adequate combustion space and the proper height of settings is being investigated in the interests of smoke prevention. A serious obstacle to any smoke studies is the unsatisfactory state of development of test methods and instruments. There is a real need of practical apparatus for measuring the smoke in the air and its effect on transmitted radiation.

Among interesting smoke studies has been the microscopic identification of smoke particles from different sources. It is claimed that the particles from different stacks have individual physical characteristics which definitely connect them with their source. On the basis of such studies it is said that nine-tenths of the smoke particles in the New York City atmosphere come from small fires in apartments, homes, and small office buildings.[38] Any improvement in conditions, if this is the case, would come slowly and only as a result of education of the public.

Engineering Employment

From a study of the employment situation in the fuel field, it is apparent that the industry has openings for men of particular ability only, whose past records give promise of achieving lower operating costs, improved salability of product, or development of profitable processes. While it is probable that the effect of the economic situation on most fuel industries has been less than in other fields, nevertheless the economic pressure has been sufficient to cause abandonment of a number of worthy but not immediately profitable enterprises. Consequently, the demand for men is mainly defined by the promise of quick profit.

Of the industries surveyed, the public utilities have shown, perhaps, the steadiest output, but the margin of profit to which they are restricted has required the exercise of caution in expansion. The metallurgical industries are especially sensitive to economic pressure. The best employment conditions seem to be in those industries where competition is intense and where new developments lead to widespread changes. Such industries are oil refining, gas- and oil-burning equipment manufacturing, both industrial and domestic, and air conditioning, among others.

With the revival of industrial activity, it is expected that the demand for engineers in the fuel industries will be greater than ever before. The depression has brought a better realization of the importance of fuel economy, which will be translated when conditions warrant into extensive investigations of the best method of performing any particular heating operation. This in turn will require research workers, designing and construction engineers, and operating engineers trained in the principles of fuel processing and utilization.

Progress in Steam-Power Engineering

General

NEW installations during the past year have been few, since the depressed state of general business has brought about a reduction in the utilities' loads and no immediate need exists for increased capacity in either the utility or industrial field.

In general power-station design, the tendency toward the use of 1200- to 1400-lb steam pressure with the necessary reheat is not so strong. The tendency is more toward the use of pressures as high as can be practically used without reheat. One plant is now in operation using a pressure of 700 lb and 850 F temperature and no reheat. Still higher pressures and temperatures are imminent, as large turbine builders declare themselves ready to build equipment for 1000 lb pressure and 1000 F temperature without reheat. The tendency is, then, toward simpler design than is accomplished with the higher pressure and reheat.

The special high-temperature turbine being tested by The Detroit Edison Company was actually operated for considerable periods of time at 1000 F temperature for the first time during this year.

There is increasing activity among the larger industrials toward the consideration of by-product power production, with or without the cooperation of the utility companies.

Developments in the use of higher pressures and temperatures have stimulated the idea of "rehabilitation" of older plants by the superposition of a high-pressure boiler and turbine in connection with existing equipment. In some cases, notably at the Burlington Generating Station of Public Service Electric and Gas Company, this expedient has, at a comparatively moderate cost, converted what was a stand-by peak-load plant into the most efficient on the system. Such a rehabilitation may also be accomplished by the use of the mercury-vapor system in conjunction with existing equipment. This may in some cases even be more attractive than the high-pressure steam system.

The tendency toward further simplification and cheapening of building design continues. Some utilities have given serious study to the development of designs omitting the conventional building to the utmost extent possible. However, these studies do not at present give any general accepted answer to this question. In certain specific cases the cost of such an "outdoor" power plant is apparently not materially less than a conventional but inexpensive building.

In order to test the possibilities of this type of plant, the General Electric Company has now under construction an "outdoor" installation at the works in Schenectady. This is a full-sized power plant providing a 20,000-kw mercury turbine and also a steam boiler. Its operation will be watched with considerable interest, as it should indicate the operating difficulties to be encountered with outdoor construction in a fairly severe climate.

There are still comparatively few plants built with only one boiler per turbine. However, with the greater reliability of boiler and fuel-burning equipment which modern design provides, the tendency toward this ideal is more pronounced. Three boilers for two turbines seems to be the minimum seriously considered at present, except in cases possessing exceptional transmission-line interconnection advantages.

The Bureau of Standards has completed its determination on the temperature-pressure relations of saturated water, and the results of this important experimental work are being made available to steam engineers through the A.S.M.E. Transactions.

Boilers

No important changes in boiler design have appeared, the tendency being rather to consolidate the new ideas of the last few years and to improve details. The use of fusion-welded drums has practically supplanted riveted construction.

More attention is being given to means and devices to prevent the carry-over of solids with the steam from the boiler. One manufacturer has developed a steam washer in which the steam, before leaving the drum, passes through a spray or rain of incoming feedwater. The elimination of solids from the steam passing to the superheater is of greater importance than is the elimination of moisture below 0.8 to 1 per cent.

The increase in boiler exit-gas temperature resulting from increasing steam pressure and rates of output per square foot of surface has made the use of economizers in addition to air preheaters more essential. Economizers when used are generally of the steaming type because of the high temperature of the feedwater coming from the regenerative feed-heating system. The trend in economizer design is toward the omission of all joints, as they have in many cases been the greatest single source of trouble. The latest designs proposed by the manufacturers consist of practically continuous welded loops.

Boiler Furnaces and Fuel Burning

Water walls have become almost universal for all larger units. Progress has been made in the design and construction of so-called wet-bottom or slag-tap furnaces. Furnace shapes and burner designs more suitable for this type of furnace have been developed. The use of water-cooled furnace floors has greatly reduced the operating difficulties present with this type of furnace. However, the "dry" versus "wet" furnace is still a moot question, each type having its apparent advantages and disadvantages.

Stokers and pulverized-fuel equipment have undergone no radical changes of design in the past year.

An inherent handicap against the use of pulverized fuel, at least in populated districts, is the cost of providing satisfactory fly-ash eliminators. The matter of fly-ash and cinder elimination is receiving more attention than heretofore. The electric precipitator seems still to lead in general effectiveness. However, a type of wet scrubber has been developed and used by one power company which indicates a degree of removal of the same order as that of the electric precipitator.

Cinder emission from stoker plants is less difficult, and both dry and wet type washers are used, depending somewhat upon the requirements of location. A large majority of the steam-power plants throughout the country are still without eliminators of any kind.

Stokers suffer somewhat from a certain limitation in kinds of fuel that may be used successfully and the increasing difficulty of providing sufficient grate area under very large boilers without undesirable complications in design.

The changing market prices of fuel oil and gas have increased the use of these fuels in steam-power plants. A number of coal-

---

Presented at the session of the Power Division, Thursday morning, December 8, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Personnel of the Executive Committee of the Power Division for 1932: Alfred Iddles, Chairman; J. M. Brentlinger, Secretary; W. F. Ryan, C. S. Gladden, and A. E. Grunert.

burning plants have installed oil-burning equipment. Most of the plants that have taken advantage of the economies at present available through this conversion have been those designed for pulverized fuel, because of the relative simplicity and small expense of making the change in a pulverized-fuel furnace.

Sponsored research at Purdue University has apparently borne fruit in the development of a fairly simple process for the manufacture of building brick from pulverized-fuel ash. This scheme contemplates the setting up of equipment to manufacture the brick at the power station where the ash is produced.

Turbines and Generators

The tendency in large turbo-generator design is distinctly toward single-shaft machines. The largest of these so far installed are two 165,000-kw tandem machines in the Hudson Avenue Station of the Brooklyn Edison Company. The order has been placed for a similar unit for the Richmond Station of the Philadelphia Electric Company. No increase in steam pressure over that of the previously existing equipment was made in either case.

Research work on the design and materials of low-pressure blading has been carried on in an effort to minimize the wear due to moisture. Special steels, chromium plating, and stellite protection have been tried. At the present time stellite seems to offer the greatest promise.

Fabricated welded-steel construction is to a large extent replacing the use of castings. Welded-steel construction has not yet been used for the cylinders of large turbines. A number of small turbines have been built in this way, and its use for large units is receiving serious consideration.

Motor-operated turning gear to keep the machines slowly rotating when out of service for comparatively short periods are now almost invariably used on the larger units. The rotation serves to eliminate inequalities of temperature in the turbine rotor and thereby permit more rapid starting. On the larger units auxiliary high-pressure oil systems are being provided to float the rotating element before starting from rest and thus avoid damage to the bearings.

In general, the progress in turbine design has been toward greater refinement of detail and increase in size of single-shaft units.

Generator efficiencies have increased somewhat, but the margin still available leaves but little room for further improvement.

Condensers

It appears that the use of fusion-welded steel shells for condensers will soon entirely supplant cast-iron construction. The 65,000-sq ft condenser for Kearny Generating Station is the largest so far built of welded steel. The rolling of tubes in both tube sheets is becoming common practice. Vertical circulating pumps are gaining in favor.

Power-Station Piping

Probably the greatest progress in steam-power engineering that has occurred within the past year has been the increasing use of fusion welding in the fabrication of the piping systems. In the latest work cast fittings have almost entirely been eliminated and flanged joints reduced to a minimum. Valve bodies of considerable size have been welded directly into the pipe lines. This is unquestionably a distinct and important step toward greater reliability and decreased maintenance.

Special Cycles

Two installations of the mercury-vapor cycle are now going forward—one at General Electric Works in Schenectady and the other at Kearny Generating Station of Public Service Electric and Gas Company of New Jersey. Each will generate 20,000 kw from the mercury turbine and supply sufficient steam to generate approximately 30,000 kw in steam turbines. The Kearny installation is rapidly nearing completion. The cost of this plant only slightly exceeds that of a high-pressure steam installation, and the heat rate will be about 20 per cent less. The principal new development in this installation compared with that at Hartford, Conn., other than an increase in capacity, is the use of mercury-cooled furnace-wall construction. Commercial operation of the Hartford mercury boiler and turbine unit continues, and a net efficiency of slightly less than 10,000 Btu per kw-hr has been maintained. This is a new economy record for this country.

The use of diphenyl oxide has been considered for a binary cycle, but no actual progress is known to have been made along this line. One installation has been made using diphenyl oxide as a heat carrier to convey heat absorbed from the flue gases to an air preheater, thus eliminating a large amount of cumbersome and expensive duct work.

Your committee has no information as to any special progress with the Benson or Loeffler cycles, though operation and experiment continue in Europe.

FSP-55-3a

Steam-Turbine-Plant Practice in the United States

By VERN E. ALDEN[1] and W. H. BALCKE,[2] BOSTON, MASS.

From the great volume of available data on the design, equipment, service requirements, and operating results of the steam-electric-generating stations serving the larger power systems in the United States, the authors have endeavored to present a cross-section of existing turbine-plant practice. The principal subjects discussed include the selection and arrangement of steam turbine-generators, their condensers, and auxiliaries, together with an analysis of published test results for many large turbines and the service-reliability records of modern installations. While some economic considerations and other controlling factors underlying the principal features are outlined, the purpose of the authors is that of describing existing practice rather than of offering any recommended solution for the many problems involved. To assist in recognizing typical rather than exceptional practices, and widespread rather than personal or minority opinions, advantage has been taken of comments and suggestions from many individuals closely associated with the development of the art.

W. H. Balcke

V. E. Alden

AMERICAN steam-turbine-plant practice has in the main been dominated by the desire to gain four objectives:

1 Improvement in reliability in order that generating capacity may, to the maximum extent possible, be available for service when needed
2 Reduction in fuel consumption per kilowatt-hour of net station output
3 Reduction in the overall investment per kilowatt of system peak load carried
4 Reduction in cost of operating labor and maintenance.

A very large percentage of all the new steam-turbine-plant capacity installed since 1920 has gone into plants serving the electric light and power systems. Practice in industrial power plants has usually followed or paralleled that in utility plants. The rapid growth in load and the extensive use of interconnections have had a most important influence as they have helped to justify the use of turbine-generators of increasing capacity.

Increases in Steam Pressure and Temperature and Capacities of Turbines

The most significant trends are the increase in the size of turbine-generators and the increases in steam pressure and temperature. The graphs shown in Figs. 1, 2, and 3, somewhat modified from the form as presented in an earlier paper,[3] may help to visualize the rate of progress. The cross-hatched areas show the limits within which representative steam-station practice has fallen. An attempt has been made to indicate what might be called conservative practice, or trend, by means of a curve drawn through each cross-hatched area. The horizontal lines extending from 1928 to 1932 in Figs. 2 and 3 indicate the views of several schools of thought as to the best steam pressure and temperature.

Reheating

Another important development has been the use of a single stage of reheating to raise the temperature of the steam, after partial expansion, to its initial temperature, or slightly higher. This development dates from the initial operation early in 1925 of two 40,000-kw turbine-generators in the Philo Station of the Ohio Power Company, with steam delivered to the turbine throttle at a pressure of 550 lb per sq in. gage and 725 F, the steam being withdrawn from the turbine after being expanded to 155 lb per sq in. gage, returned to the boiler plant, reheated to 725 F, and then expanded through the remaining turbine stages to the condenser. Since this initial development there has been installed, or is now in the course of construction, in 19 generating stations in the United States a total of 2,800,000 kw of turbine

[1] Power Engineer, Stone & Webster Engineering Corporation. Assoc-Mem. A.S.M.E. Mr. Alden received his B.S. in Electrical Engineering in 1911 from the University of Oklahoma. He was associated with the Westinghouse Electric & Manufacturing Company until 1918, and for the next eight years was with the Consolidated Gas Electric Light & Power Company of Baltimore. Since 1926 he has been engaged on power-station design work and preliminary engineering studies for Stone & Webster Engineering Corporation.
